rpm is a powerful **Package Manager**, which can be used to build, install, query, verify, update, and erase individual software packages. A **package** consists of an archive of files and meta-data used to install and erase the archive files. The meta-data includes helper scripts, file attributes, and descriptive information about the package. **Packages** come in two varieties: binary packages, used to encapsulate software to be installed, and source packages, containing the source code and recipe necessary to produce binary packages.

One of the following basic modes must be selected: **Query**, **Verify**, **Signature Check**, **Install/Upgrade/Freshen**, **Uninstall**, **Initialize Database**, **Rebuild Database**, **Resign**, **Add Signature**, **Set Owners/Groups**, **Show Querytags**, and **Show Configuration**.

General Options

These options can be used in all the different modes.

-?, --help

Print a longer usage message than normal.

--version

Print a single line containing the version number of **rpm** being used.

--quiet

Print as little as possible - normally only error messages will be displayed.

-v

Print verbose information - normally routine progress messages will be displayed.

-vv

Print lots of ugly debugging information.

--rcfile FILELIST

Each of the files in the colon separated *FILELIST* is read sequentially by **rpm** for configuration information. Only the first file in the list must exist, and tildes will be expanded to the value of **\$HOME**. The default *FILELIST* is

/usr/lib/rpm/rpmrc:/usr/lib/rpm/redhat/rpmrc:/etc/rpmrc:~/.rpmrc.

--pipe CMD

Pipes the output of **rpm** to the command *CMD*.

--dbpath DIRECTORY

Use the database in *DIRECTORY* rather than the default path */var/lib/rpm*

--root DIRECTORY

Use the file system tree rooted at *DIRECTORY* for all operations. Note that this means the database within *DIRECTORY* will be used for dependency checks and any **scriptlet**(s) (e.g. **%post** if installing, or **%prep** if building, a package) will be run after a **chroot**(2) to *DIRECTORY*.

-D, --define='MACRO EXPR'

Defines *MACRO* with value *EXPR*.

-E, --eval='EXPR'

Prints macro expansion of *EXPR*.

Install and Upgrade Options

In these options, *PACKAGE_FILE* can be either **rpm** binary file or ASCII package manifest (see **PACKAGE SELECTION OPTIONS**), and may be specified as an **ftp** or **http** URL, in which case the package will be downloaded before being installed. See **FTP/HTTP OPTIONS** for information on **rpm**'s internal **ftp** and **http** client support.

The general form of an rpm install command is

rpm {-i|--install} [install-options] PACKAGE_FILE ...

This installs a new package.

The general form of an rpm upgrade command is

rpm {-U|--upgrade} [install-options] PACKAGE_FILE ...

This upgrades or installs the package currently installed to a newer version. This is the same as install, except all other **version**(s) of the package are removed after the new package is installed.

rpm {-F|--freshen} [install-options] PACKAGE_FILE ...

This will upgrade packages, but only ones for which an earlier version is installed.

--aid

Add suggested packages to the transaction set when needed.

--allfiles

Installs or upgrades all the missingok files in the package, regardless if they exist.

--badreloc

Used with **--relocate**, permit relocations on all file paths, not just those *OLDPATH*'s included in the binary package relocation **hint**(s).

--excludepath *OLDPATH*

Don't install files whose name begins with *OLDPATH*.

--excludedocs

Don't install any files which are marked as documentation (which includes man pages and texinfo documents).

--force

Same as using **--replacepkgs**, **--replacefiles**, and **--oldpackage**.

-h, --hash

Print 50 hash marks as the package archive is unpacked. Use with **-v|--verbose** for a nicer display.

--ignoresize

Don't check mount file systems for sufficient disk space before installing this package.

--ignorearch

Allow installation or upgrading even if the architectures of the binary package and host don't match.

--ignoreos

Allow installation or upgrading even if the operating systems of the binary package and host don't match.

--includedocs

Install documentation files. This is the default behavior.

--justdb

Update only the database, not the filesystem.

--nodigest

Don't verify package or header digests when reading.

--nomanifest

Don't process non-package files as manifests.

--nosignature

Don't verify package or header signatures when reading.

--nodeps

Don't do a dependency check before installing or upgrading a package.

--nosuggest

Don't suggest **package**(s) that provide a missing dependency.

--noorder

Don't reorder the packages for an install. The list of packages would normally be reordered to satisfy dependencies.

--noscripts**--nopre****--nopost****--nopreun****--nopostun**

Don't execute the scriptlet of the same name. The **--noscripts** option is equivalent to

--nopre --nopost --nopreun

-

-

nopostun

and turns off the execution of the corresponding **%pre**, **%post**, **%preun**, and **%postun** **scriptlet**(s).

--notriggers**--notriggerin****--notriggerun****--notriggerpostun**

Don't execute any trigger scriptlet of the named type. The **--notriggers** option is equivalent to

--notriggerin --notriggerun --notriggerpostun

and turns off execution of the corresponding **%triggerin**, **%triggerun**, and **%triggerpostun** **scriptlet**(s).

--oldpackage

Allow an upgrade to replace a newer package with an older one.

--percent

Print percentages as files are unpacked from the package archive. This is intended to make **rpm** easy to run from other tools.

--prefix *NEWPATH*

For relocatable binary packages, translate all file paths that start with the installation prefix in the package relocation **hint**(s) to *NEWPATH*.

--relocate *OLDPATH=NEWPATH*

For relocatable binary packages, translate all file paths that start with *OLDPATH* in the package relocation **hint**(s) to *NEWPATH*. This option can be used repeatedly if several *OLDPATH*'s in the package are to be relocated.

--replacefiles

Install the packages even if they replace files from other, already installed, packages.

--replacepkgs

Install the packages even if some of them are already installed on this system.

--test

Do not install the package, simply check for and report potential conflicts.

Erase Options

The general form of an rpm erase command is

```
rpm {-e|--erase} [--allmatches] [--nodeps] [--noscripts] [--notriggers] [--test]  
PACKAGE_NAME...
```

The following options may also be used:

--allmatches

Remove all versions of the package which match *PACKAGE_NAME*. Normally an error is issued if *PACKAGE_NAME* matches multiple packages.

--nodeps

Don't check dependencies before uninstalling the packages.

--noscripts

--nopreun

--nopostun

Don't execute the scriptlet of the same name. The **--noscripts** option during package erase is equivalent

to

--nopreun --nopostun

and turns off the execution of the corresponding **%preun**, and **%postun** **scriptlet**(s).

--notriggers

--notriggerun

--notriggerpostun

Don't execute any trigger scriptlet of the named type. The **--notriggers** option

is equivalent to

--notriggerun --notriggerpostun

and turns off execution of the corresponding **%triggerun**, and **%triggerpostun scriptlet(s)**.

--test

Don't really uninstall anything, just go through the motions. Useful in conjunction with the **-vv** option for debugging.

Query Options

The general form of an rpm query command is

rpm {-q|--query} [select-options] [query-options]

You may specify the format that package information should be printed in. To do this, you use the

--qf|--queryformat QUERYFMT

option, followed by the *QUERYFMT* format string. Query formats are modified versions of the standard ***printf(3)*** formatting. The format is made up of static strings (which may include standard C character escapes for newlines, tabs, and other special characters) and ***printf(3)*** type formatters. As **rpm** already knows the type to print, the type specifier must be omitted however, and replaced by the name of the header tag to be printed, enclosed by **{}** characters. Tag names are case insensitive, and the leading **RPMTAG_** portion of the tag name may be omitted as well.

Alternate output formats may be requested by following the tag with **:typetag**. Currently, the following types are supported:

:armor

Wrap a public key in ASCII armor.

:arraysize

Display number of elements in array tags.

:base64

Encode binary data using base64.

:date

Use ***strftime(3)*** "%c" format.

:day

Use ***strftime(3)*** "%a %b %d %Y" format.

:depflags

Format dependency comparison operator.

:deptype

Format dependency type.

:fflags

Format file flags.

:fstate

Format file state.

:hex

Format in hexadecimal.

:octal

Format in octal.

:perms

Format file permissions.

:pgpsig

Display signature fingerprint and time.

:shescape

Escape single quotes for use in a script.

:triggertype

Display trigger suffix.

:vflags

File verification flags.

:xml

Wrap data in simple xml markup.

For example, to print only the names of the packages queried, you could use **%{NAME}** as the format string. To print the packages name and distribution information in two columns, you could use **%-30{NAME}%{DISTRIBUTION}**. **rpm** will print a list of all of the tags it knows about when it is invoked with the **--querytags** argument.

There are two subsets of options for querying: package selection, and information selection.

Package Selection Options:

PACKAGE_NAME

Query installed package named *PACKAGE_NAME*.

-a, --all

Query all installed packages.

-f, --file FILE

Query package owning *FILE*.

--fileid ID

Query package that contains a given file identifier. The *ID* is the digest of the file contents. For different packages different hash algorithms may have been used (*MD5*, *SHA1*, *SHA256*, *SHA384*, *SHA512*, ...)

-g, --group GROUP

Query packages with the group of *GROUP*.

--hdrid SHA1

Query package that contains a given header identifier, i.e. the *SHA1* digest of the immutable header region.

-p, --package *PACKAGE_FILE*

Query an (uninstalled) package *PACKAGE_FILE*. The *PACKAGE_FILE* may be specified as an **ftp** or **http** style URL, in which case the package header will be downloaded and queried. See **FTP/HTTP OPTIONS** for information on rpm's internal **ftp** and **http** client support. The *PACKAGE_FILE* argument(s), if not a binary package, will be interpreted as an ASCII package manifest unless **--nomanifest** option is used. In manifests, comments are permitted, starting with a '#', and each line of a package manifest file may include white space separated glob expressions, including URL's, that will be expanded to paths that are substituted in place of the package manifest as additional *PACKAGE_FILE* arguments to the query.

--pkgid *MD5*

Query package that contains a given package identifier, i.e. the *MD5* digest of the combined header and payload contents.

--querybynumber *HDRNUM*

Query the *HDRNUM*th database entry directly; this is useful only for debugging.

--specfile *SPECFILE*

Parse and query *SPECFILE* as if it were a package. Although not all the information (e.g. file lists) is available, this type of query permits rpm to be used to extract information from spec files without having to write a specfile parser.

--tid *TID*

Query **package**(s) that have a given *TID* transaction identifier. A unix time stamp is currently used as a transaction identifier. All **package**(s) installed or erased within a single transaction have a common identifier.

--triggeredby *PACKAGE_NAME*

Query packages that are triggered by **package**(s) *PACKAGE_NAME*.

--whatprovides *CAPABILITY*

Query all packages that provide the *CAPABILITY* capability.

--whatrequires *CAPABILITY*

Query all packages that require *CAPABILITY* for proper functioning.

Package Query Options:

--changelog

Display change information for the package.

-c, --configfiles

List only configuration files (implies **-I**).

-d, --docfiles

List only documentation files (implies **-I**).

--dump

Dump file information as follows (implies **-I**):

path size mtime digest mode owner group isconfig isdoc rdev symlink

--filesbypkg

List all the files in each selected package.

-i, --info

Display package information, including name, version, and description. This uses the **-queryformat** if one was specified.

--last

Orders the package listing by install time such that the latest packages are at the top.

-l, --list

List files in package.

--provides

List capabilities this package provides.

-R, --requires

List capabilities on which this package depends.

--scripts

List the package specific **scriptlet**(s) that are used as part of the installation and uninstallation processes.

-s, --state

Display the *states* of files in the package (implies **-l**). The state of each file is one of *normal*, *not installed*, or *replaced*.

--triggers, --triggerscripts

Display the trigger scripts, if any, which are contained in the package.

Verify Options

The general form of an rpm verify command is

rpm {-V|--verify} [select-options] [verify-options]

Verifying a package compares information about the installed files in the package with information about the files taken from the package metadata stored in the rpm database. Among other things, verifying compares the size, digest, permissions, type, owner and group of each file. Any discrepancies are displayed. Files that were not installed from the package, for example, documentation files excluded on installation using the "**--excludedocs**" option, will be silently ignored.

The package selection options are the same as for package querying (including package manifest files as arguments). Other options unique to verify mode are:

--nodeps

Don't verify dependencies of packages.

--nodigest

Don't verify package or header digests when reading.

--nofiles

Don't verify any attributes of package files.

--noscripts

Don't execute the **%verifyscript** scriptlet (if any).

--nosignature

Don't verify package or header signatures when reading.

--nolinkto

--nofiledigest (formerly --nomd5)

--nosize

--nouser

--nogroup

--nomtime

--nomode

--nordev

Don't verify the corresponding file attribute.

The format of the output is a string of 8 characters, a possible attribute marker:

```
c %config configuration file.
d %doc documentation file.
g %ghost file (i.e. the file contents are not included in the package payload).
l %license license file.
r %readme readme file.
```

from the package header, followed by the file name. Each of the 8 characters denotes the result of a comparison of **attribute(s)** of the file to the value of those **attribute(s)** recorded in the database. A single "." (period) means the test passed, while a single "?" (question mark) indicates the test could not be performed (e.g. file permissions prevent reading). Otherwise, the (mnemonically em**Boldened**) character denotes failure of the corresponding **--verify** test:

S file Size differs

M Mode differs (includes permissions and file type)

5 digest (formerly MD5 sum) differs

D Device major/minor number mismatch

L readlink(2) path mismatch

U User ownership differs

G Group ownership differs

T mTime differs

P caPabilities differ

Digital Signature and Digest Verification

The general forms of rpm digital signature commands are

rpm --import PUBKEY ...

rpm {--checksig} [--nosignature] [--nodigest] PACKAGE_FILE ...

The **--checksig** option checks all the digests and signatures contained in *PACKAGE_FILE* to ensure the integrity and origin of the package. Note that signatures are now verified whenever a package is read, and **--checksig** is useful to verify all of the digests and signatures associated with a package.

Digital signatures cannot be verified without a public key. An ASCII armored public key can be added to the **rpm** database using **--import**. An imported public key is carried in a header, and key ring management is performed exactly like package management. For example, all currently imported public keys can be displayed by:

rpm -qa gpg-pubkey*

Details about a specific public key, when imported, can be displayed by querying. Here's information about the Red Hat GPG/DSA key:

rpm -qi gpg-pubkey-db42a60e

Finally, public keys can be erased after importing just like packages. Here's how to remove the Red Hat GPG/DSA key

rpm -e gpg-pubkey-db42a60e

Signing a Package

rpm --addsign|--resign PACKAGE_FILE ...

Both of the **--addsign** and **--resign** options generate and insert new signatures for each package *PACKAGE_FILE* given, replacing any existing signatures. There are two options for historical reasons, there is no difference in behavior currently.

Using Gpg to Sign Packages

In order to sign packages using GPG, **rpm** must be configured to run GPG and be able to find a key ring with the appropriate keys. By default, **rpm** uses the same conventions as GPG to find key rings, namely the **\$GNUPGHOME** environment variable. If your key rings are not located where GPG expects them to be, you will need to configure the macro **%_gpg_path** to be the location of the GPG key rings to use.

For compatibility with older versions of GPG, PGP, and rpm, only V3 OpenPGP signature packets should be configured. Either DSA or RSA verification algorithms can be used, but DSA is preferred.

If you want to be able to sign packages you create yourself, you also need to create your own public and secret key pair (see the GPG manual). You will also need to configure the

rpm macros**%_signature**

The signature type. Right now only gpg and pgp are supported.

%_gpg_name

The name of the "user" whose key you wish to use to sign your packages.

For example, to be able to use GPG to sign packages as the user "*John Doe <jdoe@foo.com>*" from the key rings located in `/etc/rpm/.gpg` using the executable `/usr/bin/gpg` you would include

```
%_signature gpg
%_gpg_path /etc/rpm/.gpg
%_gpg_name John Doe <jdoe@foo.com>
%_gpg /usr/bin/gpg
```

in a macro configuration file. Use `/etc/rpm/macros` for per-system configuration and `~/.rpmmacros` for per-user configuration. Typically it's sufficient to set just `%_gpg_name`.

Rebuild Database Options

The general form of an rpm rebuild database command is

rpm {--initdb|--rebuilddb} [-v] [--dbpath DIRECTORY] [--root DIRECTORY]

Use **--initdb** to create a new database if one doesn't already exist (existing database is not overwritten), use **--rebuilddb** to rebuild the database indices from the installed package headers.

Miscellaneous Commands**rpm --showrc**

shows the values **rpm** will use for all of the options are currently set in `rpmrc` and `macros` configuration **file(s)**.

rpm --setperms PACKAGE_NAME

sets permissions of files in the given package.

rpm --setugids PACKAGE_NAME

sets user/group ownership of files in the given package.

Ftp/Http Options

rpm can act as an FTP and/or HTTP client so that packages can be queried or installed from the internet. Package files for install, upgrade, and query operations may be specified as an **ftp** or **http** style URL:

`ftp://USER:PASSWORD@HOST:PORT/path/to/package.rpm`

If the **:PASSWORD** portion is omitted, the password will be prompted for (once per user/hostname pair). If both the user and password are omitted, anonymous **ftp** is used. In all cases, passive (PASV) **ftp** transfers are performed.

rpm allows the following options to be used with **ftp** URLs:

--ftpproxy **HOST**

The host **HOST** will be used as a proxy server for all **ftp** transfers, which allows users to **ftp** through firewall machines which use proxy systems. This option may also be specified by configuring the macro **%_ftpproxy**.

--ftpport **PORT**

The TCP **PORT** number to use for the **ftp** connection on the proxy **ftp** server instead of the default port. This option may also be specified by configuring the macro **%_ftpport**.

rpm allows the following options to be used with **http** URLs:

--httpproxy **HOST**

The host **HOST** will be used as a proxy server for all **http** transfers. This option may also be specified by configuring the macro **%_httpproxy**.

--httpport **PORT**

The TCP **PORT** number to use for the **http** connection on the proxy **http** server instead of the default port. This option may also be specified by configuring the macro **%_httpport**.

Legacy Issues

Executing **rpmbuild**

The build modes of **rpm** are now resident in the **/usr/bin/rpmbuild** executable. Install the package containing **rpmbuild** (usually **rpm-build**) and see ***rpmbuild*(8)** for documentation of all the **rpm** build modes.

NAME

rsync-ssl – a helper script for connecting to an ssl rsync daemon

SYNOPSIS

```
rsync-ssl [--type=SSL_TYPE] RSYNC_ARGS
```

DESCRIPTION

The rsync-ssl script helps you to run an rsync copy to/from an rsync daemon that requires ssl connections.

The script requires that you specify an rsync-daemon arg in the style of either **hostname::** (with 2 colons) or **rsync://hostname/**. The default port used for connecting is 874 (one higher than the normal 873) unless overridden in the environment. You can specify an overriding port via **--port** or by including it in the normal spot in the URL format, though both of those require your rsync version to be at least 3.2.0.

OPTIONS

If the **first** arg is a **--type=SSL_TYPE** option, the script will only use that particular program to open an ssl connection instead of trying to find an openssl or stunnel executable via a simple heuristic (assuming that the **RSYNC_SSL_TYPE** environment variable is not set as well -- see below). This option must specify one of **openssl** or **stunnel**. The equal sign is required for this particular option.

All the other options are passed through to the rsync command, so consult the **rsync(1)** manpage for more information on how it works.

ENVIRONMENT VARIABLES

The ssl helper scripts are affected by the following environment variables:

RSYNC_SSL_TYPE

Specifies the program type that should be used to open the ssl connection. It must be one of **openssl** or **stunnel**. The **--type=SSL_TYPE** option overrides this, when specified.

RSYNC_SSL_PORT

If specified, the value is the port number that is used as the default when the user does not specify a port in their rsync command. When not specified, the default port number is 874. (Note that older rsync versions (prior to 3.2.0) did not communicate an overriding port number value to the helper script.)

RSYNC_SSL_CERT

If specified, the value is a filename that contains a certificate to use for the connection.

RSYNC_SSL_CA_CERT

If specified, the value is a filename that contains a certificate authority certificate that is used to validate the connection.

RSYNC_SSL_OPENSSL

Specifies the openssl executable to run when the connection type is set to openssl. If unspecified, the \$PATH is searched for "openssl".

RSYNC_SSL_GNUTLS

Specifies the gnutls-cli executable to run when the connection type is set to gnutls. If unspecified, the \$PATH is searched for "gnutls-cli".

RSYNC_SSL_STUNNEL

Specifies the stunnel executable to run when the connection type is set to stunnel. If unspecified, the \$PATH is searched first for "stunnel4" and then for "stunnel".

EXAMPLES

```
rsync-ssl -av example.com::mod/ dest  
rsync-ssl --type=openssl -av example.com::mod/ dest  
rsync-ssl -av --port 9874 example.com::mod/ dest  
rsync-ssl -av rsync://example.com:9874/mod/ dest
```

SEE ALSO

rsync(1), rsyncd.conf(5)

CAVEATS

Note that using an stunnel connection requires at least version 4 of stunnel, which should be the case on modern systems. Also, it does not verify a connection against the CA certificate collection, so it only encrypts the connection without any cert validation unless you have specified the certificate environment options.

This script also supports a **--type=gnutls** option, but at the time of this release the gnutls-cli command was dropping output, making it unusable. If that bug has been fixed in your version, feel free to put gnutls into an exported RSYNC_SSL_TYPE environment variable to make its use the default.

BUGS

Please report bugs! See the web site at <https://rsync.samba.org/>.

VERSION

This man page is current for version 3.2.3 of rsync.

CREDITS

rsync is distributed under the GNU General Public License. See the file COPYING for details.

NAME

rsync – a fast, versatile, remote (and local) file-copying tool

SYNOPSIS

Local:

```
rsync [OPTION...] SRC... [DEST]
```

Access via remote shell:

Pull:

```
rsync [OPTION...] [USER@]HOST:SRC... [DEST]
```

Push:

```
rsync [OPTION...] SRC... [USER@]HOST:DEST
```

Access via rsync daemon:

Pull:

```
rsync [OPTION...] [USER@]HOST::SRC... [DEST]
```

```
rsync [OPTION...] rsync://[USER@]HOST[:PORT]/SRC... [DEST]
```

Push:

```
rsync [OPTION...] SRC... [USER@]HOST::DEST
```

```
rsync [OPTION...] SRC... rsync://[USER@]HOST[:PORT]/DEST
```

Usages with just one SRC arg and no DEST arg will list the source files instead of copying.

DESCRIPTION

Rsync is a fast and extraordinarily versatile file copying tool. It can copy locally, to/from another host over any remote shell, or to/from a remote rsync daemon. It offers a large number of options that control every aspect of its behavior and permit very flexible specification of the set of files to be copied. It is famous for its delta-transfer algorithm, which reduces the amount of data sent over the network by sending only the differences between the source files and the existing files in the destination. Rsync is widely used for backups and mirroring and as an improved copy command for everyday use.

Rsync finds files that need to be transferred using a "quick check" algorithm (by default) that looks for files that have changed in size or in last-modified time. Any changes in the other preserved attributes (as requested by options) are made on the destination file directly when the quick check indicates that the file's data does not need to be updated.

Some of the additional features of rsync are:

- o support for copying links, devices, owners, groups, and permissions
- o exclude and exclude-from options similar to GNU tar
- o a CVS exclude mode for ignoring the same files that CVS would ignore
- o can use any transparent remote shell, including ssh or rsh
- o does not require super-user privileges
- o pipelining of file transfers to minimize latency costs
- o support for anonymous or authenticated rsync daemons (ideal for mirroring)

GENERAL

Rsync copies files either to or from a remote host, or locally on the current host (it does not support copying files between two remote hosts).

There are two different ways for rsync to contact a remote system: using a remote-shell program as the transport (such as ssh or rsh) or contacting an rsync daemon directly via TCP. The remote-shell transport is used whenever the source or destination path contains a single colon (:) separator after a host specification. Contacting an rsync daemon directly happens when the source or destination path contains a double colon (::) separator after a host specification, OR when an rsync:// URL is specified (see also the "USING RSYNC-DAEMON FEATURES VIA A REMOTE-SHELL CONNECTION" section for an exception to this latter rule).

As a special case, if a single source arg is specified without a destination, the files are listed in an output format similar to "**ls -l**".

As expected, if neither the source or destination path specify a remote host, the copy occurs locally (see also the **--list-only** option).

Rsync refers to the local side as the client and the remote side as the server. Don't confuse server with an rsync daemon. A daemon is always a server, but a server can be either a daemon or a remote-shell spawned process.

SETUP

See the file README.md for installation instructions.

Once installed, you can use rsync to any machine that you can access via a remote shell (as well as some that you can access using the rsync daemon-mode protocol). For remote transfers, a modern rsync uses ssh for its communications, but it may have been configured to use a different remote shell by default, such as rsh or remsh.

You can also specify any remote shell you like, either by using the **-e** command line option, or by setting the RSYNC_RSH environment variable.

Note that rsync must be installed on both the source and destination machines.

USAGE

You use rsync in the same way you use rcp. You must specify a source and a destination, one of which may be remote.

Perhaps the best way to explain the syntax is with some examples:

```
rsync -t *.c foo:src/
```

This would transfer all files matching the pattern ***.c** from the current directory to the directory **src** on the machine **foo**. If any of the files already exist on the remote system then the rsync remote-update protocol is used to update the file by sending only the differences in the data. Note that the expansion of wildcards on the command-line (***.c**) into a list of files is handled by the shell before it runs rsync and not by rsync itself (exactly the same as all other Posix-style programs).

```
rsync -avz foo:src/bar /data/tmp
```

This would recursively transfer all files from the directory **src/bar** on the machine **foo** into the **/data/tmp/bar** directory on the local machine. The files are transferred in archive mode, which ensures that symbolic links, devices, attributes, permissions, ownerships, etc. are preserved in the transfer. Additionally, compression will be used to reduce the size of data portions of the transfer.

```
rsync -avz foo:src/bar/ /data/tmp
```

A trailing slash on the source changes this behavior to avoid creating an additional directory level at the destination. You can think of a trailing **/** on a source as meaning "copy the contents of this directory" as opposed to "copy the directory by name", but in both cases the attributes of the containing directory are transferred to the containing directory on the destination. In other words, each of the following commands copies the files in the same way, including their setting of the attributes of **/dest/foo**:

```
rsync -av /src/foo /dest
```

```
rsync -av /src/foo/ /dest/foo
```

Note also that host and module references don't require a trailing slash to copy the contents of the default directory. For example, both of these copy the remote directory's contents into **"/dest"**:

```
rsync -av host: /dest
```

```
rsync -av host::module /dest
```

You can also use rsync in local-only mode, where both the source and destination don't have a **:** in the name. In this case it behaves like an improved copy command.

Finally, you can list all the (listable) modules available from a particular rsync daemon by leaving off the module name:

```
rsync somehost.mydomain.com::
```

See the following section for more details.

ADVANCED USAGE

The syntax for requesting multiple files from a remote host is done by specifying additional remote-host args in the same style as the first, or with the hostname omitted. For instance, all these work:

```
rsync -av host:file1 :file2 host:file{3,4} /dest/  
rsync -av host::modname/file{1,2} host::modname/file3 /dest/  
rsync -av host::modname/file1 ::modname/file{3,4}
```

Older versions of rsync required using quoted spaces in the SRC, like these examples:

```
rsync -av host:'dir1/file1 dir2/file2' /dest  
rsync host::'modname/dir1/file1 modname/dir2/file2' /dest
```

This word-splitting still works (by default) in the latest rsync, but is not as easy to use as the first method.

If you need to transfer a filename that contains whitespace, you can either specify the **--protect-args** (-s) option, or you'll need to escape the whitespace in a way that the remote shell will understand. For instance:

```
rsync -av host:'file\ name\ with\ spaces' /dest
```

CONNECTING TO AN RSYNC DAEMON

It is also possible to use rsync without a remote shell as the transport. In this case you will directly connect to a remote rsync daemon, typically using TCP port 873. (This obviously requires the daemon to be running on the remote system, so refer to the STARTING AN RSYNC DAEMON TO ACCEPT CONNECTIONS section below for information on that.)

Using rsync in this way is the same as using it with a remote shell except that:

- o you either use a double colon :: instead of a single colon to separate the hostname from the path, or you use an rsync:// URL.
- o the first word of the "path" is actually a module name.
- o the remote daemon may print a message of the day when you connect.
- o if you specify no path name on the remote daemon then the list of accessible paths on the daemon will be shown.
- o if you specify no local destination then a listing of the specified files on the remote daemon is provided.
- o you must not specify the **--rsh** (-e) option (since that overrides the daemon connection to use ssh -- see USING RSYNC-DAEMON FEATURES VIA A REMOTE-SHELL CONNECTION below).

An example that copies all the files in a remote module named "src":

```
rsync -av host::src /dest
```

Some modules on the remote daemon may require authentication. If so, you will receive a password prompt when you connect. You can avoid the password prompt by setting the environment variable RSYNC_PASSWORD to the password you want to use or using the **--password-file** option. This may be useful when scripting rsync.

WARNING: On some systems environment variables are visible to all users. On those systems using **--password-file** is recommended.

You may establish the connection via a web proxy by setting the environment variable RSYNC_PROXY to a hostname:port pair pointing to your web proxy. Note that your web proxy's configuration must support proxy connections to port 873.

You may also establish a daemon connection using a program as a proxy by setting the environment variable RSYNC_CONNECT_PROG to the commands you wish to run in place of making a direct socket connection. The string may contain the escape "%H" to represent the hostname specified in the rsync

command (so use "%%" if you need a single "%" in your string). For example:

```
export RSYNC_CONNECT_PROG='ssh proxyhost nc %H 873'
rsync -av targethost1::module/src/ /dest/
rsync -av rsync://targethost2/module/src/ /dest/
```

The command specified above uses ssh to run nc (netcat) on a proxyhost, which forwards all data to port 873 (the rsync daemon) on the targethost (%H).

Note also that if the RSYNC_SHELL environment variable is set, that program will be used to run the RSYNC_CONNECT_PROG command instead of using the default shell of the `system()` call.

USING RSYNC-DAEMON FEATURES VIA A REMOTE-SHELL CONNECTION

It is sometimes useful to use various features of an rsync daemon (such as named modules) without actually allowing any new socket connections into a system (other than what is already required to allow remote-shell access). Rsync supports connecting to a host using a remote shell and then spawning a single-use "daemon" server that expects to read its config file in the home dir of the remote user. This can be useful if you want to encrypt a daemon-style transfer's data, but since the daemon is started up fresh by the remote user, you may not be able to use features such as chroot or change the uid used by the daemon. (For another way to encrypt a daemon transfer, consider using ssh to tunnel a local port to a remote machine and configure a normal rsync daemon on that remote host to only allow connections from "localhost".)

From the user's perspective, a daemon transfer via a remote-shell connection uses nearly the same command-line syntax as a normal rsync-daemon transfer, with the only exception being that you must explicitly set the remote shell program on the command-line with the `--rsh=COMMAND` option. (Setting the RSYNC_RSH in the environment will not turn on this functionality.) For example:

```
rsync -av --rsh=ssh host::module /dest
```

If you need to specify a different remote-shell user, keep in mind that the `user@` prefix in front of the host is specifying the rsync-user value (for a module that requires user-based authentication). This means that you must give the `-l user` option to ssh when specifying the remote-shell, as in this example that uses the short version of the `--rsh` option:

```
rsync -av -e "ssh -l ssh-user" rsync-user@host::module /dest
```

The "ssh-user" will be used at the ssh level; the "rsync-user" will be used to log-in to the "module".

STARTING AN RSYNC DAEMON TO ACCEPT CONNECTIONS

In order to connect to an rsync daemon, the remote system needs to have a daemon already running (or it needs to have configured something like inetd to spawn an rsync daemon for incoming connections on a particular port). For full information on how to start a daemon that will handle incoming socket connections, see the `rsyncd.conf(5)` man page --- that is the config file for the daemon, and it contains the full details for how to run the daemon (including stand-alone and inetd configurations).

If you're using one of the remote-shell transports for the transfer, there is no need to manually start an rsync daemon.

SORTED TRANSFER ORDER

Rsync always sorts the specified filenames into its internal transfer list. This handles the merging together of the contents of identically named directories, makes it easy to remove duplicate filenames, and may confuse someone when the files are transferred in a different order than what was given on the command-line.

If you need a particular file to be transferred prior to another, either separate the files into different rsync calls, or consider using `--delay-updates` (which doesn't affect the sorted transfer order, but does make the final file-updating phase happen much more rapidly).

EXAMPLES

Here are some examples of how I use rsync.

To backup my wife's home directory, which consists of large MS Word files and mail folders, I use a cron job that runs

```
rsync -Cavz . arvidsjaur:backup
```

each night over a PPP connection to a duplicate directory on my machine "arvidsjaur".

To synchronize my samba source trees I use the following Makefile targets:

```
get:
    rsync -avuzb --exclude '*~' samba:samba/
put:
    rsync -Cavuzb . samba:samba/
sync: get put
```

This allows me to sync with a CVS directory at the other end of the connection. I then do CVS operations on the remote machine, which saves a lot of time as the remote CVS protocol isn't very efficient.

I mirror a directory between my "old" and "new" ftp sites with the command:

```
rsync -az -e ssh --delete ~ftp/pub/samba nimbus:"~ftp/pub/tridge"
```

This is launched from cron every few hours.

OPTION SUMMARY

Here is a short summary of the options available in rsync. Please refer to the detailed description below for a complete description.

--verbose, -v	increase verbosity
--info=FLAGS	fine-grained informational verbosity
--debug=FLAGS	fine-grained debug verbosity
--stderr=e a c	change stderr output mode (default: errors)
--quiet, -q	suppress non-error messages
--no-motd	suppress daemon-mode MOTD
--checksum, -c	skip based on checksum, not mod-time & size
--archive, -a	archive mode is -rlptgoD (no -A,-X,-U,-N,-H)
--no-OPTION	turn off an implied OPTION (e.g. --no-D)
--recursive, -r	recurse into directories
--relative, -R	use relative path names
--no-implied-dirs	don't send implied dirs with --relative
--backup, -b	make backups (see --suffix & --backup-dir)
--backup-dir=DIR	make backups into hierarchy based in DIR
--suffix=SUFFIX	backup suffix (default ~ w/o --backup-dir)
--update, -u	skip files that are newer on the receiver
--inplace	update destination files in-place
--append	append data onto shorter files
--append-verify	--append w/old data in file checksum
--dirs, -d	transfer directories without recursing
--mkpath	create the destination's path component
--links, -l	copy symlinks as symlinks
--copy-links, -L	transform symlink into referent file/dir
--copy-unsafe-links	only "unsafe" symlinks are transformed
--safe-links	ignore symlinks that point outside the tree
--munge-links	munge symlinks to make them safe & unusable
--copy-dirlinks, -k	transform symlink to dir into referent dir
--keep-dirlinks, -K	treat symlinked dir on receiver as dir
--hard-links, -H	preserve hard links
--perms, -p	preserve permissions
--executability, -E	preserve executability
--chmod=CHMOD	affect file and/or directory permissions
--acls, -A	preserve ACLs (implies --perms)
--xattrs, -X	preserve extended attributes
--owner, -o	preserve owner (super-user only)
--group, -g	preserve group

```
--devices      preserve device files (super-user only)
--copy-devices    copy device contents as regular file
--specials      preserve special files
-D            same as --devices --specials
--times, -t      preserve modification times
--atimes, -U      preserve access (use) times
--open-noatime    avoid changing the atime on opened files
--crtimes, -N      preserve create times (newness)
--omit-dir-times, -O  omit directories from --times
--omit-link-times, -J  omit symlinks from --times
--super        receiver attempts super-user activities
--fake-super    store/recover privileged attrs using xattrs
--sparse, -S      turn sequences of nulls into sparse blocks
--preallocate    allocate dest files before writing them
--write-devices   write to devices as files (implies --inplace)
--dry-run, -n      perform a trial run with no changes made
--whole-file, -W      copy files whole (w/o delta-xfer algorithm)
--checksum-choice=STR  choose the checksum algorithm (aka --cc)
--one-file-system, -x  don't cross filesystem boundaries
--block-size=SIZE, -B  force a fixed checksum block-size
--rsh=COMMAND, -e      specify the remote shell to use
--rsync-path=PROGRAM   specify the rsync to run on remote machine
--existing      skip creating new files on receiver
--ignore-existing    skip updating files that exist on receiver
--remove-source-files  sender removes synchronized files (non-dir)
--del          an alias for --delete-during
--delete        delete extraneous files from dest dirs
--delete-before    receiver deletes before xfer, not during
--delete-during    receiver deletes during the transfer
--delete-delay     find deletions during, delete after
--delete-after     receiver deletes after transfer, not during
--delete-excluded   also delete excluded files from dest dirs
--ignore-missing-args  ignore missing source args without error
--delete-missing-args  delete missing source args from destination
--ignore-errors     delete even if there are I/O errors
--force          force deletion of dirs even if not empty
--max-delete=NUM      don't delete more than NUM files
--max-size=SIZE      don't transfer any file larger than SIZE
--min-size=SIZE      don't transfer any file smaller than SIZE
--max-alloc=SIZE      change a limit relating to memory alloc
--partial        keep partially transferred files
--partial-dir=DIR     put a partially transferred file into DIR
--delay-updates    put all updated files into place at end
--prune-empty-dirs, -m  prune empty directory chains from file-list
--numeric-ids      don't map uid/gid values by user/group name
--usermap=STRING     custom username mapping
--groupmap=STRING    custom groupname mapping
--chown=USER:GROUP    simple username/groupname mapping
--timeout=SECONDS    set I/O timeout in seconds
--contimeout=SECONDS   set daemon connection timeout in seconds
--ignore-times, -I      don't skip files that match size and time
--size-only       skip files that match in size
--modify-window=NUM, -@  set the accuracy for mod-time comparisons
--temp-dir=DIR, -T      create temporary files in directory DIR
```

```
--fuzzy, -y      find similar file for basis if no dest file
--compare-dest=DIR  also compare destination files relative to DIR
--copy-dest=DIR    ... and include copies of unchanged files
--link-dest=DIR    hardlink to files in DIR when unchanged
--compress, -z     compress file data during the transfer
--compress-choice=STR choose the compression algorithm (aka --zc)
--compress-level=NUM explicitly set compression level (aka --zl)
--skip-compress=LIST skip compressing files with suffix in LIST
--cvs-exclude, -C auto-ignore files in the same way CVS does
--filter=RULE, -f add a file-filtering RULE
-F                 same as --filter='dir-merge ./rsync-filter'
                   repeated: --filter='-' .rsync-filter'
--exclude=PATTERN  exclude files matching PATTERN
--exclude-from=FILE read exclude patterns from FILE
--include=PATTERN   don't exclude files matching PATTERN
--include-from=FILE read include patterns from FILE
--files-from=FILE   read list of source-file names from FILE
--from0, -0         all *-from/filter files are delimited by 0s
--protect-args, -s  no space-splitting; wildcard chars only
--copy-as=USER[:GROUP] specify user & optional group for the copy
--address=ADDRESS   bind address for outgoing socket to daemon
--port=PORT         specify double-colon alternate port number
--sockopt=OPTIONS   specify custom TCP options
--blocking-io       use blocking I/O for the remote shell
--outbuf=N|L|B      set out buffering to None, Line, or Block
--stats              give some file-transfer stats
--8-bit-output, -8   leave high-bit chars unescaped in output
--human-readable, -h output numbers in a human-readable format
--progress           show progress during transfer
-P                 same as --partial --progress
--itemize-changes, -i output a change-summary for all updates
--remote-option=OPT, -M send OPTION to the remote side only
--out-format=FORMAT  output updates using the specified FORMAT
--log-file=FILE      log what we're doing to the specified FILE
--log-file-format=FMT log updates using the specified FMT
--password-file=FILE read daemon-access password from FILE
--early-input=FILE   use FILE for daemon's early exec input
--list-only          list the files instead of copying them
--bwlimit=RATE        limit socket I/O bandwidth
--stop-after=MINS    Stop rsync after MINS minutes have elapsed
--stop-at=y-m-dTh:m  Stop rsync at the specified point in time
--write-batch=FILE   write a batched update to FILE
--only-write-batch=FILE like --write-batch but w/o updating dest
--read-batch=FILE    read a batched update from FILE
--protocol=NUM        force an older protocol version to be used
--iconv=CONVERT_SPEC request charset conversion of filenames
--checksum-seed=NUM  set block/file checksum seed (advanced)
--ipv4, -4            prefer IPv4
--ipv6, -6            prefer IPv6
--version, -V          print the version + other info and exit
--help, -h (*)        show this help (* -h is help only on its own)
```

Rsync can also be run as a daemon, in which case the following options are accepted:

```
--daemon           run as an rsync daemon
--address=ADDRESS  bind to the specified address
```

```
--bwlimit=RATE      limit socket I/O bandwidth
--config=FILE       specify alternate rsyncd.conf file
--dparam=OVERRIDE, -M  override global daemon config parameter
--no-detach        do not detach from the parent
--port=PORT         listen on alternate port number
--log-file=FILE     override the "log file" setting
--log-file-format=FMT  override the "log format" setting
--sockopts=OPTIONS  specify custom TCP options
--verbose, -v       increase verbosity
--ipv4, -4          prefer IPv4
--ipv6, -6          prefer IPv6
--help, -h          show this help (when used with --daemon)
```

OPTIONS

Rsync accepts both long (double-dash + word) and short (single-dash + letter) options. The full list of the available options are described below. If an option can be specified in more than one way, the choices are comma-separated. Some options only have a long variant, not a short. If the option takes a parameter, the parameter is only listed after the long variant, even though it must also be specified for the short. When specifying a parameter, you can either use the form **--option=param** or replace the '=' with whitespace. The parameter may need to be quoted in some manner for it to survive the shell's command-line parsing. Keep in mind that a leading tilde (~) in a filename is substituted by your shell, so **--option=~foo** will not change the tilde into your home directory (remove the '=' for that).

--help, -h (*)

Print a short help page describing the options available in rsync and exit. (*) The **-h** short option will only invoke **--help** when used without other options since it normally means **--human-readable**.

--version, -V

Print the rsync version plus other info and exit.

The output includes the default list of checksum algorithms, the default list of compression algorithms, a list of compiled-in capabilities, a link to the rsync web site, and some license/copyright info.

--verbose, -v

This option increases the amount of information you are given during the transfer. By default, rsync works silently. A single **-v** will give you information about what files are being transferred and a brief summary at the end. Two **-v** options will give you information on what files are being skipped and slightly more information at the end. More than two **-v** options should only be used if you are debugging rsync.

In a modern rsync, the **-v** option is equivalent to the setting of groups of **--info** and **--debug** options. You can choose to use these newer options in addition to, or in place of using **--verbose**, as any fine-grained settings override the implied settings of **-v**. Both **--info** and **--debug** have a way to ask for help that tells you exactly what flags are set for each increase in verbosity.

However, do keep in mind that a daemon's "**max verbosity**" setting will limit how high of a level the various individual flags can be set on the daemon side. For instance, if the max is 2, then any info and/or debug flag that is set to a higher value than what would be set by **-vv** will be downgraded to the **-vv** level in the daemon's logging.

--info=FLAGS

This option lets you have fine-grained control over the information output you want to see. An individual flag name may be followed by a level number, with 0 meaning to silence that output, 1 being the default output level, and higher numbers increasing the output of that flag (for those that support higher levels). Use **--info=help** to see all the available flag names, what they output, and what flag names are added for each increase in the verbose level. Some examples:

```
rsync -a --info=progress2 src/ dest/
rsync -avv --info=stats2,misc1,flist0 src/ dest/
```

Note that **--info=name**'s output is affected by the **--out-format** and **--itemize-changes (-i)** options. See those options for more information on what is output and when.

This option was added to 3.1.0, so an older rsync on the server side might reject your attempts at fine-grained control (if one or more flags needed to be send to the server and the server was too old to understand them). See also the "**max verbosity**" caveat above when dealing with a daemon.

--debug=FLAGS

This option lets you have fine-grained control over the debug output you want to see. An individual flag name may be followed by a level number, with 0 meaning to silence that output, 1 being the default output level, and higher numbers increasing the output of that flag (for those that support higher levels). Use **--deb ug=help** to see all the available flag names, what they output, and what flag names are added for each increase in the verbose level. Some examples:

```
rsync -avvv --debug=none src/ dest/
rsync -avA --del --debug=del2,acl src/ dest/
```

Note that some debug messages will only be output when **--stderr=all** is specified, especially those pertaining to I/O and buffer debugging.

Beginning in 3.2.0, this option is no longer auto-forwarded to the server side in order to allow you to specify different debug values for each side of the transfer, as well as to specify a new debug option that is only present in one of the rsync versions. If you want to duplicate the same option on both sides, using brace expansion is an easy way to save you some typing. This works in zsh and bash:

```
rsync -av { -M, }--debug=del2 src/ dest/
```

--stderr=errors|all|client

This option controls which processes output to stderr and if info messages are also changed to stderr. The mode strings can be abbreviated, so feel free to use a single letter value. The 3 possible choices are:

- o **errors** – (the default) causes all the rsync processes to send an error directly to stderr, even if the process is on the remote side of the transfer. Info messages are sent to the client side via the protocol stream. If stderr is not available (i.e. when directly connecting with a daemon via a socket) errors fall back to being sent via the protocol stream.
- o **all** – causes all rsync messages (info and error) to get written directly to stderr from all (possible) processes. This causes stderr to become line-buffered (instead of raw) and eliminates the ability to divide up the info and error messages by file handle. For those doing debugging or using several levels of verbosity, this option can help to avoid clogging up the transfer stream (which should prevent any chance of a deadlock bug hanging things up). It also allows **--debug** to enable some extra I/O related messages.
- o **client** – causes all rsync messages to be sent to the client side via the protocol stream. One client process outputs all messages, with errors on stderr and info messages on std-out. This was the default in older rsync versions, but can cause error delays when a lot of transfer data is ahead of the messages. If you're pushing files to an older rsync, you may want to use **--stderr=all** since that idiom has been around for several releases.

This option was added in rsync 3.2.3. This version also began the forwarding of a non-default setting to the remote side, though rsync uses the backward-compatible options **--msgs2stderr** and **--no-msgs2stderr** to represent the **all** and **client** settings, respectively. A newer rsync will continue to accept these older option names to maintain compatibility.

--quiet, -q

This option decreases the amount of information you are given during the transfer, notably suppressing information messages from the remote server. This option is useful when invoking rsync

from cron.

--no-motd

This option affects the information that is output by the client at the start of a daemon transfer. This suppresses the message-of-the-day (MOTD) text, but it also affects the list of modules that the daemon sends in response to the "rsync host::" request (due to a limitation in the rsync protocol), so omit this option if you want to request the list of modules from the daemon.

--ignore-times, -I

Normally rsync will skip any files that are already the same size and have the same modification timestamp. This option turns off this "quick check" behavior, causing all files to be updated.

--size-only

This modifies rsync's "quick check" algorithm for finding files that need to be transferred, changing it from the default of transferring files with either a changed size or a changed last-modified time to just looking for files that have changed in size. This is useful when starting to use rsync after using another mirroring system which may not preserve timestamps exactly.

--modify-window=NUM, -@

When comparing two timestamps, rsync treats the timestamps as being equal if they differ by no more than the modify-window value. The default is 0, which matches just integer seconds. If you specify a negative value (and the receiver is at least version 3.1.3) then nanoseconds will also be taken into account. Specifying 1 is useful for copies to/from MS Windows FAT filesystems, because FAT represents times with a 2-second resolution (allowing times to differ from the original by up to 1 second).

If you want all your transfers to default to comparing nanoseconds, you can create a `~/.popt` file and put these lines in it:

```
rsync alias -a -a@-1
rsync alias -t -t@-1
```

With that as the default, you'd need to specify **--modify-window=0** (aka **-@0**) to override it and ignore nanoseconds, e.g. if you're copying between ext3 and ext4, or if the receiving rsync is older than 3.1.3.

--checksum, -c

This changes the way rsync checks if the files have been changed and are in need of a transfer. Without this option, rsync uses a "quick check" that (by default) checks if each file's size and time of last modification match between the sender and receiver. This option changes this to compare a 128-bit checksum for each file that has a matching size. Generating the checksums means that both sides will expend a lot of disk I/O reading all the data in the files in the transfer, so this can slow things down significantly (and this is prior to any reading that will be done to transfer changed files)

The sending side generates its checksums while it is doing the file-system scan that builds the list of the available files. The receiver generates its checksums when it is scanning for changed files, and will checksum any file that has the same size as the corresponding sender's file: files with either a changed size or a changed checksum are selected for transfer.

Note that rsync always verifies that each *transferred* file was correctly reconstructed on the receiving side by checking a whole-file checksum that is generated as the file is transferred, but that automatic after-the-transfer verification has nothing to do with this option's before-the-transfer "Does this file need to be updated?" check.

The checksum used is auto-negotiated between the client and the server, but can be overridden using either the **--checksum-choice** (**--cc**) option or an environment variable that is discussed in that option's section.

--archive, -a

This is equivalent to **-rlptgoD**. It is a quick way of saying you want recursion and want to preserve almost everything. Be aware that it does **not** include preserving ACLs (**-A**), xattrs (**-X**),

atimes (**-U**), ctimes (**-N**), nor the finding and preserving of hardlinks (**-H**).

The only exception to the above equivalence is when **--files-from** is specified, in which case **-r** is not implied.

--no-OPTION

You may turn off one or more implied options by prefixing the option name with "no-". Not all options may be prefixed with a "no-": only options that are implied by other options (e.g. **--no-D**, **--no-perms**) or have different defaults in various circumstances (e.g. **--no-whole-file**, **--no-blocking-io**, **--no-dirs**). You may specify either the short or the long option name after the "no-" prefix (e.g. **--no-R** is the same as **--no-relative**).

For example: if you want to use **-a** (**--archive**) but don't want **-o** (**--owner**), instead of converting **-a** into **-rlptgD**, you could specify **-a --no-o** (or **-a --no-owner**).

The order of the options is important: if you specify **--no-r -a**, the **-r** option would end up being turned on, the opposite of **-a --no-r**. Note also that the side-effects of the **--files-from** option are NOT positional, as it affects the default state of several options and slightly changes the meaning of **-a** (see the **--files-from** option for more details).

--recursive, -r

This tells rsync to copy directories recursively. See also **--dirs (-d)**.

Beginning with rsync 3.0.0, the recursive algorithm used is now an incremental scan that uses much less memory than before and begins the transfer after the scanning of the first few directories have been completed. This incremental scan only affects our recursion algorithm, and does not change a non-recursive transfer. It is also only possible when both ends of the transfer are at least version 3.0.0.

Some options require rsync to know the full file list, so these options disable the incremental recursion mode. These include: **--delete-before**, **--delete-after**, **--prune-empty-dirs**, and **--delay-updates**. Because of this, the default delete mode when you specify **--delete** is now **--delete-during** when both ends of the connection are at least 3.0.0 (use **--del** or **--delete-during** to request this improved deletion mode explicitly). See also the **--delete-delay** option that is a better choice than using **--delete-after**.

Incremental recursion can be disabled using the **--no-inc-recursive** option or its shorter **--no-i-r** alias.

--relative, -R

Use relative paths. This means that the full path names specified on the command line are sent to the server rather than just the last parts of the filenames. This is particularly useful when you want to send several different directories at the same time. For example, if you used this command:

```
rsync -av /foo/bar/baz.c remote:/tmp/
```

would create a file named *baz.c* in */tmp/* on the remote machine. If instead you used

```
rsync -avR /foo/bar/baz.c remote:/tmp/
```

then a file named */tmp/foo/bar/baz.c* would be created on the remote machine, preserving its full path. These extra path elements are called "implied directories" (i.e. the "foo" and the "foo/bar" directories in the above example).

Beginning with rsync 3.0.0, rsync always sends these implied directories as real directories in the file list, even if a path element is really a symlink on the sending side. This prevents some really unexpected behaviors when copying the full path of a file that you didn't realize had a symlink in its path. If you want to duplicate a server-side symlink, include both the symlink via its path, and referent directory via its real path. If you're dealing with an older rsync on the sending side, you may need to use the **--no-implied-dirs** option.

It is also possible to limit the amount of path information that is sent as implied directories for each path you specify. With a modern rsync on the sending side (beginning with 2.6.7), you can

insert a dot and a slash into the source path, like this:

```
rsync -avR /foo./bar/baz.c remote:/tmp/
```

That would create /tmp/bar/baz.c on the remote machine. (Note that the dot must be followed by a slash, so "/foo./" would not be abbreviated.) For older rsync versions, you would need to use a chdir to limit the source path. For example, when pushing files:

```
(cd /foo; rsync -avR bar/baz.c remote:/tmp/)
```

(Note that the parens put the two commands into a sub-shell, so that the "cd" command doesn't remain in effect for future commands.) If you're pulling files from an older rsync, use this idiom (but only for a non-daemon transfer):

```
rsync -avR --rsync-path="cd /foo; rsync" \
      remote:bar/baz.c /tmp/
```

--no-implied-dirs

This option affects the default behavior of the **--relative** option. When it is specified, the attributes of the implied directories from the source names are not included in the transfer. This means that the corresponding path elements on the destination system are left unchanged if they exist, and any missing implied directories are created with default attributes. This even allows these implied path elements to have big differences, such as being a symlink to a directory on the receiving side.

For instance, if a command-line arg or a files-from entry told rsync to transfer the file "path/foo/file", the directories "path" and "path/foo" are implied when **--relative** is used. If "path/foo" is a symlink to "bar" on the destination system, the receiving rsync would ordinarily delete "path/foo", recreate it as a directory, and receive the file into the new directory. With **--no-implied-dirs**, the receiving rsync updates "path/foo/file" using the existing path elements, which means that the file ends up being created in "path/bar". Another way to accomplish this link preservation is to use the **--keep-dirlinks** option (which will also affect symlinks to directories in the rest of the transfer).

When pulling files from an rsync older than 3.0.0, you may need to use this option if the sending side has a symlink in the path you request and you wish the implied directories to be transferred as normal directories.

--backup, -b

With this option, preexisting destination files are renamed as each file is transferred or deleted. You can control where the backup file goes and what (if any) suffix gets appended using the **--backup-dir** and **--suffix** options.

Note that if you don't specify **--backup-dir**, (1) the **--omit-dir-times** option will be forced on, and (2) if **--delete** is also in effect (without **--delete-excluded**), rsync will add a "protect" filter-rule for the backup suffix to the end of all your existing excludes (e.g. **-f "P *~"**). This will prevent previously backed-up files from being deleted. Note that if you are supplying your own filter rules, you may need to manually insert your own exclude/protect rule somewhere higher up in the list so that it has a high enough priority to be effective (e.g., if your rules specify a trailing inclusion/exclusion of *, the auto-added rule would never be reached).

--backup-dir=DIR

This implies the **--backup** option, and tells rsync to store all backups in the specified directory on the receiving side. This can be used for incremental backups. You can additionally specify a backup suffix using the **--suffix** option (otherwise the files backed up in the specified directory will keep their original filenames).

Note that if you specify a relative path, the backup directory will be relative to the destination directory, so you probably want to specify either an absolute path or a path that starts with "../". If an rsync daemon is the receiver, the backup dir cannot go outside the module's path hierarchy, so take extra care not to delete it or copy into it.

--suffix=SUFFIX

This option allows you to override the default backup suffix used with the **--backup (-b)** option. The default suffix is a ~ if no **--backup-dir** was specified, otherwise it is an empty string.

--update, -u

This forces rsync to skip any files which exist on the destination and have a modified time that is newer than the source file. (If an existing destination file has a modification time equal to the source file's, it will be updated if the sizes are different.)

Note that this does not affect the copying of dirs, symlinks, or other special files. Also, a difference of file format between the sender and receiver is always considered to be important enough for an update, no matter what date is on the objects. In other words, if the source has a directory where the destination has a file, the transfer would occur regardless of the timestamps.

This option is a transfer rule, not an exclude, so it doesn't affect the data that goes into the file-lists, and thus it doesn't affect deletions. It just limits the files that the receiver requests to be transferred.

--inplace

This option changes how rsync transfers a file when its data needs to be updated: instead of the default method of creating a new copy of the file and moving it into place when it is complete, rsync instead writes the updated data directly to the destination file.

This has several effects:

- o Hard links are not broken. This means the new data will be visible through other hard links to the destination file. Moreover, attempts to copy differing source files onto a multiply-linked destination file will result in a "tug of war" with the destination data changing back and forth.
- o In-use binaries cannot be updated (either the OS will prevent this from happening, or binaries that attempt to swap-in their data will misbehave or crash).
- o The file's data will be in an inconsistent state during the transfer and will be left that way if the transfer is interrupted or if an update fails.
- o A file that rsync cannot write to cannot be updated. While a super user can update any file, a normal user needs to be granted write permission for the open of the file for writing to be successful.
- o The efficiency of rsync's delta-transfer algorithm may be reduced if some data in the destination file is overwritten before it can be copied to a position later in the file. This does not apply if you use **--backup**, since rsync is smart enough to use the backup file as the basis file for the transfer.

WARNING: you should not use this option to update files that are being accessed by others, so be careful when choosing to use this for a copy.

This option is useful for transferring large files with block-based changes or appended data, and also on systems that are disk bound, not network bound. It can also help keep a copy-on-write filesystem snapshot from diverging the entire contents of a file that only has minor changes.

The option implies **--partial** (since an interrupted transfer does not delete the file), but conflicts with **--partial-dir** and **--delay-updates**. Prior to rsync 2.6.4 **--inplace** was also incompatible with **--compare-dest** and **--link-dest**.

--append

This special copy mode only works to efficiently update files that are known to be growing larger where any existing content on the receiving side is also known to be the same as the content on the sender. The use of **--append** can be **dangerous** if you aren't 100% sure that all the files in the transfer are shared, growing files. You should thus use filter rules to ensure that you weed out any files that do not fit this criteria.

Rsync updates these growing file in-place without verifying any of the existing content in the file (it only verifies the content that it is appending). Rsync skips any files that exist on the receiving side that are not shorter than the associated file on the sending side (which means that new files are transferred).

This does not interfere with the updating of a file's non-content attributes (e.g. permissions, ownership, etc.) when the file does not need to be transferred, nor does it affect the updating of any directories or non-regular files.

--append-verify

This special copy mode works like **--append** except that all the data in the file is included in the checksum verification (making it much less efficient but also potentially safer). This option **can be dangerous** if you aren't 100% sure that all the files in the transfer are shared, growing files. See the **--append** option for more details.

Note: prior to rsync 3.0.0, the **--append** option worked like **--append-verify**, so if you are interacting with an older rsync (or the transfer is using a protocol prior to 30), specifying either append option will initiate an **--append-verify** transfer.

--dirs, -d

Tell the sending side to include any directories that are encountered. Unlike **--recursive**, a directory's contents are not copied unless the directory name specified is `".` or ends with a trailing slash (e.g. `..`, `"dir/."`, `"dir/"`, etc.). Without this option or the **--recursive** option, rsync will skip all directories it encounters (and output a message to that effect for each one). If you specify both **--dirs** and **--recursive**, **--recursive** takes precedence.

The **--dirs** option is implied by the **--files-from** option or the **--list-only** option (including an implied **--list-only** usage) if **--recursive** wasn't specified (so that directories are seen in the listing). Specify **--no-dirs** (or **--no-d**) if you want to turn this off.

There is also a backward-compatibility helper option, **--old-dirs** (or **--old-d**) that tells rsync to use a hack of **-r --exclude='/*/*'** to get an older rsync to list a single directory without recursing.

--mkpath

Create a missing path component of the destination arg. This allows rsync to create multiple levels of missing destination dirs and to create a path in which to put a single renamed file. Keep in mind that you'll need to supply a trailing slash if you want the entire destination path to be treated as a directory when copying a single arg (making rsync behave the same way that it would if the path component of the destination had already existed).

For example, the following creates a copy of file `foo` as `bar` in the `sub/dir` directory, creating dirs `"sub"` and `"sub/dir"` if either do not yet exist:

```
rsync -ai --mkpath foo sub/dir/bar
```

If you instead ran the following, it would have created file `foo` in the `sub/dir/bar` directory:

```
rsync -ai --mkpath foo sub/dir/bar/
```

--links, -l

When symlinks are encountered, recreate the symlink on the destination.

--copy-links, -L

When symlinks are encountered, the item that they point to (the referent) is copied, rather than the symlink. In older versions of rsync, this option also had the side-effect of telling the receiving side to follow symlinks, such as symlinks to directories. In a modern rsync such as this one, you'll need to specify **--keep-dirlinks (-K)** to get this extra behavior. The only exception is when sending files to an rsync that is too old to understand **-K** — in that case, the **-L** option will still have the side-effect of **-K** on that older receiving rsync.

--copy-unsafe-links

This tells rsync to copy the referent of symbolic links that point outside the copied tree. Absolute symlinks are also treated like ordinary files, and so are any symlinks in the source path itself when

--relative is used. This option has no additional effect if **--copy-links** was also specified.

Note that the cut-off point is the top of the transfer, which is the part of the path that rsync isn't mentioning in the verbose output. If you copy "/src/subdir" to "/dest/" then the "subdir" directory is a name inside the transfer tree, not the top of the transfer (which is /src) so it is legal for created relative symlinks to refer to other names inside the /src and /dest directories. If you instead copy "/src/subdir/" (with a trailing slash) to "/dest/subdir" that would not allow symlinks to any files outside of "subdir".

--safe-links

This tells rsync to ignore any symbolic links which point outside the copied tree. All absolute symlinks are also ignored. Using this option in conjunction with **--relative** may give unexpected results.

--munge-links

This option tells rsync to (1) modify all symlinks on the receiving side in a way that makes them unusable but recoverable (see below), or (2) to unmunge symlinks on the sending side that had been stored in a munged state. This is useful if you don't quite trust the source of the data to not try to slip in a symlink to a unexpected place.

The way rsync disables the use of symlinks is to prefix each one with the string "/rsyncd-munged/". This prevents the links from being used as long as that directory does not exist. When this option is enabled, rsync will refuse to run if that path is a directory or a symlink to a directory.

The option only affects the client side of the transfer, so if you need it to affect the server, specify it via **--remote-option**. (Note that in a local transfer, the client side is the sender.)

This option has no affect on a daemon, since the daemon configures whether it wants munged symlinks via its "**munge symlinks**" parameter. See also the "munge-symlinks" perl script in the support directory of the source code.

--copy-dirlinks, -k

This option causes the sending side to treat a symlink to a directory as though it were a real directory. This is useful if you don't want symlinks to non-directories to be affected, as they would be using **--copy-links**.

Without this option, if the sending side has replaced a directory with a symlink to a directory, the receiving side will delete anything that is in the way of the new symlink, including a directory hierarchy (as long as **--force** or **--delete** is in effect).

See also **--keep-dirlinks** for an analogous option for the receiving side.

--copy-dirlinks applies to all symlinks to directories in the source. If you want to follow only a few specified symlinks, a trick you can use is to pass them as additional source args with a trailing slash, using **--relative** to make the paths match up right. For example:

```
rsync -r --relative src/./ src./follow-me/ dest/
```

This works because rsync calls **Istat(2)** on the source arg as given, and the trailing slash makes **Istat(2)** follow the symlink, giving rise to a directory in the file-list which overrides the symlink found during the scan of "src./".

--keep-dirlinks, -K

This option causes the receiving side to treat a symlink to a directory as though it were a real directory, but only if it matches a real directory from the sender. Without this option, the receiver's symlink would be deleted and replaced with a real directory.

For example, suppose you transfer a directory "foo" that contains a file "file", but "foo" is a symlink to directory "bar" on the receiver. Without **--keep-dirlinks**, the receiver deletes symlink "foo", recreates it as a directory, and receives the file into the new directory. With **--keep-dirlinks**, the receiver keeps the symlink and "file" ends up in "bar".

One note of caution: if you use **--keep-dirlinks**, you must trust all the symlinks in the copy! If it is possible for an untrusted user to create their own symlink to any directory, the user could then (on a subsequent copy) replace the symlink with a real directory and affect the content of whatever directory the symlink references. For backup copies, you are better off using something like a bind mount instead of a symlink to modify your receiving hierarchy.

See also **--copy-dirlinks** for an analogous option for the sending side.

--hard-links, -H

This tells rsync to look for hard-linked files in the source and link together the corresponding files on the destination. Without this option, hard-linked files in the source are treated as though they were separate files.

This option does NOT necessarily ensure that the pattern of hard links on the destination exactly matches that on the source. Cases in which the destination may end up with extra hard links include the following:

- o If the destination contains extraneous hard-links (more linking than what is present in the source file list), the copying algorithm will not break them explicitly. However, if one or more of the paths have content differences, the normal file-update process will break those extra links (unless you are using the **--inplace** option).
- o If you specify a **--link-dest** directory that contains hard links, the linking of the destination files against the **--link-dest** files can cause some paths in the destination to become linked together due to the **--link-dest** associations.

Note that rsync can only detect hard links between files that are inside the transfer set. If rsync updates a file that has extra hard-link connections to files outside the transfer, that linkage will be broken. If you are tempted to use the **--inplace** option to avoid this breakage, be very careful that you know how your files are being updated so that you are certain that no unintended changes happen due to lingering hard links (and see the **--inplace** option for more caveats).

If incremental recursion is active (see **--recursive**), rsync may transfer a missing hard-linked file before it finds that another link for that contents exists elsewhere in the hierarchy. This does not affect the accuracy of the transfer (i.e. which files are hard-linked together), just its efficiency (i.e. copying the data for a new, early copy of a hard-linked file that could have been found later in the transfer in another member of the hard-linked set of files). One way to avoid this inefficiency is to disable incremental recursion using the **--no-inc-recursive** option.

--perms, -p

This option causes the receiving rsync to set the destination permissions to be the same as the source permissions. (See also the **--chmod** option for a way to modify what rsync considers to be the source permissions.)

When this option is *off*, permissions are set as follows:

- o Existing files (including updated files) retain their existing permissions, though the **--executability** option might change just the execute permission for the file.
- o New files get their "normal" permission bits set to the source file's permissions masked with the receiving directory's default permissions (either the receiving process's umask, or the permissions specified via the destination directory's default ACL), and their special permission bits disabled except in the case where a new directory inherits a setgid bit from its parent directory.

Thus, when **--perms** and **--executability** are both disabled, rsync's behavior is the same as that of other file-copy utilities, such as **cp(1)** and **tar(1)**.

In summary: to give destination files (both old and new) the source permissions, use **--perms**. To give new files the destination-default permissions (while leaving existing files unchanged), make sure that the **--perms** option is off and use **--chmod=ugo=rwX** (which ensures that all non-masked bits get enabled). If you'd care to make this latter behavior easier to type, you could

define a popt alias for it, such as putting this line in the file `~/.popt` (the following defines the `-Z` option, and includes `--no-g` to use the default group of the destination dir):

```
rsync alias -Z --no-p --no-g --chmod=ugo=rwX
```

You could then use this new option in a command such as this one:

```
rsync -avZ src/ dest/
```

(Caveat: make sure that `-a` does not follow `-Z`, or it will re-enable the two `--no-*` options mentioned above.)

The preservation of the destination's setgid bit on newly-created directories when `--perms` is off was added in rsync 2.6.7. Older rsync versions erroneously preserved the three special permission bits for newly-created files when `--perms` was off, while overriding the destination's setgid bit setting on a newly-created directory. Default ACL observance was added to the ACL patch for rsync 2.6.7, so older (or non-ACL-enabled) rsyncs use the umask even if default ACLs are present. (Keep in mind that it is the version of the receiving rsync that affects these behaviors.)

--executability, -E

This option causes rsync to preserve the executability (or non-executability) of regular files when `--perms` is not enabled. A regular file is considered to be executable if at least one 'x' is turned on in its permissions. When an existing destination file's executability differs from that of the corresponding source file, rsync modifies the destination file's permissions as follows:

- o To make a file non-executable, rsync turns off all its 'x' permissions.
- o To make a file executable, rsync turns on each 'x' permission that has a corresponding 'r' permission enabled.

If `--perms` is enabled, this option is ignored.

--acls, -A

This option causes rsync to update the destination ACLs to be the same as the source ACLs. The option also implies `--perms`.

The source and destination systems must have compatible ACL entries for this option to work properly. See the `--fak e-super` option for a way to backup and restore ACLs that are not compatible.

--xattrs, -X

This option causes rsync to update the destination extended attributes to be the same as the source ones.

For systems that support extended-attribute namespaces, a copy being done by a super-user copies all namespaces except `system.*`. A normal user only copies the `user.*` namespace. To be able to backup and restore non-user namespaces as a normal user, see the `--fake-super` option.

The above name filtering can be overridden by using one or more filter options with the `x` modifier. When you specify an xattr-affecting filter rule, rsync requires that you do your own system/user filtering, as well as any additional filtering for what xattr names are copied and what names are allowed to be deleted. For example, to skip the system namespace, you could specify:

```
--filter=' -x system.*'
```

To skip all namespaces except the user namespace, you could specify a negated-user match:

```
--filter=' -x! user.*'
```

To prevent any attributes from being deleted, you could specify a receiver-only rule that excludes all names:

```
--filter=' -xr *'
```

Note that the `-X` option does not copy rsync's special xattr values (e.g. those used by `--fake-super`) unless you repeat the option (e.g. `-XX`). This "copy all xattrs" mode cannot be used with

--fake-super.**--chmod=CHMOD**

This option tells rsync to apply one or more comma-separated "chmod" modes to the permission of the files in the transfer. The resulting value is treated as though it were the permissions that the sending side supplied for the file, which means that this option can seem to have no effect on existing files if **--perms** is not enabled.

In addition to the normal parsing rules specified in the **chmod(1)** manpage, you can specify an item that should only apply to a directory by prefixing it with a 'D', or specify an item that should only apply to a file by prefixing it with a 'F'. For example, the following will ensure that all directories get marked set-gid, that no files are other-writable, that both are user-writable and group-writable, and that both have consistent executability across all bits:

```
--chmod=Dg+s,ug+w,Fo-w,+X
```

Using octal mode numbers is also allowed:

```
--chmod=D2775,F664
```

It is also legal to specify multiple **--chmod** options, as each additional option is just appended to the list of changes to make.

See the **--perms** and **--executability** options for how the resulting permission value can be applied to the files in the transfer.

--owner, -o

This option causes rsync to set the owner of the destination file to be the same as the source file, but only if the receiving rsync is being run as the super-user (see also the **--super** and **--fake-super** options). Without this option, the owner of new and/or transferred files are set to the invoking user on the receiving side.

The preservation of ownership will associate matching names by default, but may fall back to using the ID number in some circumstances (see also the **--numeric-ids** option for a full discussion).

--group, -g

This option causes rsync to set the group of the destination file to be the same as the source file. If the receiving program is not running as the super-user (or if **--no-super** was specified), only groups that the invoking user on the receiving side is a member of will be preserved. Without this option, the group is set to the default group of the invoking user on the receiving side.

The preservation of group information will associate matching names by default, but may fall back to using the ID number in some circumstances (see also the **--numeric-ids** option for a full discussion).

--devices

This option causes rsync to transfer character and block device files to the remote system to recreate these devices. This option has no effect if the receiving rsync is not run as the super-user (see also the **--super** and **--fake-super** options).

--specials

This option causes rsync to transfer special files such as named sockets and fifos.

-D The **-D** option is equivalent to **--devices --specials**.

--write-devices

This tells rsync to treat a device on the receiving side as a regular file, allowing the writing of file data into a device.

This option implies the **--inplace** option.

Be careful using this, as you should know what devices are present on the receiving side of the transfer, especially if running rsync as root.

This option is refused by an rsync daemon.

--times, -t

This tells rsync to transfer modification times along with the files and update them on the remote system. Note that if this option is not used, the optimization that excludes files that have not been modified cannot be effective; in other words, a missing **-t** or **-a** will cause the next transfer to behave as if it used **-I**, causing all files to be updated (though rsync's delta-transfer algorithm will make the update fairly efficient if the files haven't actually changed, you're much better off using **-t**).

--atimes, -U

This tells rsync to set the access (use) times of the destination files to the same value as the source files.

If repeated, it also sets the **--open-noatime** option, which can help you to make the sending and receiving systems have the same access times on the transferred files without needing to run rsync an extra time after a file is transferred.

Note that some older rsync versions (prior to 3.2.0) may have been built with a pre-release **--atimes** patch that does not imply **--open-noatime** when this option is repeated.

--open-noatime

This tells rsync to open files with the O_NOATIME flag (on systems that support it) to avoid changing the access time of the files that are being transferred. If your OS does not support the O_NOATIME flag then rsync will silently ignore this option. Note also that some filesystems are mounted to avoid updating the atime on read access even without the O_NOATIME flag being set.

--crtimes, -N,

This tells rsync to set the create times (newness) of the destination files to the same value as the source files.

--omit-dir-times, -O

This tells rsync to omit directories when it is preserving modification times (see **--times**). If NFS is sharing the directories on the receiving side, it is a good idea to use **-O**. This option is inferred if you use **--backup** without **--backup-dir**.

This option also has the side-effect of avoiding early creation of directories in incremental recursion copies. The default **--inc-recursive** copying normally does an early-create pass of all the sub-directories in a parent directory in order for it to be able to then set the modify time of the parent directory right away (without having to delay that until a bunch of recursive copying has finished). This early-create idiom is not necessary if directory modify times are not being preserved, so it is skipped. Since early-create directories don't have accurate mode, mtime, or ownership, the use of this option can help when someone wants to avoid these partially-finished directories.

--omit-link-times, -J

This tells rsync to omit symlinks when it is preserving modification times (see **--times**).

--super

This tells the receiving side to attempt super-user activities even if the receiving rsync wasn't run by the super-user. These activities include: preserving users via the **--owner** option, preserving all groups (not just the current user's groups) via the **--group** option, and copying devices via the **--devices** option. This is useful for systems that allow such activities without being the super-user, and also for ensuring that you will get errors if the receiving side isn't being run as the super-user. To turn off super-user activities, the super-user can use **--no-super**.

--fake-super

When this option is enabled, rsync simulates super-user activities by saving/restoring the privileged attributes via special extended attributes that are attached to each file (as needed). This includes the file's owner and group (if it is not the default), the file's device info (device & special files are created as empty text files), and any permission bits that we won't allow to be set on the real file (e.g. the real file gets u-s,g-s,o-t for safety) or that would limit the owner's access (since

the real super-user can always access/change a file, the files we create can always be accessed/changed by the creating user). This option also handles ACLs (if **--acls** was specified) and non-user extended attributes (if **--xattrs** was specified).

This is a good way to backup data without using a super-user, and to store ACLs from incompatible systems.

The **--fake-super** option only affects the side where the option is used. To affect the remote side of a remote-shell connection, use the **--remote-option (-M)** option:

```
rsync -av -M--fake-super /src/ host:/dest/
```

For a local copy, this option affects both the source and the destination. If you wish a local copy to enable this option just for the destination files, specify **-M--fake-super**. If you wish a local copy to enable this option just for the source files, combine **--fake-super** with **-M--super**.

This option is overridden by both **--super** and **--no-super**.

See also the "fake super" setting in the daemon's rsyncd.conf file.

--sparse, -S

Try to handle sparse files efficiently so they take up less space on the destination. If combined with **--inplace** the file created might not end up with sparse blocks with some combinations of kernel version and/or filesystem type. If **--whole-file** is in effect (e.g. for a local copy) then it will always work because rsync truncates the file prior to writing out the updated version.

Note that versions of rsync older than 3.1.3 will reject the combination of **--sparse** and **--inplace**.

--preallocate

This tells the receiver to allocate each destination file to its eventual size before writing data to the file. Rsync will only use the real filesystem-level preallocation support provided by Linux's **fallocate(2)** system call or Cygwin's **posix_fallocate(3)**, not the slow glibc implementation that writes a null byte into each block.

Without this option, larger files may not be entirely contiguous on the filesystem, but with this option rsync will probably copy more slowly. If the destination is not an extent-supporting filesystem (such as ext4, xfs, NTFS, etc.), this option may have no positive effect at all.

If combined with **--sparse**, the file will only have sparse blocks (as opposed to allocated sequences of null bytes) if the kernel version and filesystem type support creating holes in the allocated data.

--dry-run, -n

This makes rsync perform a trial run that doesn't make any changes (and produces mostly the same output as a real run). It is most commonly used in combination with the **--verbose, -v** and/or **--itemize-changes, -i** options to see what an rsync command is going to do before one actually runs it.

The output of **--itemize-changes** is supposed to be exactly the same on a dry run and a subsequent real run (barring intentional trickery and system call failures); if it isn't, that's a bug. Other output should be mostly unchanged, but may differ in some areas. Notably, a dry run does not send the actual data for file transfers, so **--progress** has no effect, the "bytes sent", "bytes received", "literal data", and "matched data" statistics are too small, and the "speedup" value is equivalent to a run where no file transfers were needed.

--whole-file, -W

This option disables rsync's delta-transfer algorithm, which causes all transferred files to be sent whole. The transfer may be faster if this option is used when the bandwidth between the source and destination machines is higher than the bandwidth to disk (especially when the "disk" is actually a networked filesystem). This is the default when both the source and destination are specified as local paths, but only if no batch-writing option is in effect.

--checksum-choice=STR, --cc=STR

This option overrides the checksum algorithms. If one algorithm name is specified, it is used for both the transfer checksums and (assuming **--checksum** is specified) the pre-transfer checksums. If two comma-separated names are supplied, the first name affects the transfer checksums, and the second name affects the pre-transfer checksums (**-c**).

The checksum options that you may be able to use are:

- o **auto** (the default automatic choice)
- o **xxh128**
- o **xxh3**
- o **xxh64** (aka **xxhash**)
- o **md5**
- o **md4**
- o **none**

Run **rsync --version** to see the default checksum list compiled into your version (which may differ from the list above).

If "none" is specified for the first (or only) name, the **--whole-file** option is forced on and no checksum verification is performed on the transferred data. If "none" is specified for the second (or only) name, the **--checksum** option cannot be used.

The "auto" option is the default, where rsync bases its algorithm choice on a negotiation between the client and the server as follows:

When both sides of the transfer are at least 3.2.0, rsync chooses the first algorithm in the client's list of choices that is also in the server's list of choices. If no common checksum choice is found, rsync exits with an error. If the remote rsync is too old to support checksum negotiation, a value is chosen based on the protocol version (which chooses between MD5 and various flavors of MD4 based on protocol age).

The default order can be customized by setting the environment variable **RSYNC_CHECKSUM_LIST** to a space-separated list of acceptable checksum names. If the string contains a "&" character, it is separated into the "client string & server string", otherwise the same string applies to both. If the string (or string portion) contains no non-whitespace characters, the default checksum list is used. This method does not allow you to specify the transfer checksum separately from the pre-transfer checksum, and it discards "auto" and all unknown checksum names. A list with only invalid names results in a failed negotiation.

The use of the **--checksum-choice** option overrides this environment list.

--one-file-system, -x

This tells rsync to avoid crossing a filesystem boundary when recursing. This does not limit the user's ability to specify items to copy from multiple filesystems, just rsync's recursion through the hierarchy of each directory that the user specified, and also the analogous recursion on the receiving side during deletion. Also keep in mind that rsync treats a "bind" mount to the same device as being on the same filesystem.

If this option is repeated, rsync omits all mount-point directories from the copy. Otherwise, it includes an empty directory at each mount-point it encounters (using the attributes of the mounted directory because those of the underlying mount-point directory are inaccessible).

If rsync has been told to collapse symlinks (via **--copy-links** or **--copy-unsafe-links**), a symlink to a directory on another device is treated like a mount-point. Symlinks to non-directories are unaffected by this option.

--existing, --ignore-non-existing

This tells rsync to skip creating files (including directories) that do not exist yet on the destination. If this option is combined with the **--ignore-existing** option, no files will be updated (which can be useful if all you want to do is delete extraneous files).

This option is a transfer rule, not an exclude, so it doesn't affect the data that goes into the file-lists, and thus it doesn't affect deletions. It just limits the files that the receiver requests to be transferred.

--ignore-existing

This tells rsync to skip updating files that already exist on the destination (this does *not* ignore existing directories, or nothing would get done). See also **--existing**.

This option is a transfer rule, not an exclude, so it doesn't affect the data that goes into the file-lists, and thus it doesn't affect deletions. It just limits the files that the receiver requests to be transferred.

This option can be useful for those doing backups using the **--link-dest** option when they need to continue a backup run that got interrupted. Since a **--link-dest** run is copied into a new directory hierarchy (when it is used properly), using **--ignore-existing** will ensure that the already-handled files don't get tweaked (which avoids a change in permissions on the hard-linked files). This does mean that this option is only looking at the existing files in the destination hierarchy itself.

--remove-source-files

This tells rsync to remove from the sending side the files (meaning non-directories) that are a part of the transfer and have been successfully duplicated on the receiving side.

Note that you should only use this option on source files that are quiescent. If you are using this to move files that show up in a particular directory over to another host, make sure that the finished files get renamed into the source directory, not directly written into it, so that rsync can't possibly transfer a file that is not yet fully written. If you can't first write the files into a different directory, you should use a naming idiom that lets rsync avoid transferring files that are not yet finished (e.g. name the file "foo.new" when it is written, rename it to "foo" when it is done, and then use the option **--exclude='*.new'** for the rsync transfer).

Starting with 3.1.0, rsync will skip the sender-side removal (and output an error) if the file's size or modify time has not stayed unchanged.

--delete

This tells rsync to delete extraneous files from the receiving side (ones that aren't on the sending side), but only for the directories that are being synchronized. You must have asked rsync to send the whole directory (e.g. "**dir**" or "**dir/**") without using a wildcard for the directory's contents (e.g. "**dir/***") since the wildcard is expanded by the shell and rsync thus gets a request to transfer individual files, not the files' parent directory. Files that are excluded from the transfer are also excluded from being deleted unless you use the **--delete-excluded** option or mark the rules as only matching on the sending side (see the include/exclude modifiers in the FILTER RULES section).

Prior to rsync 2.6.7, this option would have no effect unless **--recursive** was enabled. Beginning with 2.6.7, deletions will also occur when **--dirs (-d)** is enabled, but only for directories whose contents are being copied.

This option can be dangerous if used incorrectly! It is a very good idea to first try a run using the **--dry-run** option (**-n**) to see what files are going to be deleted.

If the sending side detects any I/O errors, then the deletion of any files at the destination will be automatically disabled. This is to prevent temporary filesystem failures (such as NFS errors) on the sending side from causing a massive deletion of files on the destination. You can override this with the **--ignore-errors** option.

The **--delete** option may be combined with one of the **--delete-WHEN** options without conflict, as well as **--delete-excluded**. However, if none of the **--delete-WHEN** options are specified, rsync will choose the **--delete-during** algorithm when talking to rsync 3.0.0 or newer, and the

--delete-before algorithm when talking to an older rsync. See also **--delete-delay** and **--delete-after**.

--delete-before

Request that the file-deletions on the receiving side be done before the transfer starts. See **--delete** (which is implied) for more details on file-deletion.

Deleting before the transfer is helpful if the filesystem is tight for space and removing extraneous files would help to make the transfer possible. However, it does introduce a delay before the start of the transfer, and this delay might cause the transfer to timeout (if **--timeout** was specified). It also forces rsync to use the old, non-incremental recursion algorithm that requires rsync to scan all the files in the transfer into memory at once (see **--recursive**).

--delete-during, --del

Request that the file-deletions on the receiving side be done incrementally as the transfer happens. The per-directory delete scan is done right before each directory is checked for updates, so it behaves like a more efficient **--delete-before**, including doing the deletions prior to any per-directory filter files being updated. This option was first added in rsync version 2.6.4. See **--delete** (which is implied) for more details on file-deletion.

--delete-delay

Request that the file-deletions on the receiving side be computed during the transfer (like **--delete-during**), and then removed after the transfer completes. This is useful when combined with **--delay-updates** and/or **--fuzzy**, and is more efficient than using **--delete-after** (but can behave differently, since **--delete-after** computes the deletions in a separate pass after all updates are done). If the number of removed files overflows an internal buffer, a temporary file will be created on the receiving side to hold the names (it is removed while open, so you shouldn't see it during the transfer). If the creation of the temporary file fails, rsync will try to fall back to using **--delete-after** (which it cannot do if **--recursive** is doing an incremental scan). See **--delete** (which is implied) for more details on file-deletion.

--delete-after

Request that the file-deletions on the receiving side be done after the transfer has completed. This is useful if you are sending new per-directory merge files as a part of the transfer and you want their exclusions to take effect for the delete phase of the current transfer. It also forces rsync to use the old, non-incremental recursion algorithm that requires rsync to scan all the files in the transfer into memory at once (see **--recursive**). See **--delete** (which is implied) for more details on file-deletion.

--delete-excluded

In addition to deleting the files on the receiving side that are not on the sending side, this tells rsync to also delete any files on the receiving side that are excluded (see **--exclude**). See the FILTER RULES section for a way to make individual exclusions behave this way on the receiver, and for a way to protect files from **--delete-excluded**. See **--delete** (which is implied) for more details on file-deletion.

--ignore-missing-args

When rsync is first processing the explicitly requested source files (e.g. command-line arguments or **--files-from** entries), it is normally an error if the file cannot be found. This option suppresses that error, and does not try to transfer the file. This does not affect subsequent vanished-file errors if a file was initially found to be present and later is no longer there.

--delete-missing-args

This option takes the behavior of (the implied) **--ignore-missing-args** option a step farther: each missing arg will become a deletion request of the corresponding destination file on the receiving side (should it exist). If the destination file is a non-empty directory, it will only be successfully deleted if **--force** or **--delete** are in effect. Other than that, this option is independent of any other type of delete processing.

The missing source files are represented by special file-list entries which display as a "***missing**" entry in the **--list-only** output.

--ignore-errors

Tells **--delete** to go ahead and delete files even when there are I/O errors.

--force

This option tells rsync to delete a non-empty directory when it is to be replaced by a non-directory. This is only relevant if deletions are not active (see **--delete** for details).

Note for older rsync versions: **--force** used to still be required when using **--delete-after**, and it used to be non-functional unless the **--recursive** option was also enabled.

--max-delete=NUM

This tells rsync not to delete more than NUM files or directories. If that limit is exceeded, all further deletions are skipped through the end of the transfer. At the end, rsync outputs a warning (including a count of the skipped deletions) and exits with an error code of 25 (unless some more important error condition also occurred).

Beginning with version 3.0.0, you may specify **--max-delete=0** to be warned about any extraneous files in the destination without removing any of them. Older clients interpreted this as "unlimited", so if you don't know what version the client is, you can use the less obvious **--max-delete=-1** as a backward-compatible way to specify that no deletions be allowed (though really old versions didn't warn when the limit was exceeded).

--max-size=SIZE

This tells rsync to avoid transferring any file that is larger than the specified SIZE. A numeric value can be suffixed with a string to indicate the numeric units or left unqualified to specify bytes. Feel free to use a fractional value along with the units, such as **--max-size=1.5m**.

This option is a transfer rule, not an exclude, so it doesn't affect the data that goes into the file-lists, and thus it doesn't affect deletions. It just limits the files that the receiver requests to be transferred.

The first letter of a units string can be **B** (bytes), **K** (kilo), **M** (mega), **G** (giga), **T** (tera), or **P** (peta). If the string is a single char or has "ib" added to it (e.g. "G" or "GiB") then the units are multiples of 1024. If you use a two-letter suffix that ends with a "B" (e.g. "kb") then you get units that are multiples of 1000. The string's letters can be any mix of upper and lower-case that you want to use.

Finally, if the string ends with either "+1" or "-1", it is offset by one byte in the indicated direction. The largest possible value is usually **8192P-1**.

Examples: **--max-size=1.5mb-1** is 1499999 bytes, and **--max-size=2g+1** is 2147483649 bytes.

Note that rsync versions prior to 3.1.0 did not allow **--max-size=0**.

--min-size=SIZE

This tells rsync to avoid transferring any file that is smaller than the specified SIZE, which can help in not transferring small, junk files. See the **--max-size** option for a description of SIZE and other information.

Note that rsync versions prior to 3.1.0 did not allow **--min-size=0**.

--max-alloc=SIZE

By default rsync limits an individual malloc/realloc to about 1GB in size. For most people this limit works just fine and prevents a protocol error causing rsync to request massive amounts of memory. However, if you have many millions of files in a transfer, a large amount of server memory, and you don't want to split up your transfer into multiple parts, you can increase the per-allocation limit to something larger and rsync will consume more memory.

Keep in mind that this is not a limit on the total size of allocated memory. It is a sanity-check value for each individual allocation.

See the **--max-size** option for a description of how SIZE can be specified. The default suffix if none is given is bytes.

Beginning in 3.2.3, a value of 0 specifies no limit.

You can set a default value using the environment variable RSYNC_MAX_ALLOC using the same SIZE values as supported by this option. If the remote rsync doesn't understand the **--max-alloc** option, you can override an environmental value by specifying **--max-alloc=1g**, which will make rsync avoid sending the option to the remote side (because "1G" is the default).

--block-size=SIZE, -B

This forces the block size used in rsync's delta-transfer algorithm to a fixed value. It is normally selected based on the size of each file being updated. See the technical report for details.

Beginning in 3.2.3 the SIZE can be specified with a suffix as detailed in the **--max-size** option. Older versions only accepted a byte count.

--rsh=COMMAND, -e

This option allows you to choose an alternative remote shell program to use for communication between the local and remote copies of rsync. Typically, rsync is configured to use ssh by default, but you may prefer to use rsh on a local network.

If this option is used with **[user@]host::module/path**, then the remote shell *COMMAND* will be used to run an rsync daemon on the remote host, and all data will be transmitted through that remote shell connection, rather than through a direct socket connection to a running rsync daemon on the remote host. See the section "USING RSYNC-DAEMON FEATURES VIA A REMOTE-SHELL CONNECTION" above.

Beginning with rsync 3.2.0, the RSYNC_PORT environment variable will be set when a daemon connection is being made via a remote-shell connection. It is set to 0 if the default daemon port is being assumed, or it is set to the value of the rsync port that was specified via either the **--port** option or a non-empty port value in an rsync:// URL. This allows the script to discern if a non-default port is being requested, allowing for things such as an SSL or stunnel helper script to connect to a default or alternate port.

Command-line arguments are permitted in COMMAND provided that COMMAND is presented to rsync as a single argument. You must use spaces (not tabs or other whitespace) to separate the command and args from each other, and you can use single- and/or double-quotes to preserve spaces in an argument (but not backslashes). Note that doubling a single-quote inside a single-quoted string gives you a single-quote; likewise for double-quotes (though you need to pay attention to which quotes your shell is parsing and which quotes rsync is parsing). Some examples:

```
-e 'ssh -p 2234'  
-e 'ssh -o "ProxyCommand nohup ssh firewall nc -w1 %h %p"'
```

(Note that ssh users can alternately customize site-specific connect options in their .ssh/config file.)

You can also choose the remote shell program using the RSYNC_RSH environment variable, which accepts the same range of values as **-e**.

See also the **--blocking-io** option which is affected by this option.

--rsync-path=PROGRAM

Use this to specify what program is to be run on the remote machine to start-up rsync. Often used when rsync is not in the default remote-shell's path (e.g. **--rsync-path=/usr/local/bin/rsync**). Note that PROGRAM is run with the help of a shell, so it can be any program, script, or command sequence you'd care to run, so long as it does not corrupt the standard-in & standard-out that rsync is using to communicate.

One tricky example is to set a different default directory on the remote machine for use with the **--relative** option. For instance:

```
rsync -avR --rsync-path="cd /a/b && rsync" host:c/d /e/
```

--remote-option=OPTION, -M

This option is used for more advanced situations where you want certain effects to be limited to one side of the transfer only. For instance, if you want to pass **--log-file=FILE** and **--fake-super** to the remote system, specify it like this:

```
rsync -av -M --log-file=foo -M--fake-super src/ dest/
```

If you want to have an option affect only the local side of a transfer when it normally affects both sides, send its negation to the remote side. Like this:

```
rsync -av -x -M--no-x src/ dest/
```

Be cautious using this, as it is possible to toggle an option that will cause rsync to have a different idea about what data to expect next over the socket, and that will make it fail in a cryptic fashion.

Note that it is best to use a separate **--remote-option** for each option you want to pass. This makes your usage compatible with the **--protect-args** option. If that option is off, any spaces in your remote options will be split by the remote shell unless you take steps to protect them.

When performing a local transfer, the "local" side is the sender and the "remote" side is the receiver.

Note some versions of the popt option-parsing library have a bug in them that prevents you from using an adjacent arg with an equal in it next to a short option letter (e.g. **-M--log-file=/tmp/foo**). If this bug affects your version of popt, you can use the version of popt that is included with rsync.

--cvs-exclude, -C

This is a useful shorthand for excluding a broad range of files that you often don't want to transfer between systems. It uses a similar algorithm to CVS to determine if a file should be ignored.

The exclude list is initialized to exclude the following items (these initial items are marked as perishable -- see the FILTER RULES section):

```
RCS SCCS CVS CVS.adm RCSLOG cvslog.* tags TAGS .make.state .nse_depinf~ #*  
.##,* _$* *$ *.old *.bak *.BAK *.orig *.rej .del-* *.a *.olb *.o *.obj *.so *.exe *.Z *.elc  
*.ln core .svn/ .git/ .hg/ .bzr/
```

then, files listed in a \$HOME/.cvsignore are added to the list and any files listed in the CVSIGNORE environment variable (all cvsignore names are delimited by whitespace).

Finally, any file is ignored if it is in the same directory as a .cvsignore file and matches one of the patterns listed therein. Unlike rsync's filter/exclude files, these patterns are split on whitespace. See the **cvs(1)** manual for more information.

If you're combining **-C** with your own **--filter** rules, you should note that these CVS excludes are appended at the end of your own rules, regardless of where the **-C** was placed on the command-line. This makes them a lower priority than any rules you specified explicitly. If you want to control where these CVS excludes get inserted into your filter rules, you should omit the **-C** as a command-line option and use a combination of **--filter=:C** and **--filter=-C** (either on your command-line or by putting the ":C" and "-C" rules into a filter file with your other rules). The first option turns on the per-directory scanning for the .cvsignore file. The second option does a one-time import of the CVS excludes mentioned above.

--filter=RULE, -f

This option allows you to add rules to selectively exclude certain files from the list of files to be transferred. This is most useful in combination with a recursive transfer.

You may use as many **--filter** options on the command line as you like to build up the list of files to exclude. If the filter contains whitespace, be sure to quote it so that the shell gives the rule to rsync as a single argument. The text below also mentions that you can use an underscore to replace the space that separates a rule from its arg.

See the FILTER RULES section for detailed information on this option.

- F** The **-F** option is a shorthand for adding two **--filter** rules to your command. The first time it is used is a shorthand for this rule:

```
--filter='dir-merge .rsync-filter'
```

This tells rsync to look for per-directory .rsync-filter files that have been sprinkled through the hierarchy and use their rules to filter the files in the transfer. If **-F** is repeated, it is a shorthand for this rule:

```
--filter='exclude .rsync-filter'
```

This filters out the .rsync-filter files themselves from the transfer.

See the FILTER RULES section for detailed information on how these options work.

--exclude=PATTERN

This option is a simplified form of the **--filter** option that defaults to an exclude rule and does not allow the full rule-parsing syntax of normal filter rules.

See the FILTER RULES section for detailed information on this option.

--exclude-from=FILE

This option is related to the **--exclude** option, but it specifies a FILE that contains exclude patterns (one per line). Blank lines in the file are ignored, as are whole-line comments that start with ';' or '#' (filename rules that contain those characters are unaffected).

If *FILE* is '**-**', the list will be read from standard input.

--include=PATTERN

This option is a simplified form of the **--filter** option that defaults to an include rule and does not allow the full rule-parsing syntax of normal filter rules.

See the FILTER RULES section for detailed information on this option.

--include-from=FILE

This option is related to the **--include** option, but it specifies a FILE that contains include patterns (one per line). Blank lines in the file are ignored, as are whole-line comments that start with ';' or '#' (filename rules that contain those characters are unaffected).

If *FILE* is '**-**', the list will be read from standard input.

--files-from=FILE

Using this option allows you to specify the exact list of files to transfer (as read from the specified FILE or '**-**' for standard input). It also tweaks the default behavior of rsync to make transferring just the specified files and directories easier:

- o The **--relative (-R)** option is implied, which preserves the path information that is specified for each item in the file (use **--no-relative** or **--no-R** if you want to turn that off).
- o The **--dirs (-d)** option is implied, which will create directories specified in the list on the destination rather than noisily skipping them (use **--no-dirs** or **--no-d** if you want to turn that off).
- o The **--archive (-a)** option's behavior does not imply **--recursive (-r)**, so specify it explicitly, if you want it.
- o These side-effects change the default state of rsync, so the position of the **--files-from** option on the command-line has no bearing on how other options are parsed (e.g. **-a** works the same before or after **--files-from**, as does **--no-R** and all other options).

The filenames that are read from the FILE are all relative to the source dir — any leading slashes are removed and no ".." references are allowed to go higher than the source dir. For example, take this command:

```
rsync -a --files-from=/tmp/foo /usr remote:/backup
```

If /tmp/foo contains the string "bin" (or even "/bin"), the /usr/bin directory will be created as /backup/bin on the remote host. If it contains "bin/" (note the trailing slash), the immediate contents of the directory would also be sent (without needing to be explicitly mentioned in the file — this began in version 2.6.4). In both cases, if the **-r** option was enabled, that dir's entire hierarchy would also be transferred (keep in mind that **-r** needs to be specified explicitly with **--files-from**, since it is not implied by **-a**). Also note that the effect of the (enabled by default) **--relative** option is to duplicate only the path info that is read from the file — it does not force the duplication of the source-spec path (/usr in this case).

In addition, the **--files-from** file can be read from the remote host instead of the local host if you specify a "host:" in front of the file (the host must match one end of the transfer). As a short-cut, you can specify just a prefix of ":" to mean "use the remote end of the transfer". For example:

```
rsync -a --files-from=:/path/file-list src:/ /tmp/copy
```

This would copy all the files specified in the /path/file-list file that was located on the remote "src" host.

If the **--iconv** and **--protect-args** options are specified and the **--files-from** filenames are being sent from one host to another, the filenames will be translated from the sending host's charset to the receiving host's charset.

NOTE: sorting the list of files in the **--files-from** input helps rsync to be more efficient, as it will avoid re-visiting the path elements that are shared between adjacent entries. If the input is not sorted, some path elements (implied directories) may end up being scanned multiple times, and rsync will eventually unduplicate them after they get turned into file-list elements.

--from0, -0

This tells rsync that the rules/filenames it reads from a file are terminated by a null ('\0') character, not a NL, CR, or CR+LF. This affects **--exclude-from**, **--include-from**, **--files-from**, and any merged files specified in a **--filter** rule. It does not affect **--cvs-exclude** (since all names read from a .cvignore file are split on whitespace).

--protect-args, -s

This option sends all filenames and most options to the remote rsync without allowing the remote shell to interpret them. This means that spaces are not split in names, and any non-wildcard special characters are not translated (such as ~, \$, ;, &, etc.). Wildcards are expanded on the remote host by rsync (instead of the shell doing it).

If you use this option with **--iconv**, the args related to the remote side will also be translated from the local to the remote character-set. The translation happens before wild-cards are expanded. See also the **--files-from** option.

You may also control this option via the RSYNC_PROTECT_ARGS environment variable. If this variable has a non-zero value, this option will be enabled by default, otherwise it will be disabled by default. Either state is overridden by a manually specified positive or negative version of this option (note that **--no-s** and **--no-protect-args** are the negative versions). Since this option was first introduced in 3.0.0, you'll need to make sure it's disabled if you ever need to interact with a remote rsync that is older than that.

Rsync can also be configured (at build time) to have this option enabled by default (with is overridden by both the environment and the command-line). Run **rsync --version** to check if this is the case, as it will display "default protect-args" or "optional protect-args" depending on how it was compiled.

This option will eventually become a new default setting at some as-yet-undetermined point in the future.

--copy-as=USER[:GROUP]

This option instructs rsync to use the USER and (if specified after a colon) the GROUP for the copy operations. This only works if the user that is running rsync has the ability to change users. If the group is not specified then the user's default groups are used.

This option can help to reduce the risk of an rsync being run as root into or out of a directory that might have live changes happening to it and you want to make sure that root-level read or write actions of system files are not possible. While you could alternatively run all of rsync as the specified user, sometimes you need the root-level host-access credentials to be used, so this allows rsync to drop root for the copying part of the operation after the remote-shell or daemon connection is established.

The option only affects one side of the transfer unless the transfer is local, in which case it affects both sides. Use the **--remote-option** to affect the remote side, such as **-M--copy-as=joe**. For a local transfer, the lsh (or lsh.sh) support file provides a local-shell helper script that can be used to allow a "localhost:" or "lh:" host-spec to be specified without needing to setup any remote shells, allowing you to specify remote options that affect the side of the transfer that is using the host-spec (and using hostname "lh" avoids the overriding of the remote directory to the user's home dir).

For example, the following rsync writes the local files as user "joe":

```
sudo rsync -aiv --copy-as=joe host1:backups/joe/ /home/joe/
```

This makes all files owned by user "joe", limits the groups to those that are available to that user, and makes it impossible for the joe user to do a timed exploit of the path to induce a change to a file that the joe user has no permissions to change.

The following command does a local copy into the "dest/" dir as user "joe" (assuming you've installed support/lsh into a dir on your \$PATH):

```
sudo rsync -aive lsh -M--copy-as=joe src/ lh:dest/
```

--temp-dir=DIR, -T

This option instructs rsync to use DIR as a scratch directory when creating temporary copies of the files transferred on the receiving side. The default behavior is to create each temporary file in the same directory as the associated destination file. Beginning with rsync 3.1.1, the temp-file names inside the specified DIR will not be prefixed with an extra dot (though they will still have a random suffix added).

This option is most often used when the receiving disk partition does not have enough free space to hold a copy of the largest file in the transfer. In this case (i.e. when the scratch directory is on a different disk partition), rsync will not be able to rename each received temporary file over the top of the associated destination file, but instead must copy it into place. Rsync does this by copying the file over the top of the destination file, which means that the destination file will contain truncated data during this copy. If this were not done this way (even if the destination file were first removed, the data locally copied to a temporary file in the destination directory, and then renamed into place) it would be possible for the old file to continue taking up disk space (if someone had it open), and thus there might not be enough room to fit the new version on the disk at the same time.

If you are using this option for reasons other than a shortage of disk space, you may wish to combine it with the **--delay-updates** option, which will ensure that all copied files get put into subdirectories in the destination hierarchy, awaiting the end of the transfer. If you don't have enough room to duplicate all the arriving files on the destination partition, another way to tell rsync that you aren't overly concerned about disk space is to use the **--partial-dir** option with a relative path; because this tells rsync that it is OK to stash off a copy of a single file in a subdir in the destination hierarchy, rsync will use the partial-dir as a staging area to bring over the copied file, and then rename it into place from there. (Specifying a **--partial-dir** with an absolute path does not have this side-effect.)

--fuzzy, -y

This option tells rsync that it should look for a basis file for any destination file that is missing. The current algorithm looks in the same directory as the destination file for either a file that has an identical size and modified-time, or a similarly-named file. If found, rsync uses the fuzzy basis file to try to speed up the transfer.

If the option is repeated, the fuzzy scan will also be done in any matching alternate destination directories that are specified via **--compare-dest**, **--copy-dest**, or **--link-dest**.

Note that the use of the **--delete** option might get rid of any potential fuzzy-match files, so either use **--delete-after** or specify some filename exclusions if you need to prevent this.

--compare-dest=DIR

This option instructs rsync to use *DIR* on the destination machine as an additional hierarchy to compare destination files against doing transfers (if the files are missing in the destination directory). If a file is found in *DIR* that is identical to the sender's file, the file will NOT be transferred to the destination directory. This is useful for creating a sparse backup of just files that have changed from an earlier backup. This option is typically used to copy into an empty (or newly created) directory.

Beginning in version 2.6.4, multiple **--compare-dest** directories may be provided, which will cause rsync to search the list in the order specified for an exact match. If a match is found that differs only in attributes, a local copy is made and the attributes updated. If a match is not found, a basis file from one of the *DIRs* will be selected to try to speed up the transfer.

If *DIR* is a relative path, it is relative to the destination directory. See also **--copy-dest** and **--link-dest**.

NOTE: beginning with version 3.1.0, rsync will remove a file from a non-empty destination hierarchy if an exact match is found in one of the compare-dest hierarchies (making the end result more closely match a fresh copy).

--copy-dest=DIR

This option behaves like **--compare-dest**, but rsync will also copy unchanged files found in *DIR* to the destination directory using a local copy. This is useful for doing transfers to a new destination while leaving existing files intact, and then doing a flash-cutover when all files have been successfully transferred.

Multiple **--copy-dest** directories may be provided, which will cause rsync to search the list in the order specified for an unchanged file. If a match is not found, a basis file from one of the *DIRs* will be selected to try to speed up the transfer.

If *DIR* is a relative path, it is relative to the destination directory. See also **--compare-dest** and **--link-dest**.

--link-dest=DIR

This option behaves like **--copy-dest**, but unchanged files are hard linked from *DIR* to the destination directory. The files must be identical in all preserved attributes (e.g. permissions, possibly ownership) in order for the files to be linked together. An example:

```
rsync -av --link-dest=$PWD/prior_dir host:src_dir/ new_dir/
```

If file's aren't linking, double-check their attributes. Also check if some attributes are getting forced outside of rsync's control, such a mount option that squishes root to a single user, or mounts a removable drive with generic ownership (such as OS X's "Ignore ownership on this volume" option).

Beginning in version 2.6.4, multiple **--link-dest** directories may be provided, which will cause rsync to search the list in the order specified for an exact match (there is a limit of 20 such directories). If a match is found that differs only in attributes, a local copy is made and the attributes updated. If a match is not found, a basis file from one of the *DIRs* will be selected to try to speed up the transfer.

This option works best when copying into an empty destination hierarchy, as existing files may get their attributes tweaked, and that can affect alternate destination files via hard-links. Also, itemizing of changes can get a bit muddled. Note that prior to version 3.1.0, an alternate-directory exact match would never be found (nor linked into the destination) when a destination file already exists.

Note that if you combine this option with **--ignore-times**, rsync will not link any files together because it only links identical files together as a substitute for transferring the file, never as an additional check after the file is updated.

If *DIR* is a relative path, it is relative to the destination directory. See also **--compare** **e-dest** and **--copy-dest**.

Note that rsync versions prior to 2.6.1 had a bug that could prevent **--link-dest** from working properly for a non-super-user when **-o** was specified (or implied by **-a**). You can work-around this bug by avoiding the **-o** option when sending to an old rsync.

--compress, -z

With this option, rsync compresses the file data as it is sent to the destination machine, which reduces the amount of data being transmitted — something that is useful over a slow connection.

Rsync supports multiple compression methods and will choose one for you unless you force the choice using the **--compress-choice** (**--zc**) option.

Run **rsync --version** to see the default compress list compiled into your version.

When both sides of the transfer are at least 3.2.0, rsync chooses the first algorithm in the client's list of choices that is also in the server's list of choices. If no common compress choice is found, rsync exits with an error. If the remote rsync is too old to support checksum negotiation, its list is assumed to be "zlib".

The default order can be customized by setting the environment variable **RSYNC_COMPRESS_LIST** to a space-separated list of acceptable compression names. If the string contains a "&" character, it is separated into the "client string & server string", otherwise the same string applies to both. If the string (or string portion) contains no non-whitespace characters, the default compress list is used. Any unknown compression names are discarded from the list, but a list with only invalid names results in a failed negotiation.

There are some older rsync versions that were configured to reject a **-z** option and require the use of **-zz** because their compression library was not compatible with the default zlib compression method. You can usually ignore this weirdness unless the rsync server complains and tells you to specify **-zz**.

See also the **--skip-compress** option for the default list of file suffixes that will be transferred with no (or minimal) compression.

--compress-choice=STR, --zc=STR

This option can be used to override the automatic negotiation of the compression algorithm that occurs when **--compress** is used. The option implies **--compress** unless "none" was specified, which instead implies **--no-compress**.

The compression options that you may be able to use are:

- o **zstd**
- o **lz4**
- o **zlibx**
- o **zlib**
- o **none**

Run **rsync --version** to see the default compress list compiled into your version (which may differ from the list above).

Note that if you see an error about an option named **--old-compress** or **--new-compress**, this is rsync trying to send the **--compress-choice=zlib** or **--compress-choice=zlibx** option in a backward-compatible manner that more rsync versions understand. This error indicates that the older rsync version on the server will not allow you to force the compression type.

Note that the "zlibx" compression algorithm is just the "zlib" algorithm with matched data excluded from the compression stream (to try to make it more compatible with an external zlib implementation).

--compress-level=NUM, --zl=NUM

Explicitly set the compression level to use (see **--compress**, **-z**) instead of letting it default. The **--compress** option is implied as long as the level chosen is not a "don't compress" level for the compression algorithm that is in effect (e.g. zlib compression treats level 0 as "off").

The level values vary depending on the checksum in effect. Because rsync will negotiate a checksum choice by default (when the remote rsync is new enough), it can be good to combine this option with a **--compress-choice** (**--zc**) option unless you're sure of the choice in effect. For example:

```
rsync -av --zc=zstd --zl=22 host:src/ dest/
```

For zlib & zlibx compression the valid values are from 1 to 9 with 6 being the default. Specifying 0 turns compression off, and specifying -1 chooses the default of 6.

For zstd compression the valid values are from -131072 to 22 with 3 being the default. Specifying 0 chooses the default of 3.

For lz4 compression there are no levels, so the value is always 0.

If you specify a too-large or too-small value, the number is silently limited to a valid value. This allows you to specify something like **--zl=999999999** and be assured that you'll end up with the maximum compression level no matter what algorithm was chosen.

If you want to know the compression level that is in effect, specify **--debug=nstr** to see the "negotiated string" results. This will report something like "**Client compress: zstd (level 3)**" (along with the checksum choice in effect).

--skip-compress=LIST

Override the list of file suffixes that will be compressed as little as possible. Rsync sets the compression level on a per-file basis based on the file's suffix. If the compression algorithm has an "off" level (such as zlib/zlibx) then no compression occurs for those files. Other algorithms that support changing the streaming level on-the-fly will have the level minimized to reduce the CPU usage as much as possible for a matching file. At this time, only zlib & zlibx compression support this changing of levels on a per-file basis.

The **LIST** should be one or more file suffixes (without the dot) separated by slashes (/). You may specify an empty string to indicate that no files should be skipped.

Simple character-class matching is supported: each must consist of a list of letters inside the square brackets (e.g. no special classes, such as "[[:alpha:]]", are supported, and '-' has no special meaning).

The characters asterisk (*) and question-mark (?) have no special meaning.

Here's an example that specifies 6 suffixes to skip (since 1 of the 5 rules matches 2 suffixes):

```
--skip-compress=gz/jpg/mp[34]/7z/bz2
```

The default file suffixes in the skip-compress list in this version of rsync are:

```
3g2 3gp 7z aac ace apk avi bz2 deb dmg ear f4v flac flv gpg gz iso jar jpeg jpg lrz lz lz4 lzma
lzo m1a m1v m2a m2ts m2v m4a m4b m4p m4r m4v mka mkv mov mp1 mp2 mp3 mp4 mpa
mpeg mpg mpv mts odb odf odi odm odp ods odt oga ogg ogm ogv ogx opus otg oth otp
ots ott oxt png qt rar rpm rz rzip spx squashfs sxc sxd sxa sgm sz tbz tbz2 tgz tlz ts txz
tzo vob war webm webp xz z zip zst
```

This list will be replaced by your **--skip-compress** list in all but one situation: a copy from a daemon rsync will add your skipped suffixes to its list of non-compressing files (and its list may be configured to a different default).

--numeric-ids

With this option rsync will transfer numeric group and user IDs rather than using user and group names and mapping them at both ends.

By default rsync will use the username and groupname to determine what ownership to give files. The special uid 0 and the special group 0 are never mapped via user/group names even if the **--numeric-ids** option is not specified.

If a user or group has no name on the source system or it has no match on the destination system, then the numeric ID from the source system is used instead. See also the comments on the "**use chroot**" setting in the rsyncd.conf manpage for information on how the chroot setting affects rsync's ability to look up the names of the users and groups and what you can do about it.

--usermap=STRING, --groupmap=STRING

These options allow you to specify users and groups that should be mapped to other values by the receiving side. The **STRING** is one or more **FROM:TO** pairs of values separated by commas. Any matching **FROM** value from the sender is replaced with a **TO** value from the receiver. You may specify usernames or user IDs for the **FROM** and **TO** values, and the **FROM** value may also be a wild-card string, which will be matched against the sender's names (wild-cards do NOT match against ID numbers, though see below for why a '*' matches everything). You may instead specify a range of ID numbers via an inclusive range: **LOW-HIGH**. For example:

```
--usermap=0-99:nobody,wayne:admin,*:normal --groupmap=usr:1,1:usr
```

The first match in the list is the one that is used. You should specify all your user mappings using a single **--usermap** option, and/or all your group mappings using a single **--groupmap** option.

Note that the sender's name for the 0 user and group are not transmitted to the receiver, so you should either match these values using a 0, or use the names in effect on the receiving side (typically "root"). All other **FROM** names match those in use on the sending side. All **TO** names match those in use on the receiving side.

Any IDs that do not have a name on the sending side are treated as having an empty name for the purpose of matching. This allows them to be matched via a "*" or using an empty name. For instance:

```
--usermap=:nobody --groupmap=:nobody
```

When the **--numeric-ids** option is used, the sender does not send any names, so all the IDs are treated as having an empty name. This means that you will need to specify numeric **FROM** values if you want to map these nameless IDs to different values.

For the **--usermap** option to have any effect, the **-o** (**--owner**) option must be used (or implied), and the receiver will need to be running as a super-user (see also the **--fake-super** option). For the **--groupmap** option to have any effect, the **-g** (**--group**) option must be used (or implied), and the receiver will need to have permissions to set that group.

If your shell complains about the wildcards, use **--protect-args** (**-s**).

--chown=USER:GROUP

This option forces all files to be owned by USER with group GROUP. This is a simpler interface than using **--usermap** and **--groupmap** directly, but it is implemented using those options internally, so you cannot mix them. If either the USER or GROUP is empty, no mapping for the omitted user/group will occur. If GROUP is empty, the trailing colon may be omitted, but if USER is empty, a leading colon must be supplied.

If you specify "**--chown=foo:bar**", this is exactly the same as specifying "**--usermap=*:foo --groupmap=*:bar**", only easier. If your shell complains about the wildcards, use **--protect-args** (**-s**).

--timeout=SECONDS

This option allows you to set a maximum I/O timeout in seconds. If no data is transferred for the specified time then rsync will exit. The default is 0, which means no timeout.

--contimeout=SECONDS

This option allows you to set the amount of time that rsync will wait for its connection to an rsync daemon to succeed. If the timeout is reached, rsync exits with an error.

--address=ADDRESS

By default rsync will bind to the wildcard address when connecting to an rsync daemon. The **--address** option allows you to specify a specific IP address (or hostname) to bind to. See also this option in the **--daemon** mode section.

--port=PORT

This specifies an alternate TCP port number to use rather than the default of 873. This is only needed if you are using the double-colon (::) syntax to connect with an rsync daemon (since the URL syntax has a way to specify the port as a part of the URL). See also this option in the **--daemon** mode section.

--sockopts=OPTIONS

This option can provide endless fun for people who like to tune their systems to the utmost degree. You can set all sorts of socket options which may make transfers faster (or slower!). Read the man page for the **setsockopt()** system call for details on some of the options you may be able to set. By default no special socket options are set. This only affects direct socket connections to a remote rsync daemon.

This option also exists in the **--daemon** mode section.

--blocking-io

This tells rsync to use blocking I/O when launching a remote shell transport. If the remote shell is either rsh or remsh, rsync defaults to using blocking I/O, otherwise it defaults to using non-blocking I/O. (Note that ssh prefers non-blocking I/O.)

--outbuf=MODE

This sets the output buffering mode. The mode can be None (aka Unbuffered), Line, or Block (aka Full). You may specify as little as a single letter for the mode, and use upper or lower case.

The main use of this option is to change Full buffering to Line buffering when rsync's output is going to a file or pipe.

--itemize-changes, -i

Requests a simple itemized list of the changes that are being made to each file, including attribute changes. This is exactly the same as specifying **--out-format='%i %n%L'**. If you repeat the option, unchanged files will also be output, but only if the receiving rsync is at least version 2.6.7 (you can use **-vv** with older versions of rsync, but that also turns on the output of other verbose messages).

The "%i" escape has a cryptic output that is 11 letters long. The general format is like the string **YXcstpqguax**, where **Y** is replaced by the type of update being done, **X** is replaced by the file-type, and the other letters represent attributes that may be output if they are being modified.

The update types that replace the **Y** are as follows:

- o A < means that a file is being transferred to the remote host (sent).
- o A > means that a file is being transferred to the local host (received).
- o A c means that a local change/creation is occurring for the item (such as the creation of a directory or the changing of a symlink, etc.).
- o A h means that the item is a hard link to another item (requires **--hard-links**).
- o A . means that the item is not being updated (though it might have attributes that are being modified).

- o A * means that the rest of the itemized-output area contains a message (e.g. "deleting").

The file-types that replace the **X** are: **f** for a file, a **d** for a directory, an **L** for a symlink, a **D** for a device, and a **S** for a special file (e.g. named sockets and fifos).

The other letters in the string indicate if some attributes of the file have changed, as follows:

- o "." – the attribute is unchanged.
- o "+" – the file is newly created.
- o " " – all the attributes are unchanged (all dots turn to spaces).
- o "?" – the change is unknown (when the remote rsync is old).
- o A letter indicates an attribute is being updated.

The attribute that is associated with each letter is as follows:

- o A **c** means either that a regular file has a different checksum (requires **--checksum**) or that a symlink, device, or special file has a changed value. Note that if you are sending files to an rsync prior to 3.0.1, this change flag will be present only for checksum-differing regular files.
- o A **s** means the size of a regular file is different and will be updated by the file transfer.
- o A **t** means the modification time is different and is being updated to the sender's value (requires **--times**). An alternate value of **T** means that the modification time will be set to the transfer time, which happens when a file/symlink/device is updated without **--times** and when a symlink is changed and the receiver can't set its time. (Note: when using an rsync 3.0.0 client, you might see the **s** flag combined with **t** instead of the proper **T** flag for this time-setting failure.)
- o A **p** means the permissions are different and are being updated to the sender's value (requires **--perms**).
- o An **o** means the owner is different and is being updated to the sender's value (requires **--owner** and super-user privileges).
- o A **g** means the group is different and is being updated to the sender's value (requires **--group** and the authority to set the group).
- o A **u|n|b** indicates the following information: **u** means the access (use) time is different and is being updated to the sender's value (requires **--atimes**); **n** means the create time (newness) is different and is being updated to the sender's value (requires **--crtimes**); **b** means that both the access and create times are being updated.
- o The **a** means that the ACL information is being changed.
- o The **x** means that the extended attribute information is being changed.

One other output is possible: when deleting files, the "%i" will output the string "***deleting**" for each item that is being removed (assuming that you are talking to a recent enough rsync that it logs deletions instead of outputting them as a verbose message).

--out-format=FORMAT

This allows you to specify exactly what the rsync client outputs to the user on a per-update basis. The format is a text string containing embedded single-character escape sequences prefixed with a percent (%) character. A default format of "%n%L" is assumed if either **--info=name** or **-v** is specified (this tells you just the name of the file and, if the item is a link, where it points). For a full list of the possible escape characters, see the "**log format**" setting in the rsyncd.conf manpage.

Specifying the **--out-format** option implies the **--info=name** option, which will mention each file, dir, etc. that gets updated in a significant way (a transferred file, a recreated symlink/device, or a touched directory). In addition, if the itemize-changes escape (%i) is included in the string (e.g. if the **--itemize-changes** option was used), the logging of names increases to mention any item

that is changed in any way (as long as the receiving side is at least 2.6.4). See the **--itemize-changes** option for a description of the output of "%i".

Rsync will output the out-format string prior to a file's transfer unless one of the transfer-statistic escapes is requested, in which case the logging is done at the end of the file's transfer. When this late logging is in effect and **--progress** is also specified, rsync will also output the name of the file being transferred prior to its progress information (followed, of course, by the out-format output).

--log-file=FILE

This option causes rsync to log what it is doing to a file. This is similar to the logging that a daemon does, but can be requested for the client side and/or the server side of a non-daemon transfer. If specified as a client option, transfer logging will be enabled with a default format of "%i %n%L". See the **--log-file-format** option if you wish to override this.

Here's a example command that requests the remote side to log what is happening:

```
rsync -av --remote-option=--log-file=/tmp/rlog src/ dest/
```

This is very useful if you need to debug why a connection is closing unexpectedly.

--log-file-format=FORMAT

This allows you to specify exactly what per-update logging is put into the file specified by the **--log-file** option (which must also be specified for this option to have any effect). If you specify an empty string, updated files will not be mentioned in the log file. For a list of the possible escape characters, see the "log format" setting in the rsyncd.conf manpage.

The default FORMAT used if **--log-file** is specified and this option is not is '%i %n%L'.

--stats This tells rsync to print a verbose set of statistics on the file transfer, allowing you to tell how effective rsync's delta-transfer algorithm is for your data. This option is equivalent to **--info=stats2** if combined with 0 or 1 **-v** options, or **--info=stats3** if combined with 2 or more **-v** options.

The current statistics are as follows:

- o **Number of files** is the count of all "files" (in the generic sense), which includes directories, symlinks, etc. The total count will be followed by a list of counts by filetype (if the total is non-zero). For example: "(reg: 5, dir: 3, link: 2, dev: 1, special: 1)" lists the totals for regular files, directories, symlinks, devices, and special files. If any of value is 0, it is completely omitted from the list.
- o **Number of created files** is the count of how many "files" (generic sense) were created (as opposed to updated). The total count will be followed by a list of counts by filetype (if the total is non-zero).
- o **Number of deleted files** is the count of how many "files" (generic sense) were deleted. The total count will be followed by a list of counts by filetype (if the total is non-zero). Note that this line is only output if deletions are in effect, and only if protocol 31 is being used (the default for rsync 3.1.x).
- o **Number of regular files transferred** is the count of normal files that were updated via rsync's delta-transfer algorithm, which does not include dirs, symlinks, etc. Note that rsync 3.1.0 added the word "regular" into this heading.
- o **Total file size** is the total sum of all file sizes in the transfer. This does not count any size for directories or special files, but does include the size of symlinks.
- o **Total transferred file size** is the total sum of all files sizes for just the transferred files.
- o **Literal data** is how much unmatched file-update data we had to send to the receiver for it to recreate the updated files.
- o **Matched data** is how much data the receiver got locally when recreating the updated files.

- o **File list size** is how big the file-list data was when the sender sent it to the receiver. This is smaller than the in-memory size for the file list due to some compressing of duplicated data when rsync sends the list.
- o **File list generation time** is the number of seconds that the sender spent creating the file list. This requires a modern rsync on the sending side for this to be present.
- o **File list transfer time** is the number of seconds that the sender spent sending the file list to the receiver.
- o **Total bytes sent** is the count of all the bytes that rsync sent from the client side to the server side.
- o **Total bytes received** is the count of all non-message bytes that rsync received by the client side from the server side. "Non-message" bytes means that we don't count the bytes for a verbose message that the server sent to us, which makes the stats more consistent.

--8-bit-output, -8

This tells rsync to leave all high-bit characters unescaped in the output instead of trying to test them to see if they're valid in the current locale and escaping the invalid ones. All control characters (but never tabs) are always escaped, regardless of this option's setting.

The escape idiom that started in 2.6.7 is to output a literal backslash (\) and a hash (#), followed by exactly 3 octal digits. For example, a newline would output as "\#012". A literal backslash that is in a filename is not escaped unless it is followed by a hash and 3 digits (0-9).

--human-readable, -h

Output numbers in a more human-readable format. There are 3 possible levels: (1) output numbers with a separator between each set of 3 digits (either a comma or a period, depending on if the decimal point is represented by a period or a comma); (2) output numbers in units of 1000 (with a character suffix for larger units — see below); (3) output numbers in units of 1024.

The default is human-readable level 1. Each **-h** option increases the level by one. You can take the level down to 0 (to output numbers as pure digits) by specifying the **--no-human-readable** (**--no-h**) option.

The unit letters that are appended in levels 2 and 3 are: **K** (kilo), **M** (mega), **G** (giga), **T** (tera), or **P** (peta). For example, a 1234567-byte file would output as 1.23M in level-2 (assuming that a period is your local decimal point).

Backward compatibility note: versions of rsync prior to 3.1.0 do not support human-readable level 1, and they default to level 0. Thus, specifying one or two **-h** options will behave in a comparable manner in old and new versions as long as you didn't specify a **--no-h** option prior to one or more **-h** options. See the **--list-only** option for one difference.

--partial

By default, rsync will delete any partially transferred file if the transfer is interrupted. In some circumstances it is more desirable to keep partially transferred files. Using the **--partial** option tells rsync to keep the partial file which should make a subsequent transfer of the rest of the file much faster.

--partial-dir=DIR

A better way to keep partial files than the **--partial** option is to specify a *DIR* that will be used to hold the partial data (instead of writing it out to the destination file). On the next transfer, rsync will use a file found in this dir as data to speed up the resumption of the transfer and then delete it after it has served its purpose.

Note that if **--whole-file** is specified (or implied), any partial-dir file that is found for a file that is being updated will simply be removed (since rsync is sending files without using rsync's delta-transfer algorithm).

Rsync will create the *DIR* if it is missing (just the last dir --- not the whole path). This makes it easy to use a relative path (such as "**--partial-dir=.rsync-partial**") to have rsync create the partial-directory in the destination file's directory when needed, and then remove it again when the partial file is deleted. Note that the directory is only removed if it is a relative pathname, as it is expected that an absolute path is to a directory that is reserved for partial-dir work.

If the partial-dir value is not an absolute path, rsync will add an exclude rule at the end of all your existing excludes. This will prevent the sending of any partial-dir files that may exist on the sending side, and will also prevent the untimely deletion of partial-dir items on the receiving side. An example: the above **--partial-dir** option would add the equivalent of "**-f '-p .rsync-partial/'**" at the end of any other filter rules.

If you are supplying your own exclude rules, you may need to add your own exclude/protect rule for the partial-dir because (1) the auto-added rule may be ineffective at the end of your other rules, or (2) you may wish to override rsync's exclude choice. For instance, if you want to make rsync clean-up any left-over partial-dirs that may be lying around, you should specify **--delete-after** and add a "risk" filter rule, e.g. **-f 'R .rsync-partial'**. (Avoid using **--delete-before** or **--delete-during** unless you don't need rsync to use any of the left-over partial-dir data during the current run.)

IMPORTANT: the **--partial-dir** should not be writable by other users or it is a security risk. E.g. AVOID "/tmp".

You can also set the partial-dir value the RSYNC_PARTIAL_DIR environment variable. Setting this in the environment does not force **--partial** to be enabled, but rather it affects where partial files go when **--partial** is specified. For instance, instead of using **--partial-dir=.rsync-tmp** along with **--progress**, you could set RSYNC_PARTIAL_DIR=.rsync-tmp in your environment and then just use the **-P** option to turn on the use of the .rsync-tmp dir for partial transfers. The only times that the **--partial** option does not look for this environment value are (1) when **--in-place** was specified (since **--inplace** conflicts with **--partial-dir**), and (2) when **--delay-updates** was specified (see below).

When a modern rsync resumes the transfer of a file in the partial-dir, that partial file is now updated in-place instead of creating yet another tmp-file copy (so it maxes out at dest + tmp instead of dest + partial + tmp). This requires both ends of the transfer to be at least version 3.2.0.

For the purposes of the daemon-config's "refuse options" setting, **--partial-dir** does *not* imply **--partial**. This is so that a refusal of the **--partial** option can be used to disallow the overwriting of destination files with a partial transfer, while still allowing the safer idiom provided by **--partial-dir**.

--delay-updates

This option puts the temporary file from each updated file into a holding directory until the end of the transfer, at which time all the files are renamed into place in rapid succession. This attempts to make the updating of the files a little more atomic. By default the files are placed into a directory named **.~tmp~** in each file's destination directory, but if you've specified the **--partial-dir** option, that directory will be used instead. See the comments in the **--partial-dir** section for a discussion of how this **.~tmp~** dir will be excluded from the transfer, and what you can do if you want rsync to cleanup old **.~tmp~** dirs that might be lying around. Conflicts with **--inplace** and **--append**.

This option implies **--no-inc-recursive** since it needs the full file list in memory in order to be able to iterate over it at the end.

This option uses more memory on the receiving side (one bit per file transferred) and also requires enough free disk space on the receiving side to hold an additional copy of all the updated files. Note also that you should not use an absolute path to **--partial-dir** unless (1) there is no chance of any of the files in the transfer having the same name (since all the updated files will be put into a single directory if the path is absolute) and (2) there are no mount points in the hierarchy (since the delayed updates will fail if they can't be renamed into place).

See also the "atomic-rsync" perl script in the "support" subdir for an update algorithm that is even more atomic (it uses **--link-dest** and a parallel hierarchy of files).

--prune-empty-dirs, -m

This option tells the receiving rsync to get rid of empty directories from the file-list, including nested directories that have no non-directory children. This is useful for avoiding the creation of a bunch of useless directories when the sending rsync is recursively scanning a hierarchy of files using include/exclude/filter rules.

Note that the use of transfer rules, such as the **--min-size** option, does not affect what goes into the file list, and thus does not leave directories empty, even if none of the files in a directory match the transfer rule.

Because the file-list is actually being pruned, this option also affects what directories get deleted when a delete is active. However, keep in mind that excluded files and directories can prevent existing items from being deleted due to an exclude both hiding source files and protecting destination files. See the perishable filter-rule option for how to avoid this.

You can prevent the pruning of certain empty directories from the file-list by using a global "protect" filter. For instance, this option would ensure that the directory "emptydir" was kept in the file-list:

```
--filter 'protect emptydir/'
```

Here's an example that copies all .pdf files in a hierarchy, only creating the necessary destination directories to hold the .pdf files, and ensures that any superfluous files and directories in the destination are removed (note the hide filter of non-directories being used instead of an exclude):

```
rsync -avm --del --include='*.pdf' -f 'hide,! /*' src/ dest
```

If you didn't want to remove superfluous destination files, the more time-honored options of **--include='/*'** **--exclude='/*'** would work fine in place of the hide-filter (if that is more natural to you).

--progress

This option tells rsync to print information showing the progress of the transfer. This gives a bored user something to watch. With a modern rsync this is the same as specifying **--info=flist2,name,progress**, but any user-supplied settings for those info flags takes precedence (e.g. "**--info=flist0 --progress**").

While rsync is transferring a regular file, it updates a progress line that looks like this:

```
782448 63% 110.64kB/s 0:00:04
```

In this example, the receiver has reconstructed 782448 bytes or 63% of the sender's file, which is being reconstructed at a rate of 110.64 kilobytes per second, and the transfer will finish in 4 seconds if the current rate is maintained until the end.

These statistics can be misleading if rsync's delta-transfer algorithm is in use. For example, if the sender's file consists of the basis file followed by additional data, the reported rate will probably drop dramatically when the receiver gets to the literal data, and the transfer will probably take much longer to finish than the receiver estimated as it was finishing the matched part of the file.

When the file transfer finishes, rsync replaces the progress line with a summary line that looks like this:

```
1,238,099 100% 146.38kB/s 0:00:08 (xfr#5, to-chk=169/396)
```

In this example, the file was 1,238,099 bytes long in total, the average rate of transfer for the whole file was 146.38 kilobytes per second over the 8 seconds that it took to complete, it was the 5th transfer of a regular file during the current rsync session, and there are 169 more files for the receiver to check (to see if they are up-to-date or not) remaining out of the 396 total files in the file-list.

In an incremental recursion scan, rsync won't know the total number of files in the file-list until it reaches the ends of the scan, but since it starts to transfer files during the scan, it will display a line with the text "ir-chk" (for incremental recursion check) instead of "to-chk" until the point that it knows the full size of the list, at which point it will switch to using "to-chk". Thus, seeing "ir-chk" lets you know that the total count of files in the file list is still going to increase (and each time it does, the count of files left to check will increase by the number of the files added to the list).

- P** The **-P** option is equivalent to **--partial --progress**. Its purpose is to make it much easier to specify these two options for a long transfer that may be interrupted.

There is also a **--info=progress2** option that outputs statistics based on the whole transfer, rather than individual files. Use this flag without outputting a filename (e.g. avoid **-v** or specify **--info=name0**) if you want to see how the transfer is doing without scrolling the screen with a lot of names. (You don't need to specify the **--progress** option in order to use **--info=progress2**.)

Finally, you can get an instant progress report by sending rsync a signal of either SIGINFO or SIGVTALRM. On BSD systems, a SIGINFO is generated by typing a Ctrl+T (Linux doesn't currently support a SIGINFO signal). When the client-side process receives one of those signals, it sets a flag to output a single progress report which is output when the current file transfer finishes (so it may take a little time if a big file is being handled when the signal arrives). A filename is output (if needed) followed by the **--info=progress2** format of progress info. If you don't know which of the 3 rsync processes is the client process, it's OK to signal all of them (since the non-client processes ignore the signal).

CAUTION: sending SIGVTALRM to an older rsync (pre-3.2.0) will kill it.

--password-file=FILE

This option allows you to provide a password for accessing an rsync daemon via a file or via standard input if **FILE** is **-**. The file should contain just the password on the first line (all other lines are ignored). Rsync will exit with an error if **FILE** is world readable or if a root-run rsync command finds a non-root-owned file.

This option does not supply a password to a remote shell transport such as ssh; to learn how to do that, consult the remote shell's documentation. When accessing an rsync daemon using a remote shell as the transport, this option only comes into effect after the remote shell finishes its authentication (i.e. if you have also specified a password in the daemon's config file).

--early-input=FILE

This option allows rsync to send up to 5K of data to the "early exec" script on its stdin. One possible use of this data is to give the script a secret that can be used to mount an encrypted filesystem (which you should unmount in the the "post-xfer exec" script).

The daemon must be at least version 3.2.1.

--list-only

This option will cause the source files to be listed instead of transferred. This option is inferred if there is a single source arg and no destination specified, so its main uses are: (1) to turn a copy command that includes a destination arg into a file-listing command, or (2) to be able to specify more than one source arg (note: be sure to include the destination). Caution: keep in mind that a source arg with a wild-card is expanded by the shell into multiple args, so it is never safe to try to list such an arg without using this option. For example:

```
rsync -av --list-only foo* dest/
```

Starting with rsync 3.1.0, the sizes output by **--list-only** are affected by the **--human-readable** option. By default they will contain digit separators, but higher levels of readability will output the sizes with unit suffixes. Note also that the column width for the size output has increased from 11 to 14 characters for all human-readable levels. Use **--no-h** if you want just digits in the sizes, and the old column width of 11 characters.

Compatibility note: when requesting a remote listing of files from an rsync that is version 2.6.3 or older, you may encounter an error if you ask for a non-recursive listing. This is because a file

listing implies the **--dirs** option w/o **--recursive**, and older rsyncs don't have that option. To avoid this problem, either specify the **--no-dirs** option (if you don't need to expand a directory's content), or turn on recursion and exclude the content of subdirectories: **-r --exclude='/*/*'**.

--bwlimit=RATE

This option allows you to specify the maximum transfer rate for the data sent over the socket, specified in units per second. The RATE value can be suffixed with a string to indicate a size multiplier, and may be a fractional value (e.g. "**--bwlimit=1.5m**"). If no suffix is specified, the value will be assumed to be in units of 1024 bytes (as if "K" or "KiB" had been appended). See the **--max-size** option for a description of all the available suffixes. A value of 0 specifies no limit.

For backward-compatibility reasons, the rate limit will be rounded to the nearest KiB unit, so no rate smaller than 1024 bytes per second is possible.

Rsync writes data over the socket in blocks, and this option both limits the size of the blocks that rsync writes, and tries to keep the average transfer rate at the requested limit. Some burstiness may be seen where rsync writes out a block of data and then sleeps to bring the average rate into compliance.

Due to the internal buffering of data, the **--progress** option may not be an accurate reflection on how fast the data is being sent. This is because some files can show up as being rapidly sent when the data is quickly buffered, while others can show up as very slow when the flushing of the output buffer occurs. This may be fixed in a future version.

'**--stop-after=MINS**

This option tells rsync to stop copying when the specified number of minutes has elapsed.

Rsync also accepts an earlier version of this option: **--time-limit=MINS**.

For maximal flexibility, rsync does not communicate this option to the remote rsync since it is usually enough that one side of the connection quits as specified. This allows the option's use even when only one side of the connection supports it. You can tell the remote side about the time limit using **--remote-option (-M)**, should the need arise.

'**--stop-at=y-m-dTh:m**

This option tells rsync to stop copying when the specified point in time has been reached. The date & time can be fully specified in a numeric format of year-month-dayThour:minute (e.g. 2000-12-31T23:59) in the local timezone. You may choose to separate the date numbers using slashes instead of dashes.

The value can also be abbreviated in a variety of ways, such as specifying a 2-digit year and/or leaving off various values. In all cases, the value will be taken to be the next possible point in time where the supplied information matches. If the value specifies the current time or a past time, rsync exits with an error.

For example, "1-30" specifies the next January 30th (at midnight local time), "14:00" specifies the next 2 P.M., "1" specifies the next 1st of the month at midnight, "31" specifies the next month where we can stop on its 31st day, and ":59" specifies the next 59th minute after the hour.

For maximal flexibility, rsync does not communicate this option to the remote rsync since it is usually enough that one side of the connection quits as specified. This allows the option's use even when only one side of the connection supports it. You can tell the remote side about the time limit using **--remote-option (-M)**, should the need arise. Do keep in mind that the remote host may have a different default timezone than your local host.

--write-batch=FILE

Record a file that can later be applied to another identical destination with **--read-batch**. See the "BATCH MODE" section for details, and also the **--only-write-batch** option.

This option overrides the negotiated checksum & compress lists and always negotiates a choice based on old-school md5/md4/zlib choices. If you want a more modern choice, use the **--checksum-choice (--cc)** and/or **--compress-choice (--zc)** options.

--only-write-batch=FILE

Works like **--write-batch**, except that no updates are made on the destination system when creating the batch. This lets you transport the changes to the destination system via some other means and then apply the changes via **--read-batch**.

Note that you can feel free to write the batch directly to some portable media: if this media fills to capacity before the end of the transfer, you can just apply that partial transfer to the destination and repeat the whole process to get the rest of the changes (as long as you don't mind a partially updated destination system while the multi-update cycle is happening).

Also note that you only save bandwidth when pushing changes to a remote system because this allows the batched data to be diverted from the sender into the batch file without having to flow over the wire to the receiver (when pulling, the sender is remote, and thus can't write the batch).

--read-batch=FILE

Apply all of the changes stored in FILE, a file previously generated by **--write-batch**. If FILE is `-`, the batch data will be read from standard input. See the "BATCH MODE" section for details.

--protocol=NUM

Force an older protocol version to be used. This is useful for creating a batch file that is compatible with an older version of rsync. For instance, if rsync 2.6.4 is being used with the **--write-batch** option, but rsync 2.6.3 is what will be used to run the **--read-batch** option, you should use "`--protocol=28`" when creating the batch file to force the older protocol version to be used in the batch file (assuming you can't upgrade the rsync on the reading system).

--iconv=CONVERT_SPEC

Rsync can convert filenames between character sets using this option. Using a CONVERT_SPEC of `".."` tells rsync to look up the default character-set via the locale setting. Alternately, you can fully specify what conversion to do by giving a local and a remote charset separated by a comma in the order **--iconv=LOCAL,REMOTE**, e.g. **--iconv=utf8,iso88591**. This order ensures that the option will stay the same whether you're pushing or pulling files. Finally, you can specify either **--no-iconv** or a CONVERT_SPEC of `"-"` to turn off any conversion. The default setting of this option is site-specific, and can also be affected via the RSYNC_ICONV environment variable.

For a list of what charset names your local iconv library supports, you can run `"iconv --list"`.

If you specify the **--protect-args** option (`-s`), rsync will translate the filenames you specify on the command-line that are being sent to the remote host. See also the **--files-from** option.

Note that rsync does not do any conversion of names in filter files (including include/exclude files). It is up to you to ensure that you're specifying matching rules that can match on both sides of the transfer. For instance, you can specify extra include/exclude rules if there are filename differences on the two sides that need to be accounted for.

When you pass an **--iconv** option to an rsync daemon that allows it, the daemon uses the charset specified in its "charset" configuration parameter regardless of the remote charset you actually pass. Thus, you may feel free to specify just the local charset for a daemon transfer (e.g. **--iconv=utf8**).

--ipv4, -4 or --ipv6, -6

Tells rsync to prefer IPv4/IPv6 when creating sockets or running ssh. This affects sockets that rsync has direct control over, such as the outgoing socket when directly contacting an rsync daemon, as well as the forwarding of the **-4** or **-6** option to ssh when rsync can deduce that ssh is being used as the remote shell. For other remote shells you'll need to specify the "**--rsh SHELL -4**" option directly (or whatever ipv4/ipv6 hint options it uses).

These options also exist in the **--daemon** mode section.

If rsync was compiled without support for IPv6, the **--ipv6** option will have no effect. The **rsync --version** output will contain **"no IPv6"** if is the case.

--checksum-seed=NUM

Set the checksum seed to the integer NUM. This 4 byte checksum seed is included in each block and MD4 file checksum calculation (the more modern MD5 file checksums don't use a seed). By default the checksum seed is generated by the server and defaults to the current **time()**. This option is used to set a specific checksum seed, which is useful for applications that want repeatable block checksums, or in the case where the user wants a more random checksum seed. Setting NUM to 0 causes rsync to use the default of **time()** for checksum seed.

DAEMON OPTIONS

The options allowed when starting an rsync daemon are as follows:

--daemon

This tells rsync that it is to run as a daemon. The daemon you start running may be accessed using an rsync client using the **host::module** or **rsync://host/module/** syntax.

If standard input is a socket then rsync will assume that it is being run via inetd, otherwise it will detach from the current terminal and become a background daemon. The daemon will read the config file (**rsyncd.conf**) on each connect made by a client and respond to requests accordingly. See the **rsyncd.conf(5)** man page for more details.

--address=ADDRESS

By default rsync will bind to the wildcard address when run as a daemon with the **--daemon** option. The **--address** option allows you to specify a specific IP address (or hostname) to bind to. This makes virtual hosting possible in conjunction with the **--config** option. See also the "address" global option in the **rsyncd.conf** manpage.

--bwlimit=RATE

This option allows you to specify the maximum transfer rate for the data the daemon sends over the socket. The client can still specify a smaller **--bwlimit** value, but no larger value will be allowed. See the client version of this option (above) for some extra details.

--config=FILE

This specifies an alternate config file than the default. This is only relevant when **--daemon** is specified. The default is **/etc/rsyncd.conf** unless the daemon is running over a remote shell program and the remote user is not the super-user; in that case the default is **rsyncd.conf** in the current directory (typically **\$HOME**).

--dparam=OVERRIDE, -M

This option can be used to set a daemon-config parameter when starting up rsync in daemon mode. It is equivalent to adding the parameter at the end of the global settings prior to the first module's definition. The parameter names can be specified without spaces, if you so desire. For instance:

```
rsync --daemon -M pidfile=/path/rsync.pid
```

--no-detach

When running as a daemon, this option instructs rsync to not detach itself and become a background process. This option is required when running as a service on Cygwin, and may also be useful when rsync is supervised by a program such as **daemontools** or AIX's **System Resource Controller**. **--no-detach** is also recommended when rsync is run under a debugger. This option has no effect if rsync is run from inetd or sshd.

--port=PORT

This specifies an alternate TCP port number for the daemon to listen on rather than the default of 873. See also the "port" global option in the **rsyncd.conf** manpage.

--log-file=FILE

This option tells the rsync daemon to use the given log-file name instead of using the "**log file**" setting in the config file.

--log-file-format=FORMAT

This option tells the rsync daemon to use the given FORMAT string instead of using the "**log format**" setting in the config file. It also enables "**transfer logging**" unless the string is empty, in

which case transfer logging is turned off.

--sockopts

This overrides the **socket options** setting in the rsyncd.conf file and has the same syntax.

--verbose, -v

This option increases the amount of information the daemon logs during its startup phase. After the client connects, the daemon's verbosity level will be controlled by the options that the client used and the "**max verbosity**" setting in the module's config section.

--ipv4, -4 or --ipv6, -6

Tells rsync to prefer IPv4/IPv6 when creating the incoming sockets that the rsync daemon will use to listen for connections. One of these options may be required in older versions of Linux to work around an IPv6 bug in the kernel (if you see an "address already in use" error when nothing else is using the port, try specifying **--ipv6** or **--ipv4** when starting the daemon).

These options also exist in the regular rsync options section.

If rsync was compiled without support for IPv6, the **--ipv6** option will have no effect. The **rsync --version** output will contain "**no IPv6**" if is the case.

--help, -h

When specified after **--daemon**, print a short help page describing the options available for starting an rsync daemon.

FILTER RULES

The filter rules allow for flexible selection of which files to transfer (include) and which files to skip (exclude). The rules either directly specify include/exclude patterns or they specify a way to acquire more include/exclude patterns (e.g. to read them from a file).

As the list of files/directories to transfer is built, rsync checks each name to be transferred against the list of include/exclude patterns in turn, and the first matching pattern is acted on: if it is an exclude pattern, then that file is skipped; if it is an include pattern then that filename is not skipped; if no matching pattern is found, then the filename is not skipped.

Rsync builds an ordered list of filter rules as specified on the command-line. Filter rules have the following syntax:

```
RULE [PATTERN_OR_FILENAME]
      RULE,MODIFIERS [PATTERN_OR_FILENAME]
```

You have your choice of using either short or long RULE names, as described below. If you use a short-named rule, the ',' separating the RULE from the MODIFIERS is optional. The PATTERN or FILENAME that follows (when present) must come after either a single space or an underscore (_). Here are the available rule prefixes:

exclude, '-'

specifies an exclude pattern.

include, '+'

specifies an include pattern.

merge, ':'

specifies a merge-file to read for more rules.

dir-merge, ':'

specifies a per-directory merge-file.

hide, 'H'

specifies a pattern for hiding files from the transfer.

show, 'S'

files that match the pattern are not hidden.

protect, 'P'

specifies a pattern for protecting files from deletion.

risk, 'R'

files that match the pattern are not protected.

clear, '!'*

clears the current include/exclude list (takes no arg)

When rules are being read from a file, empty lines are ignored, as are whole-line comments that start with a '#' (filename rules that contain a hash are unaffected).

Note that the **--include** & **--exclude** command-line options do not allow the full range of rule parsing as described above — they only allow the specification of include / exclude patterns plus a "!" token to clear the list (and the normal comment parsing when rules are read from a file). If a pattern does not begin with "-" (dash, space) or "+" (plus, space), then the rule will be interpreted as if "+" (for an include option) or "-" (for an exclude option) were prefixed to the string. A **--filter** option, on the other hand, must always contain either a short or long rule name at the start of the rule.

Note also that the **--filter**, **--include**, and **--exclude** options take one rule/pattern each. To add multiple ones, you can repeat the options on the command-line, use the merge-file syntax of the **--filter** option, or the **--include-from** / **--exclude-from** options.

INCLUDE/EXCLUDE PATTERN RULES

You can include and exclude files by specifying patterns using the "+", "-", etc. filter rules (as introduced in the FILTER RULES section above). The include/exclude rules each specify a pattern that is matched against the names of the files that are going to be transferred. These patterns can take several forms:

- o if the pattern starts with a / then it is anchored to a particular spot in the hierarchy of files, otherwise it is matched against the end of the pathname. This is similar to a leading ^ in regular expressions. Thus/**f oo** would match a name of "foo" at either the "root of the transfer" (for a global rule) or in the merge-file's directory (for a per-directory rule). An unqualified **foo** would match a name of "foo" anywhere in the tree because the algorithm is applied recursively from the top down; it behaves as if each path component gets a turn at being the end of the filename. Even the unanchored "sub/foo" would match at any point in the hierarchy where a "foo" was found within a directory named "sub". See the section on ANCHORING INCLUDE/EXCLUDE PATTERNS for a full discussion of how to specify a pattern that matches at the root of the transfer.
- o if the pattern ends with a / then it will only match a directory, not a regular file, symlink, or device.
- o rsync chooses between doing a simple string match and wildcard matching by checking if the pattern contains one of these three wildcard characters: '*', '?', and '[' .
- o a '*' matches any path component, but it stops at slashes.
- o use '**' to match anything, including slashes.
- o a '?' matches any character except a slash (/).
- o a '[' introduces a character class, such as **[a-z]** or **[:alpha:]**.
- o in a wildcard pattern, a backslash can be used to escape a wildcard character, but it is matched literally when no wildcards are present. This means that there is an extra level of backslash removal when a pattern contains wildcard characters compared to a pattern that has none. e.g. if you add a wildcard to "**foo\bar**" (which matches the backslash) you would need to use "**foo\\bar***" to avoid the "\b" becoming just "b".
- o if the pattern contains a / (not counting a trailing /) or a "**", then it is matched against the full pathname, including any leading directories. If the pattern doesn't contain a / or a "**", then it is matched only against the final component of the filename. (Remember that the algorithm is applied recursively so "full filename" can actually be any portion of a path from the starting directory on down.)

- o a trailing "**dir_name**/**" will match both the directory (as if "dir_name/" had been specified) and everything in the directory (as if "dir_name/*" had been specified). This behavior was added in version 2.6.7.

Note that, when using the **--recursive (-r)** option (which is implied by **-a**), every subdir component of every path is visited left to right, with each directory having a chance for exclusion before its content. In this way include/exclude patterns are applied recursively to the pathname of each node in the filesystem's tree (those inside the transfer). The exclude patterns short-circuit the directory traversal stage as rsync finds the files to send.

For instance, to include "**/foo/bar/baz**", the directories "**/foo**" and "**/foo/bar**" must not be excluded. Excluding one of those parent directories prevents the examination of its content, cutting off rsync's recursion into those paths and rendering the include for "**/foo/bar/baz**" ineffectual (since rsync can't match something it never sees in the cut-off section of the directory hierarchy).

The concept path exclusion is particularly important when using a trailing '*' rule. For instance, this won't work:

```
+ /some/path/this-file-will-not-be-found
+ /file-is-included
- *
```

This fails because the parent directory "some" is excluded by the '*' rule, so rsync never visits any of the files in the "some" or "some/path" directories. One solution is to ask for all directories in the hierarchy to be included by using a single rule: "+ /*" (put it somewhere before the "- *" rule), and perhaps use the **--prune-empty-dirs** option. Another solution is to add specific include rules for all the parent dirs that need to be visited. For instance, this set of rules works fine:

```
+ /some/
+ /some/path/
+ /some/path/this-file-is-found
+ /file-also-included
- *
```

Here are some examples of exclude/include matching:

- o "**- *.o**" would exclude all names matching ***.o**
- o "**- /foo**" would exclude a file (or directory) named foo in the transfer-root directory
- o "**- foo/**" would exclude any directory named foo
- o "**- /foo/*/bar**" would exclude any file named bar which is at two levels below a directory named foo in the transfer-root directory
- o "**- /foo/**/bar**" would exclude any file named bar two or more levels below a directory named foo in the transfer-root directory
- o The combination of "+ /*", "+ *.c", and "- *" would include all directories and C source files but nothing else (see also the **--prune-empty-dirs** option)
- o The combination of "**+ foo/**", "**+ foo/bar.c**", and "**- ***" would include only the foo directory and foo/bar.c (the foo directory must be explicitly included or it would be excluded by the "*")

The following modifiers are accepted after a "+" or "-":

- o A **/** specifies that the include/exclude rule should be matched against the absolute pathname of the current item. For example, "**-/ /etc/passwd**" would exclude the passwd file any time the transfer was sending files from the "/etc" directory, and "**-/ subdir/foo**" would always exclude "foo" when it is in a dir named "subdir", even if "foo" is at the root of the current transfer.
- o A **!** specifies that the include/exclude should take effect if the pattern fails to match. For instance, "**-! /***" would exclude all non-directories.

- o A **C** is used to indicate that all the global CVS-exclude rules should be inserted as excludes in place of the "-C". No arg should follow.
- o An **s** is used to indicate that the rule applies to the sending side. When a rule affects the sending side, it prevents files from being transferred. The default is for a rule to affect both sides unless **--delete-excluded** was specified, in which case default rules become sender-side only. See also the hide (H) and show (S) rules, which are an alternate way to specify sending-side includes/excludes.
- o An **r** is used to indicate that the rule applies to the receiving side. When a rule affects the receiving side, it prevents files from being deleted. See the **s** modifier for more info. See also the protect (P) and risk (R) rules, which are an alternate way to specify receiver-side includes/excludes.
- o A **p** indicates that a rule is perishable, meaning that it is ignored in directories that are being deleted. For instance, the **-C** option's default rules that exclude things like "CVS" and "*.**o**" are marked as perishable, and will not prevent a directory that was removed on the source from being deleted on the destination.
- o An **x** indicates that a rule affects xattr names in xattr copy/delete operations (and is thus ignored when matching file/dir names). If no xattr-matching rules are specified, a default xattr filtering rule is used (see the **--xattrs** option).

MERGE-FILE FILTER RULES

You can merge whole files into your filter rules by specifying either a merge (.) or a dir-merge (:) filter rule (as introduced in the FILTER RULES section above).

There are two kinds of merged files -- single-instance ('.') and per-directory (':'). A single-instance merge file is read one time, and its rules are incorporated into the filter list in the place of the "." rule. For per-directory merge files, rsync will scan every directory that it traverses for the named file, merging its contents when the file exists into the current list of inherited rules. These per-directory rule files must be created on the sending side because it is the sending side that is being scanned for the available files to transfer. These rule files may also need to be transferred to the receiving side if you want them to affect what files don't get deleted (see PER-DIRECTORY RULES AND DELETE below).

Some examples:

```
merge /etc/rsync/default.rules
./etc/rsync/default.rules
dir-merge .per-dir-filter
dir-merge,n- .non-inherited-per-dir-excludes
:n- .non-inherited-per-dir-excludes
```

The following modifiers are accepted after a merge or dir-merge rule:

- o A **-** specifies that the file should consist of only exclude patterns, with no other rule-parsing except for in-file comments.
- o A **+** specifies that the file should consist of only include patterns, with no other rule-parsing except for in-file comments.
- o A **C** is a way to specify that the file should be read in a CVS-compatible manner. This turns on '**n**', '**w**', and '**-**', but also allows the list-clearing token (!) to be specified. If no filename is provided, ".cvignore" is assumed.
- o A **e** will exclude the merge-file name from the transfer; e.g. "dir-merge,e .rules" is like "dir-merge .rules" and "- .rules".
- o An **n** specifies that the rules are not inherited by subdirectories.
- o A **w** specifies that the rules are word-split on whitespace instead of the normal line-splitting. This also turns off comments. Note: the space that separates the prefix from the rule is treated specially, so "**- foo + bar**" is parsed as two rules (assuming that prefix-parsing wasn't also disabled).

- o You may also specify any of the modifiers for the "+" or "-" rules (above) in order to have the rules that are read in from the file default to having that modifier set (except for the ! modifier, which would not be useful). For instance, "merge,-/.excl" would treat the contents of .excl as absolute-path excludes, while "dir-merge,s .filt" and ":sC" would each make all their per-directory rules apply only on the sending side. If the merge rule specifies sides to affect (via the **s** or **r** modifier or both), then the rules in the file must not specify sides (via a modifier or a rule prefix such as **hide**).

Per-directory rules are inherited in all subdirectories of the directory where the merge-file was found unless the '**n**' modifier was used. Each subdirectory's rules are prefixed to the inherited per-directory rules from its parents, which gives the newest rules a higher priority than the inherited rules. The entire set of dir-merge rules are grouped together in the spot where the merge-file was specified, so it is possible to override dir-merge rules via a rule that got specified earlier in the list of global rules. When the list-clearing rule ("!") is read from a per-directory file, it only clears the inherited rules for the current merge file.

Another way to prevent a single rule from a dir-merge file from being inherited is to anchor it with a leading slash. Anchored rules in a per-directory merge-file are relative to the merge-file's directory, so a pattern "/foo" would only match the file "foo" in the directory where the dir-merge filter file was found.

Here's an example filter file which you'd specify via **--filter=". file"**:

```
merge /home/user/.global-filter
- *.gz
dir-merge .rules
+ *.[ch]
- *.o
- foo*
```

This will merge the contents of the /home/user/.global-filter file at the start of the list and also turns the ".rules" filename into a per-directory filter file. All rules read in prior to the start of the directory scan follow the global anchoring rules (i.e. a leading slash matches at the root of the transfer).

If a per-directory merge-file is specified with a path that is a parent directory of the first transfer directory, rsync will scan all the parent dirs from that starting point to the transfer directory for the indicated per-directory file. For instance, here is a common filter (see **-F**):

```
--filter=':./rsync-filter'
```

That rule tells rsync to scan for the file .rsync-filter in all directories from the root down through the parent directory of the transfer prior to the start of the normal directory scan of the file in the directories that are sent as a part of the transfer. (Note: for an rsync daemon, the root is always the same as the module's "path".)

Some examples of this pre-scanning for per-directory files:

```
rsync -avF /src/path/ /dest/dir
rsync -av --filter=': ../../.rsync-filter' /src/path/ /dest/dir
rsync -av --filter=': .rsync-filter' /src/path/ /dest/dir
```

The first two commands above will look for ".rsync-filter" in "/" and "/src" before the normal scan begins looking for the file in "/src/path" and its subdirectories. The last command avoids the parent-dir scan and only looks for the ".rsync-filter" files in each directory that is a part of the transfer.

If you want to include the contents of a ".cvsignore" in your patterns, you should use the rule ":C", which creates a dir-merge of the .cvsignore file, but parsed in a CVS-compatible manner. You can use this to affect where the **--cvs-exclude (-C)** option's inclusion of the per-directory .cvsignore file gets placed into your rules by putting the ":C" wherever you like in your filter rules. Without this, rsync would add the dir-merge rule for the .cvsignore file at the end of all your other rules (giving it a lower priority than your command-line rules). For example:

```
cat <<EOT | rsync -avC --filter=': -' a/ b
+ foo.o
```

```
:C
- *.old
EOT
rsync -avC --include=foo.o -f :C --exclude='*.old' a/ b
```

Both of the above rsync commands are identical. Each one will merge all the per-directory .cvsignore rules in the middle of the list rather than at the end. This allows their dir-specific rules to supersede the rules that follow the :C instead of being subservient to all your rules. To affect the other CVS exclude rules (i.e. the default list of exclusions, the contents of \$HOME/.cvsignore, and the value of \$CVSIGNORE) you should omit the **-C** command-line option and instead insert a "**-C**" rule into your filter rules; e.g. "**--filter=-C**".

LIST-CLEARING FILTER RULE

You can clear the current include/exclude list by using the "!" filter rule (as introduced in the FILTER RULES section above). The "current" list is either the global list of rules (if the rule is encountered while parsing the filter options) or a set of per-directory rules (which are inherited in their own sub-list, so a sub-directory can use this to clear out the parent's rules).

ANCHORING INCLUDE/EXCLUDE PATTERNS

As mentioned earlier, global include/exclude patterns are anchored at the "root of the transfer" (as opposed to per-directory patterns, which are anchored at the merge-file's directory). If you think of the transfer as a subtree of names that are being sent from sender to receiver, the transfer-root is where the tree starts to be duplicated in the destination directory. This root governs where patterns that start with a / match.

Because the matching is relative to the transfer-root, changing the trailing slash on a source path or changing your use of the **--relative** option affects the path you need to use in your matching (in addition to changing how much of the file tree is duplicated on the destination host). The following examples demonstrate this.

Let's say that we want to match two source files, one with an absolute path of "/home/me/foo/bar", and one with a path of "/home/you/bar/baz". Here is how the various command choices differ for a 2-source transfer:

Example cmd: rsync -a /home/me /home/you /dest
 +/- pattern: /me/foo/bar
 +/- pattern: /you/bar/baz
 Target file: /dest/me/foo/bar
 Target file: /dest/you/bar/baz

Example cmd: rsync -a /home/me/ /home/you/ /dest
 +/- pattern: /foo/bar (note missing "me")
 +/- pattern: /bar/baz (note missing "you")
 Target file: /dest/foo/bar
 Target file: /dest/bar/baz

Example cmd: rsync -a --relative /home/me/ /home/you /dest
 +/- pattern: /home/me/foo/bar (note full path)
 +/- pattern: /home/you/bar/baz (ditto)
 Target file: /dest/home/me/foo/bar
 Target file: /dest/home/you/bar/baz

Example cmd: cd /home; rsync -a --relative me/foo you/ /dest
 +/- pattern: /me/foo/bar (starts at specified path)
 +/- pattern: /you/bar/baz (ditto)
 Target file: /dest/me/foo/bar
 Target file: /dest/you/bar/baz

The easiest way to see what name you should filter is to just look at the output when using **--verbose** and put a / in front of the name (use the **--dry-run** option if you're not yet ready to copy any files).

PER-DIRECTORY RULES AND DELETE

Without a delete option, per-directory rules are only relevant on the sending side, so you can feel free to exclude the merge files themselves without affecting the transfer. To make this easy, the '`e`' modifier adds this exclude for you, as seen in these two equivalent commands:

```
rsync -av --filter=': .excl' --exclude=.excl host:src/dir /dest
rsync -av --filter=':e .excl' host:src/dir /dest
```

However, if you want to do a delete on the receiving side AND you want some files to be excluded from being deleted, you'll need to be sure that the receiving side knows what files to exclude. The easiest way is to include the per-directory merge files in the transfer and use **--delete-after**, because this ensures that the receiving side gets all the same exclude rules as the sending side before it tries to delete anything:

```
rsync -avF --delete-after host:src/dir /dest
```

However, if the merge files are not a part of the transfer, you'll need to either specify some global exclude rules (i.e. specified on the command line), or you'll need to maintain your own per-directory merge files on the receiving side. An example of the first is this (assume that the remote `.rules` files exclude themselves):

```
rsync -av --filter=': .rules' --filter=': ./my/extra.rules'
--delete host:src/dir /dest
```

In the above example the `extra.rules` file can affect both sides of the transfer, but (on the sending side) the rules are subservient to the rules merged from the `.rules` files because they were specified after the per-directory merge rule.

In one final example, the remote side is excluding the `.rsync-filter` files from the transfer, but we want to use our own `.rsync-filter` files to control what gets deleted on the receiving side. To do this we must specifically exclude the per-directory merge files (so that they don't get deleted) and then put rules into the local files to control what else should not get deleted. Like one of these commands:

```
rsync -av --filter=':e /.rsync-filter' --delete \
host:src/dir /dest
rsync -avFF --delete host:src/dir /dest
```

BATCH MODE

Batch mode can be used to apply the same set of updates to many identical systems. Suppose one has a tree which is replicated on a number of hosts. Now suppose some changes have been made to this source tree and those changes need to be propagated to the other hosts. In order to do this using batch mode, rsync is run with the write-batch option to apply the changes made to the source tree to one of the destination trees. The write-batch option causes the rsync client to store in a "batch file" all the information needed to repeat this operation against other, identical destination trees.

Generating the batch file once saves having to perform the file status, checksum, and data block generation more than once when updating multiple destination trees. Multicast transport protocols can be used to transfer the batch update files in parallel to many hosts at once, instead of sending the same data to every host individually.

To apply the recorded changes to another destination tree, run rsync with the read-batch option, specifying the name of the same batch file, and the destination tree. Rsync updates the destination tree using the information stored in the batch file.

For your convenience, a script file is also created when the write-batch option is used: it will be named the same as the batch file with ".sh" appended. This script file contains a command-line suitable for updating a destination tree using the associated batch file. It can be executed using a Bourne (or Bourne-like) shell, optionally passing in an alternate destination tree pathname which is then used instead of the original destination path. This is useful when the destination tree path on the current host differs from the one used to create the batch file.

Examples:

```
$ rsync --write-batch=foo -a host:/source/dir/ /adest/dir/
$ scp foo* remote:
```

```
$ ssh remote ./foo.sh /bdest/dir/
$ rsync --write-batch=foo -a /source/dir/ /adest/dir/
$ ssh remote rsync --read-batch=- -a /bdest/dir/ <foo
```

In these examples, rsync is used to update /adest/dir/ from /source/dir/ and the information to repeat this operation is stored in "foo" and "foo.sh". The host "remote" is then updated with the batched data going into the directory /bdest/dir. The differences between the two examples reveals some of the flexibility you have in how you deal with batches:

- o The first example shows that the initial copy doesn't have to be local -- you can push or pull data to/from a remote host using either the remote-shell syntax or rsync daemon syntax, as desired.
- o The first example uses the created "foo.sh" file to get the right rsync options when running the read-batch command on the remote host.
- o The second example reads the batch data via standard input so that the batch file doesn't need to be copied to the remote machine first. This example avoids the foo.sh script because it needed to use a modified **--read-batch** option, but you could edit the script file if you wished to make use of it (just be sure that no other option is trying to use standard input, such as the "**--exclude-from=-**" option).

Caveats:

The read-batch option expects the destination tree that it is updating to be identical to the destination tree that was used to create the batch update fileset. When a difference between the destination trees is encountered the update might be discarded with a warning (if the file appears to be up-to-date already) or the file-update may be attempted and then, if the file fails to verify, the update discarded with an error. This means that it should be safe to re-run a read-batch operation if the command got interrupted. If you wish to force the batched-update to always be attempted regardless of the file's size and date, use the **-I** option (when reading the batch). If an error occurs, the destination tree will probably be in a partially updated state. In that case, rsync can be used in its regular (non-batch) mode of operation to fix up the destination tree.

The rsync version used on all destinations must be at least as new as the one used to generate the batch file. Rsync will die with an error if the protocol version in the batch file is too new for the batch-reading rsync to handle. See also the **--proto** option for a way to have the creating rsync generate a batch file that an older rsync can understand. (Note that batch files changed format in version 2.6.3, so mixing versions older than that with newer versions will not work.)

When reading a batch file, rsync will force the value of certain options to match the data in the batch file if you didn't set them to the same as the batch-writing command. Other options can (and should) be changed. For instance **--write-batch** changes to **--read-batch**, **--files-from** is dropped, and the **--filter** / **--include** / **--exclude** options are not needed unless one of the **--delete** options is specified.

The code that creates the BATCH.sh file transforms any filter/include/exclude options into a single list that is appended as a "here" document to the shell script file. An advanced user can use this to modify the exclude list if a change in what gets deleted by **--delete** is desired. A normal user can ignore this detail and just use the shell script as an easy way to run the appropriate **--read-batch** command for the batched data.

The original batch mode in rsync was based on "rsync+", but the latest version uses a new implementation.

SYMBOLIC LINKS

Three basic behaviors are possible when rsync encounters a symbolic link in the source directory.

By default, symbolic links are not transferred at all. A message "skipping non-regular" file is emitted for any symlinks that exist.

If **--links** is specified, then symlinks are recreated with the same target on the destination. Note that **--archive** implies **--links**.

If **--copy-links** is specified, then symlinks are "collapsed" by copying their referent, rather than the symlink.

Rsync can also distinguish "safe" and "unsafe" symbolic links. An example where this might be used is a

web site mirror that wishes to ensure that the rsync module that is copied does not include symbolic links to **/etc/passwd** in the public section of the site. Using **--copy-unsafe-links** will cause any links to be copied as the file they point to on the destination. Using **--safe-links** will cause unsafe links to be omitted altogether. (Note that you must specify **--links** for **--safe-links** to have any effect.)

Symbolic links are considered unsafe if they are absolute symlinks (start with `/`), empty, or if they contain enough `..` components to ascend from the directory being copied.

Here's a summary of how the symlink options are interpreted. The list is in order of precedence, so if your combination of options isn't mentioned, use the first line that is a complete subset of your options:

--copy-links

Turn all symlinks into normal files (leaving no symlinks for any other options to affect).

--links --copy-unsafe-links

Turn all unsafe symlinks into files and duplicate all safe symlinks.

--copy-unsafe-links

Turn all unsafe symlinks into files, noisily skip all safe symlinks.

--links --safe-links

Duplicate safe symlinks and skip unsafe ones.

--links

Duplicate all symlinks.

DIAGNOSTICS

rsync occasionally produces error messages that may seem a little cryptic. The one that seems to cause the most confusion is "protocol version mismatch -- is your shell clean?".

This message is usually caused by your startup scripts or remote shell facility producing unwanted garbage on the stream that rsync is using for its transport. The way to diagnose this problem is to run your remote shell like this:

```
ssh remotehost /bin/true > out.dat
```

then look at out.dat. If everything is working correctly then out.dat should be a zero length file. If you are getting the above error from rsync then you will probably find that out.dat contains some text or data. Look at the contents and try to work out what is producing it. The most common cause is incorrectly configured shell startup scripts (such as .cshrc or .profile) that contain output statements for non-interactive logins.

If you are having trouble debugging filter patterns, then try specifying the **-vv** option. At this level of verbosity rsync will show why each individual file is included or excluded.

EXIT VALUES

0	Success
1	Syntax or usage error
2	Protocol incompatibility
3	Errors selecting input/output files, dirs
4	Requested action not supported: an attempt was made to manipulate 64-bit files on a platform that cannot support them; or an option was specified that is supported by the client and not by the server.
5	Error starting client-server protocol
6	Daemon unable to append to log-file
10	Error in socket I/O
11	Error in file I/O
12	Error in rsync protocol data stream

13	Errors with program diagnostics
14	Error in IPC code
20	Received SIGUSR1 or SIGINT
21	Some error returned by <code>waitpid()</code>
22	Error allocating core memory buffers
23	Partial transfer due to error
24	Partial transfer due to vanished source files
25	The --max-delete limit stopped deletions
30	Timeout in data send/receive
35	Timeout waiting for daemon connection

ENVIRONMENT VARIABLES

CVSIGNORE

The CVSIGNORE environment variable supplements any ignore patterns in .cvsignore files. See the `--cvs-exclude` option for more details.

RSYNC_ICONV

Specify a default `--iconv` setting using this environment variable. (First supported in 3.0.0.)

RSYNC_PROTECT_ARGS

Specify a non-zero numeric value if you want the `--protect-args` option to be enabled by default, or a zero value to make sure that it is disabled by default. (First supported in 3.1.0.)

RSYNC_RSH

The RSYNC_RSH environment variable allows you to override the default shell used as the transport for rsync. Command line options are permitted after the command name, just as in the `-e` option.

RSYNC_PROXY

The RSYNC_PROXY environment variable allows you to redirect your rsync client to use a web proxy when connecting to a rsync daemon. You should set RSYNC_PROXY to a hostname:port pair.

RSYNC_PASSWORD

Setting RSYNC_PASSWORD to the required password allows you to run authenticated rsync connections to an rsync daemon without user intervention. Note that this does not supply a password to a remote shell transport such as ssh; to learn how to do that, consult the remote shell's documentation.

USER or LOGNAME

The USER or LOGNAME environment variables are used to determine the default username sent to an rsync daemon. If neither is set, the username defaults to "nobody".

HOME

The HOME environment variable is used to find the user's default .cvsignore file.

FILES

/etc/rsyncd.conf or rsyncd.conf

SEE ALSO

`rsync-ssl(1)`, `rsyncd.conf(5)`

BUGS

times are transferred as *nix time_t values

When transferring to FAT filesystems rsync may re-sync unmodified files. See the comments on the `--modify-window` option.

file permissions, devices, etc. are transferred as native numerical values

see also the comments on the **--delete** option

Please report bugs! See the web site at <https://rsync.samba.org/>.

VERSION

This man page is current for version 3.2.3 of rsync.

INTERNAL OPTIONS

The options **--server** and **--sender** are used internally by rsync, and should never be typed by a user under normal circumstances. Some awareness of these options may be needed in certain scenarios, such as when setting up a login that can only run an rsync command. For instance, the support directory of the rsync distribution has an example script named `rrsync` (for restricted rsync) that can be used with a restricted ssh login.

CREDITS

rsync is distributed under the GNU General Public License. See the file COPYING for details.

A web site is available at <https://rsync.samba.org/>. The site includes an FAQ-O-Matic which may cover questions unanswered by this manual page.

We would be delighted to hear from you if you like this program. Please contact the mailing-list at rsync@lists.samba.org.

This program uses the excellent zlib compression library written by Jean-loup Gailly and Mark Adler.

THANKS

Special thanks go out to: John Van Essen, Matt McCutchen, Wesley W. Terpstra, David Dykstra, Jos Backus, Sebastian Krahmer, Martin Pool, and our gone-but-not-forgotten compadre, J.W. Schultz.

Thanks also to Richard Brent, Brendan Mackay, Bill Waite, Stephen Rothwell and David Bell. I've probably missed some people, my apologies if I have.

AUTHOR

rsync was originally written by Andrew Tridgell and Paul Mackerras. Many people have later contributed to it. It is currently maintained by Wayne Davison.

Mailing lists for support and development are available at <https://lists.samba.org/>.

NAME

rsyncd.conf – configuration file for rsync in daemon mode

SYNOPSIS

rsyncd.conf

DESCRIPTION

The rsyncd.conf file is the runtime configuration file for rsync when run as an rsync daemon.

The rsyncd.conf file controls authentication, access, logging and available modules.

FILE FORMAT

The file consists of modules and parameters. A module begins with the name of the module in square brackets and continues until the next module begins. Modules contain parameters of the form **name = value**.

The file is line-based -- that is, each newline-terminated line represents either a comment, a module name or a parameter.

Only the first equals sign in a parameter is significant. Whitespace before or after the first equals sign is discarded. Leading, trailing and internal whitespace in module and parameter names is irrelevant. Leading and trailing whitespace in a parameter value is discarded. Internal whitespace within a parameter value is retained verbatim.

Any line **beginning** with a hash (#) is ignored, as are lines containing only whitespace. (If a hash occurs after anything other than leading whitespace, it is considered a part of the line's content.)

Any line ending in a \ is "continued" on the next line in the customary UNIX fashion.

The values following the equals sign in parameters are all either a string (no quotes needed) or a boolean, which may be given as yes/no, 0/1 or true/false. Case is not significant in boolean values, but is preserved in string values.

LAUNCHING THE RSYNC DAEMON

The rsync daemon is launched by specifying the **--daemon** option to rsync.

The daemon must run with root privileges if you wish to use chroot, to bind to a port numbered under 1024 (as is the default 873), or to set file ownership. Otherwise, it must just have permission to read and write the appropriate data, log, and lock files.

You can launch it either via inetd, as a stand-alone daemon, or from an rsync client via a remote shell. If run as a stand-alone daemon then just run the command "**rsync --daemon**" from a suitable startup script.

When run via inetd you should add a line like this to /etc/services:

```
rsync      873/tcp
```

and a single line something like this to /etc/inetd.conf:

```
rsync  stream  tcp  nowait  root  /usr/bin/rsync rsyncd --daemon
```

Replace "/usr/bin/rsync" with the path to where you have rsync installed on your system. You will then need to send inetd a HUP signal to tell it to reread its config file.

Note that you should **not** send the rsync daemon a HUP signal to force it to reread the **rsyncd.conf** file. The file is re-read on each client connection.

GLOBAL PARAMETERS

The first parameters in the file (before a [module] header) are the global parameters. Rsync also allows for the use of a "[global]" module name to indicate the start of one or more global-parameter sections (the name must be lower case).

You may also include any module parameters in the global part of the config file in which case the supplied value will override the default for that parameter.

You may use references to environment variables in the values of parameters. String parameters will have %VAR% references expanded as late as possible (when the string is first used in the program), allowing for

the use of variables that rsync sets at connection time, such as RSYNC_USER_NAME. Non-string parameters (such as true/false settings) are expanded when read from the config file. If a variable does not exist in the environment, or if a sequence of characters is not a valid reference (such as an un-paired percent sign), the raw characters are passed through unchanged. This helps with backward compatibility and safety (e.g. expanding a non-existent %VAR% to an empty string in a path could result in a very unsafe path). The safest way to insert a literal % into a value is to use %%.

motd file

This parameter allows you to specify a "message of the day" to display to clients on each connect. This usually contains site information and any legal notices. The default is no motd file. This can be overridden by the **--dparam=motdfile=FILE** command-line option when starting the daemon.

pid file This parameter tells the rsync daemon to write its process ID to that file. The rsync keeps the file locked so that it can know when it is safe to overwrite an existing file.

The filename can be overridden by the **--dparam=pidfile=FILE** command-line option when starting the daemon.

port You can override the default port the daemon will listen on by specifying this value (defaults to 873). This is ignored if the daemon is being run by inetd, and is superseded by the **--port** command-line option.

address

You can override the default IP address the daemon will listen on by specifying this value. This is ignored if the daemon is being run by inetd, and is superseded by the **--address** command-line option.

socket options

This parameter can provide endless fun for people who like to tune their systems to the utmost degree. You can set all sorts of socket options which may make transfers faster (or slower!). Read the man page for the **setsockopt()** system call for details on some of the options you may be able to set. By default no special socket options are set. These settings can also be specified via the **--sockopts** command-line option.

listen backlog

You can override the default backlog value when the daemon listens for connections. It defaults to 5.

MODULE PARAMETERS

After the global parameters you should define a number of modules, each module exports a directory tree as a symbolic name. Modules are exported by specifying a module name in square brackets [module] followed by the parameters for that module. The module name cannot contain a slash or a closing square bracket. If the name contains whitespace, each internal sequence of whitespace will be changed into a single space, while leading or trailing whitespace will be discarded. Also, the name cannot be "global" as that exact name indicates that global parameters follow (see above).

As with GLOBAL PARAMETERS, you may use references to environment variables in the values of parameters. See the GLOBAL PARAMETERS section for more details.

comment

This parameter specifies a description string that is displayed next to the module name when clients obtain a list of available modules. The default is no comment.

path This parameter specifies the directory in the daemon's filesystem to make available in this module. You must specify this parameter for each module in **rsyncd.conf**.

You may base the path's value off of an environment variable by surrounding the variable name with percent signs. You can even reference a variable that is set by rsync when the user connects. For example, this would use the authorizing user's name in the path:

path = /home/%RSYNC_USER_NAME%

It is fine if the path includes internal spaces — they will be retained verbatim (which means that you shouldn't try to escape them). If your final directory has a trailing space (and this is somehow not something you wish to fix), append a trailing slash to the path to avoid losing the trailing whitespace.

use chroot

If "use chroot" is true, the rsync daemon will chroot to the "path" before starting the file transfer with the client. This has the advantage of extra protection against possible implementation security holes, but it has the disadvantages of requiring super-user privileges, of not being able to follow symbolic links that are either absolute or outside of the new root path, and of complicating the preservation of users and groups by name (see below).

As an additional safety feature, you can specify a dot-dir in the module's "path" to indicate the point where the chroot should occur. This allows rsync to run in a chroot with a non-"/" path for the top of the transfer hierarchy. Doing this guards against unintended library loading (since those absolute paths will not be inside the transfer hierarchy unless you have used an unwise pathname), and lets you setup libraries for the chroot that are outside of the transfer. For example, specifying "/var/rsync/.module1" will chroot to the "/var/rsync" directory and set the inside-chroot path to "/module1". If you had omitted the dot-dir, the chroot would have used the whole path, and the inside-chroot path would have been "/".

When both "use chroot" and "daemon chroot" are false, OR the inside-chroot path of "use chroot" is not "/", rsync will: (1) munge symlinks by default for security reasons (see "munge symlinks" for a way to turn this off, but only if you trust your users), (2) substitute leading slashes in absolute paths with the module's path (so that options such as **--backup-dir**, **--compare-dest**, etc. interpret an absolute path as rooted in the module's "path" dir), and (3) trim ".." path elements from args if rsync believes they would escape the module hierarchy. The default for "use chroot" is true, and is the safer choice (especially if the module is not read-only).

When this parameter is enabled *and* the "name converter" parameter is *not* set, the "numeric ids" parameter will default to being enabled (disabling name lookups). This means that if you manually setup name-lookup libraries in your chroot (instead of using a name converter) that you need to explicitly set **numeric ids = false** for rsync to do name lookups.

If you copy library resources into the module's chroot area, you should protect them through your OS's normal user/group or ACL settings (to prevent the rsync module's user from being able to change them), and then hide them from the user's view via "exclude" (see how in the discussion of that parameter). However, it's easier and safer to setup a name converter.

daemon chroot

This parameter specifies a path to which the daemon will chroot before beginning communication with clients. Module paths (and any "use chroot" settings) will then be related to this one. This lets you choose if you want the whole daemon to be chrooted (with this setting), just the transfers to be chrooted (with "use chroot"), or both. Keep in mind that the "daemon chroot" area may need various OS/lib/etc files installed to allow the daemon to function. By default the daemon runs without any chrooting.

proxy protocol

When this parameter is enabled, all incoming connections must start with a V1 or V2 proxy protocol header. If the header is not found, the connection is closed.

Setting this to **true** requires a proxy server to forward source IP information to rsync, allowing you to log proper IP/host info and make use of client-oriented IP restrictions. The default of **false** means that the IP information comes directly from the socket's metadata. If rsync is not behind a proxy, this should be disabled.

CAUTION: using this option can be dangerous if you do not ensure that only the proxy is allowed to connect to the rsync port. If any non-proxied connections are allowed through, the client will be

able to use a modified rsync to spoof any remote IP address that they desire. You can lock this down using something like iptables **--uid-owner root** rules (for strict localhost access), various firewall rules, or you can require password authorization so that any spoofing by users will not grant extra access.

This setting is global. If you need some modules to require this and not others, then you will need to setup multiple rsync daemon processes on different ports.

name converter

This parameter lets you specify a program that will be run by the rsync daemon to do user & group conversions between names & ids. This script is started prior to any chroot being setup, and runs as the daemon user (not the transfer user). You can specify a fully qualified pathname or a program name that is on the \$PATH.

The program can be used to do normal user & group lookups without having to put any extra files into the chroot area of the module *or* you can do customized conversions.

The nameconvert program has access to all of the environment variables that are described in the section on **pre-xfer exec**. This is useful if you want to customize the conversion using information about the module and/or the copy request.

There is a sample python script in the support dir named "nameconvert" that implements the normal user & group lookups. Feel free to customize it or just use it as documentation to implement your own.

numeric ids

Enabling this parameter disables the mapping of users and groups by name for the current daemon module. This prevents the daemon from trying to load any user/group-related files or libraries. This enabling makes the transfer behave as if the client had passed the **--numeric-ids** command-line option. By default, this parameter is enabled for chroot modules and disabled for non-chroot modules. Also keep in mind that uid/gid preservation requires the module to be running as root (see "uid") or for "fake super" to be configured.

A chroot-enabled module should not have this parameter set to false unless you're using a "name converter" program *or* you've taken steps to ensure that the module has the necessary resources it needs to translate names and that it is not possible for a user to change those resources.

munge symlinks

This parameter tells rsync to modify all symlinks in the same way as the (non-daemon-affecting) **--munge-links** command-line option (using a method described below). This should help protect your files from user trickery when your daemon module is writable. The default is disabled when "use chroot" is on with an inside-chroot path of "/", OR if "daemon chroot" is on, otherwise it is enabled.

If you disable this parameter on a daemon that is not read-only, there are tricks that a user can play with uploaded symlinks to access daemon-excluded items (if your module has any), and, if "use chroot" is off, rsync can even be tricked into showing or changing data that is outside the module's path (as access-permissions allow).

The way rsync disables the use of symlinks is to prefix each one with the string "/rsyncd-munged/". This prevents the links from being used as long as that directory does not exist. When this parameter is enabled, rsync will refuse to run if that path is a directory or a symlink to a directory. When using the "munge symlinks" parameter in a chroot area that has an inside-chroot path of "/", you should add "/rsyncd-munged/" to the exclude setting for the module so that a user can't try to create it.

Note: rsync makes no attempt to verify that any pre-existing symlinks in the module's hierarchy are as safe as you want them to be (unless, of course, it just copied in the whole hierarchy). If you setup an rsync daemon on a new area or locally add symlinks, you can manually protect your symlinks from being abused by prefixing "/rsyncd-munged/" to the start of every symlink's value. There is a perl script in the support directory of the source code named "munge-symlinks" that can

be used to add or remove this prefix from your symlinks.

When this parameter is disabled on a writable module and "use chroot" is off (or the inside-chroot path is not "/"), incoming symlinks will be modified to drop a leading slash and to remove ".." path elements that rsync believes will allow a symlink to escape the module's hierarchy. There are tricky ways to work around this, though, so you had better trust your users if you choose this combination of parameters.

charset

This specifies the name of the character set in which the module's filenames are stored. If the client uses an **--iconv** option, the daemon will use the value of the "charset" parameter regardless of the character set the client actually passed. This allows the daemon to support charset conversion in a chroot module without extra files in the chroot area, and also ensures that name-transliteration is done in a consistent manner. If the "charset" parameter is not set, the **--iconv** option is refused, just as if "iconv" had been specified via "refuse options".

If you wish to force users to always use **--iconv** for a particular module, add "no-iconv" to the "refuse options" parameter. Keep in mind that this will restrict access to your module to very new rsync clients.

max connections

This parameter allows you to specify the maximum number of simultaneous connections you will allow. Any clients connecting when the maximum has been reached will receive a message telling them to try later. The default is 0, which means no limit. A negative value disables the module. See also the "lock file" parameter.

log file When the "log file" parameter is set to a non-empty string, the rsync daemon will log messages to the indicated file rather than using syslog. This is particularly useful on systems (such as AIX) where **syslog()** doesn't work for chrooted programs. The file is opened before **chroot()** is called, allowing it to be placed outside the transfer. If this value is set on a per-module basis instead of globally, the global log will still contain any authorization failures or config-file error messages.

If the daemon fails to open the specified file, it will fall back to using syslog and output an error about the failure. (Note that the failure to open the specified log file used to be a fatal error.)

This setting can be overridden by using the **--log-file=FILE** or **--dparam=logfile=FILE** command-line options. The former overrides all the log-file parameters of the daemon and all module settings. The latter sets the daemon's log file and the default for all the modules, which still allows modules to override the default setting.

syslog facility

This parameter allows you to specify the syslog facility name to use when logging messages from the rsync daemon. You may use any standard syslog facility name which is defined on your system. Common names are auth, authpriv, cron, daemon, ftp, kern, lpr, mail, news, security, syslog, user, uucp, local0, local1, local2, local3, local4, local5, local6 and local7. The default is daemon. This setting has no effect if the "log file" setting is a non-empty string (either set in the per-modules settings, or inherited from the global settings).

syslog tag

This parameter allows you to specify the syslog tag to use when logging messages from the rsync daemon. The default is "rsyncd". This setting has no effect if the "log file" setting is a non-empty string (either set in the per-modules settings, or inherited from the global settings).

For example, if you wanted each authenticated user's name to be included in the syslog tag, you could do something like this:

```
syslog tag = rsyncd.%RSYNC_USER_NAME%
```

max verbosity

This parameter allows you to control the maximum amount of verbose information that you'll allow the daemon to generate (since the information goes into the log file). The default is 1, which allows the client to request one level of verbosity.

This also affects the user's ability to request higher levels of **--info** and **--debug** logging. If the max value is 2, then no info and/or debug value that is higher than what would be set by **-vv** will be honored by the daemon in its logging. To see how high of a verbosity level you need to accept for a particular info/debug level, refer to **rsync --info=help** and **rsync --debug=help**. For instance, it takes max-verbosity 4 to be able to output debug TIME2 and FLIST3.

lock file

This parameter specifies the file to use to support the "max connections" parameter. The rsync daemon uses record locking on this file to ensure that the max connections limit is not exceeded for the modules sharing the lock file. The default is **/var/run/rsyncd.lock**.

read only

This parameter determines whether clients will be able to upload files or not. If "read only" is true then any attempted uploads will fail. If "read only" is false then uploads will be possible if file permissions on the daemon side allow them. The default is for all modules to be read only.

Note that "auth users" can override this setting on a per-user basis.

write only

This parameter determines whether clients will be able to download files or not. If "write only" is true then any attempted downloads will fail. If "write only" is false then downloads will be possible if file permissions on the daemon side allow them. The default is for this parameter to be disabled.

Helpful hint: you probably want to specify "refuse options = delete" for a write-only module.

open noatime

When set to True, this parameter tells the rsync daemon to open files with the O_NOATIME flag (on systems that support it) to avoid changing the access time of the files that are being transferred. If your OS does not support the O_NOATIME flag then rsync will silently ignore this option. Note also that some filesystems are mounted to avoid updating the atime on read access even without the O_NOATIME flag being set.

When set to False, this parameters ensures that files on the server are not opened with O_NOATIME.

When set to Unset (the default) the user controls the setting via **--open-noatime**.

list This parameter determines whether this module is listed when the client asks for a listing of available modules. In addition, if this is false, the daemon will pretend the module does not exist when a client denied by "hosts allow" or "hosts deny" attempts to access it. Realize that if "reverse lookup" is disabled globally but enabled for the module, the resulting reverse lookup to a potentially client-controlled DNS server may still reveal to the client that it hit an existing module. The default is for modules to be listable.

uid This parameter specifies the user name or user ID that file transfers to and from that module should take place as when the daemon was run as root. In combination with the "gid" parameter this determines what file permissions are available. The default when run by a super-user is to switch to the system's "nobody" user. The default for a non-super-user is to not try to change the user. See also the "gid" parameter.

The RSYNC_USER_NAME environment variable may be used to request that rsync run as the authorizing user. For example, if you want a rsync to run as the same user that was received for the rsync authentication, this setup is useful:

```
uid = %RSYNC_USER_NAME%
gid = *
```

gid This parameter specifies one or more group names/IDs that will be used when accessing the module. The first one will be the default group, and any extra ones be set as supplemental groups. You may also specify a "*" as the first gid in the list, which will be replaced by all the normal groups for the transfer's user (see "uid"). The default when run by a super-user is to switch to your OS's

"nobody" (or perhaps "nogroup") group with no other supplementary groups. The default for a non-super-user is to not change any group attributes (and indeed, your OS may not allow a non-super-user to try to change their group settings).

The specified list is normally split into tokens based on spaces and commas. However, if the list starts with a comma, then the list is only split on commas, which allows a group name to contain a space. In either case any leading and/or trailing whitespace is removed from the tokens and empty tokens are ignored.

daemon uid

This parameter specifies a uid under which the daemon will run. The daemon usually runs as user root, and when this is left unset the user is left unchanged. See also the "uid" parameter.

daemon gid

This parameter specifies a gid under which the daemon will run. The daemon usually runs as group root, and when this is left unset, the group is left unchanged. See also the "gid" parameter.

fake super

Setting "fake super = yes" for a module causes the daemon side to behave as if the **--fake-super** command-line option had been specified. This allows the full attributes of a file to be stored without having to have the daemon actually running as root.

filter

The daemon has its own filter chain that determines what files it will let the client access. This chain is not sent to the client and is independent of any filters the client may have specified. Files excluded by the daemon filter chain (**daemon-excluded** files) are treated as non-existent if the client tries to pull them, are skipped with an error message if the client tries to push them (triggering exit code 23), and are never deleted from the module. You can use daemon filters to prevent clients from downloading or tampering with private administrative files, such as files you may add to support uid/gid name translations.

The daemon filter chain is built from the "filter", "include from", "include", "exclude from", and "exclude" parameters, in that order of priority. Anchored patterns are anchored at the root of the module. To prevent access to an entire subtree, for example, "/secret", you **must** exclude everything in the subtree; the easiest way to do this is with a triple-star pattern like "/secret/**".

The "filter" parameter takes a space-separated list of daemon filter rules, though it is smart enough to know not to split a token at an internal space in a rule (e.g. "- /foo - /bar" is parsed as two rules). You may specify one or more merge-file rules using the normal syntax. Only one "filter" parameter can apply to a given module in the config file, so put all the rules you want in a single parameter. Note that per-directory merge-file rules do not provide as much protection as global rules, but they can be used to make **--delete** work better during a client download operation if the per-dir merge files are included in the transfer and the client requests that they be used.

exclude

This parameter takes a space-separated list of daemon exclude patterns. As with the client **--exclude** option, patterns can be qualified with "-" or "+" to explicitly indicate exclude/include. Only one "exclude" parameter can apply to a given module. See the "filter" parameter for a description of how excluded files affect the daemon.

include

Use an "include" to override the effects of the "exclude" parameter. Only one "include" parameter can apply to a given module. See the "filter" parameter for a description of how excluded files affect the daemon.

exclude from

This parameter specifies the name of a file on the daemon that contains daemon exclude patterns, one per line. Only one "exclude from" parameter can apply to a given module; if you have multiple exclude-from files, you can specify them as a merge file in the "filter" parameter. See the "filter" parameter for a description of how excluded files affect the daemon.

include from

Analogue of "exclude from" for a file of daemon include patterns. Only one "include from" parameter can apply to a given module. See the "filter" parameter for a description of how excluded files affect the daemon.

incoming chmod

This parameter allows you to specify a set of comma-separated chmod strings that will affect the permissions of all incoming files (files that are being received by the daemon). These changes happen after all other permission calculations, and this will even override destination-default and/or existing permissions when the client does not specify **--perms**. See the description of the **--chmod** rsync option and the **chmod(1)** manpage for information on the format of this string.

outgoing chmod

This parameter allows you to specify a set of comma-separated chmod strings that will affect the permissions of all outgoing files (files that are being sent out from the daemon). These changes happen first, making the sent permissions appear to be different than those stored in the filesystem itself. For instance, you could disable group write permissions on the server while having it appear to be on to the clients. See the description of the **--chmod** rsync option and the **chmod(1)** manpage for information on the format of this string.

auth users

This parameter specifies a comma and/or space-separated list of authorization rules. In its simplest form, you list the usernames that will be allowed to connect to this module. The usernames do not need to exist on the local system. The rules may contain shell wildcard characters that will be matched against the username provided by the client for authentication. If "auth users" is set then the client will be challenged to supply a username and password to connect to the module. A challenge response authentication protocol is used for this exchange. The plain text usernames and passwords are stored in the file specified by the "secrets file" parameter. The default is for all users to be able to connect without a password (this is called "anonymous rsync").

In addition to username matching, you can specify groupname matching via a '@' prefix. When using groupname matching, the authenticating username must be a real user on the system, or it will be assumed to be a member of no groups. For example, specifying "@rsync" will match the authenticating user if the named user is a member of the rsync group.

Finally, options may be specified after a colon (:). The options allow you to "deny" a user or a group, set the access to "ro" (read-only), or set the access to "rw" (read/write). Setting an auth-rule-specific ro/rw setting overrides the module's "read only" setting.

Be sure to put the rules in the order you want them to be matched, because the checking stops at the first matching user or group, and that is the only auth that is checked. For example:

```
auth users = joe:deny @guest:deny admin:rw @rsync:ro susan joe sam
```

In the above rule, user joe will be denied access no matter what. Any user that is in the group "guest" is also denied access. The user "admin" gets access in read/write mode, but only if the admin user is not in group "guest" (because the admin user-matching rule would never be reached if the user is in group "guest"). Any other user who is in group "rsync" will get read-only access. Finally, users susan, joe, and sam get the ro/rw setting of the module, but only if the user didn't match an earlier group-matching rule.

If you need to specify a user or group name with a space in it, start your list with a comma to indicate that the list should only be split on commas (though leading and trailing whitespace will also be removed, and empty entries are just ignored). For example:

```
auth users = , joe:deny, @Some Group:deny, admin:rw, @RO Group:ro
```

See the description of the secrets file for how you can have per-user passwords as well as per-group passwords. It also explains how a user can authenticate using their user password or (when applicable) a group password, depending on what rule is being authenticated.

See also the section entitled "USING RSYNC-DAEMON FEATURES VIA A REMOTE SHELL CONNECTION" in **rsync(1)** for information on how handle an rsyncd.conf-level username that differs from the remote-shell-level username when using a remote shell to connect to an rsync daemon.

secrets file

This parameter specifies the name of a file that contains the username:password and/or @group-name:password pairs used for authenticating this module. This file is only consulted if the "auth users" parameter is specified. The file is line-based and contains one name:password pair per line. Any line has a hash (#) as the very first character on the line is considered a comment and is skipped. The passwords can contain any characters but be warned that many operating systems limit the length of passwords that can be typed at the client end, so you may find that passwords longer than 8 characters don't work.

The use of group-specific lines are only relevant when the module is being authorized using a matching "@groupname" rule. When that happens, the user can be authorized via either their "username:password" line or the "@groupname:password" line for the group that triggered the authentication.

It is up to you what kind of password entries you want to include, either users, groups, or both. The use of group rules in "auth users" does not require that you specify a group password if you do not want to use shared passwords.

There is no default for the "secrets file" parameter, you must choose a name (such as /etc/rsyncd.secrets). The file must normally not be readable by "other"; see "strict modes". If the file is not found or is rejected, no logins for a "user auth" module will be possible.

strict modes

This parameter determines whether or not the permissions on the secrets file will be checked. If "strict modes" is true, then the secrets file must not be readable by any user ID other than the one that the rsync daemon is running under. If "strict modes" is false, the check is not performed. The default is true. This parameter was added to accommodate rsync running on the Windows operating system.

hosts allow

This parameter allows you to specify a list of comma- and/or whitespace-separated patterns that are matched against a connecting client's hostname and IP address. If none of the patterns match, then the connection is rejected.

Each pattern can be in one of six forms:

- o a dotted decimal IPv4 address of the form a.b.c.d, or an IPv6 address of the form a:b:c::d:e:f. In this case the incoming machine's IP address must match exactly.
- o an address/mask in the form ipaddr/n where ipaddr is the IP address and n is the number of one bits in the netmask. All IP addresses which match the masked IP address will be allowed in.
- o an address/mask in the form ipaddr/maskaddr where ipaddr is the IP address and maskaddr is the netmask in dotted decimal notation for IPv4, or similar for IPv6, e.g. ffff:ffff:ffff:ffff:: instead of /64. All IP addresses which match the masked IP address will be allowed in.
- o a hostname pattern using wildcards. If the hostname of the connecting IP (as determined by a reverse lookup) matches the wildcarded name (using the same rules as normal unix filename matching), the client is allowed in. This only works if "reverse lookup" is enabled (the default).
- o a hostname. A plain hostname is matched against the reverse DNS of the connecting IP (if "reverse lookup" is enabled), and/or the IP of the given hostname is matched against the connecting IP (if "forward lookup" is enabled, as it is by default). Any match will be allowed in.

- o an '@' followed by a netgroup name, which will match if the reverse DNS of the connecting IP is in the specified netgroup.

Note IPv6 link-local addresses can have a scope in the address specification:

```
fe80::1%link1
fe80::%link1/64
fe80::%link1/ffff:ffff:ffff::
```

You can also combine "hosts allow" with "hosts deny" as a way to add exceptions to your deny list. When both parameters are specified, the "hosts allow" parameter is checked first and a match results in the client being able to connect. A non-allowed host is then matched against the "hosts deny" list to see if it should be rejected. A host that does not match either list is allowed to connect.

The default is no "hosts allow" parameter, which means all hosts can connect.

hosts deny

This parameter allows you to specify a list of comma- and/or whitespace-separated patterns that are matched against a connecting clients hostname and IP address. If the pattern matches then the connection is rejected. See the "hosts allow" parameter for more information.

The default is no "hosts deny" parameter, which means all hosts can connect.

reverse lookup

Controls whether the daemon performs a reverse lookup on the client's IP address to determine its hostname, which is used for "hosts allow" & "hosts deny" checks and the "%h" log escape. This is enabled by default, but you may wish to disable it to save time if you know the lookup will not return a useful result, in which case the daemon will use the name "UNDETERMINED" instead.

If this parameter is enabled globally (even by default), rsync performs the lookup as soon as a client connects, so disabling it for a module will not avoid the lookup. Thus, you probably want to disable it globally and then enable it for modules that need the information.

forward lookup

Controls whether the daemon performs a forward lookup on any hostname specified in an hosts allow/deny setting. By default this is enabled, allowing the use of an explicit hostname that would not be returned by reverse DNS of the connecting IP.

ignore errors

This parameter tells rsyncd to ignore I/O errors on the daemon when deciding whether to run the delete phase of the transfer. Normally rsync skips the --**delete** step if any I/O errors have occurred in order to prevent disastrous deletion due to a temporary resource shortage or other I/O error. In some cases this test is counter productive so you can use this parameter to turn off this behavior.

ignore nonreadable

This tells the rsync daemon to completely ignore files that are not readable by the user. This is useful for public archives that may have some non-readable files among the directories, and the sysadmin doesn't want those files to be seen at all.

transfer logging

This parameter enables per-file logging of downloads and uploads in a format somewhat similar to that used by ftp daemons. The daemon always logs the transfer at the end, so if a transfer is aborted, no mention will be made in the log file.

If you want to customize the log lines, see the "log format" parameter.

log format

This parameter allows you to specify the format used for logging file transfers when transfer logging is enabled. The format is a text string containing embedded single-character escape sequences prefixed with a percent (%) character. An optional numeric field width may also be specified between the percent and the escape letter (e.g. "%-50n %8I %07p"). In addition, one or more apostrophes may be specified prior to a numerical escape to indicate that the numerical value

should be made more human-readable. The 3 supported levels are the same as for the **--human-readable** command-line option, though the default is for human-readability to be off. Each added apostrophe increases the level (e.g. "%'"l %'b %'f").

The default log format is "%o %h [%a] %m (%u) %f %l", and a "%t [%p]" is always prefixed when using the "log file" parameter. (A perl script that will summarize this default log format is included in the rsync source code distribution in the "support" subdirectory: rsyncstats.)

The single-character escapes that are understood are as follows:

- o %a the remote IP address (only available for a daemon)
- o %b the number of bytes actually transferred
- o %B the permission bits of the file (e.g. rwxrwxrwt)
- o %c the total size of the block checksums received for the basis file (only when sending)
- o %C the full-file checksum if it is known for the file. For older rsync protocols/versions, the checksum was salted, and is thus not a useful value (and is not displayed when that is the case). For the checksum to output for a file, either the **--checksum** option must be in-effect or the file must have been transferred without a salted checksum being used. See the **--checksum-choice** option for a way to choose the algorithm.
- o %f the filename (long form on sender; no trailing "/")
- o %G the gid of the file (decimal) or "DEFAULT"
- o %h the remote host name (only available for a daemon)
- o %i an itemized list of what is being updated
- o %l the length of the file in bytes
- o %L the string "-> SYMLINK", "=> HARDLINK", or "" (where **SYMLINK** or **HARDLINK** is a filename)
- o %m the module name
- o %M the last-modified time of the file
- o %n the filename (short form; trailing "/" on dir)
- o %o the operation, which is "send", "recv", or "del." (the latter includes the trailing period)
- o %p the process ID of this rsync session
- o %P the module path
- o %t the current date time
- o %u the authenticated username or an empty string
- o %U the uid of the file (decimal)

For a list of what the characters mean that are output by "%i", see the **--itemize-changes** option in the rsync manpage.

Note that some of the logged output changes when talking with older rsync versions. For instance, deleted files were only output as verbose messages prior to rsync 2.6.4.

timeout

This parameter allows you to override the clients choice for I/O timeout for this module. Using this parameter you can ensure that rsync won't wait on a dead client forever. The timeout is specified in seconds. A value of zero means no timeout and is the default. A good choice for anonymous rsync daemons may be 600 (giving a 10 minute timeout).

refuse options

This parameter allows you to specify a space-separated list of rsync command-line options that will be refused by your rsync daemon. You may specify the full option name, its one-letter

abbreviation, or a wild-card string that matches multiple options. Beginning in 3.2.0, you can also negate a match term by starting it with a "!".

When an option is refused, the daemon prints an error message and exits.

For example, this would refuse **--checksum** (**-c**) and all the various delete options:

```
refuse options = c delete
```

The reason the above refuses all delete options is that the options imply **--delete**, and implied options are refused just like explicit options.

The use of a negated match allows you to fine-tune your refusals after a wild-card, such as this:

```
refuse options = delete-* !delete-during
```

Negated matching can also turn your list of refused options into a list of accepted options. To do this, begin the list with a "*" (to refuse all options) and then specify one or more negated matches to accept. For example:

```
refuse options = * !a !v !compress*
```

Don't worry that the "*" will refuse certain vital options such as **--dry-run**, **--server**, **--no-iconv**, **--protect-args**, etc. These important options are not matched by wild-card, so they must be overridden by their exact name. For instance, if you're forcing iconv transfers you could use something like this:

```
refuse options = * no-iconv !a !v
```

As an additional aid (beginning in 3.2.0), refusing (or "**!refusing**") the "a" or "archive" option also affects all the options that the **--archive** option implies (**-rdlptgoD**), but only if the option is matched explicitly (not using a wildcard). If you want to do something tricky, you can use "**archive***" to avoid this side-effect, but keep in mind that no normal rsync client ever sends the actual archive option to the server.

As an additional safety feature, the refusal of "delete" also refuses **remove-source-files** when the daemon is the sender; if you want the latter without the former, instead refuse "**delete-***" as that refuses all the delete modes without affecting **remove-source-files**. (Keep in mind that the client's **--delete** option typically results in **--delete-during**.)

When un-refusing delete options, you should either specify "**!delete***" (to accept all delete options) or specify a limited set that includes "delete", such as:

```
refuse options = * !a !delete !delete-during
```

... whereas this accepts any delete option except **--delete-after**:

```
refuse options = * !a !delete* delete-after
```

A note on refusing "compress" -- it is better to set the "dont compress" daemon parameter to "*" because that disables compression silently instead of returning an error that forces the client to remove the **-z** option.

If you are un-refusing the compress option, you probably want to match "**!compress***" so that you also accept the **--compress-level** option.

Note that the "copy-devices" & "write-devices" options are refused by default, but they can be explicitly accepted with "**!copy-devices**" and/or "**!write-devices**". The options "log-file" and "log-file-format" are forcibly refused and cannot be accepted.

Here are all the options that are not matched by wild-cards:

- o **--server**: Required for rsync to even work.
- o **--rsh**, **-e**: Required to convey compatibility flags to the server.
- o **--out-format**: This is required to convey output behavior to a remote receiver. While rsync passes the older alias **--log-format** for compatibility reasons, this options should

not be confused with **--log-file-format**.

- o **--sender**: Use "write only" parameter instead of refusing this.
- o **--dry-run, -n**: Who would want to disable this?
- o **--protect-args, -s**: This actually makes transfers safer.
- o **--from0, -0**: Makes it easier to accept/refuse **--files-from** without affecting this helpful modifier.
- o **--iconv**: This is auto-disabled based on "charset" parameter.
- o **--no-iconv**: Most transfers use this option.
- o **--checksum-seed**: Is a fairly rare, safe option.
- o **--write-devices**: Is non-wild but also auto-disabled.

dont compress

This parameter allows you to select filenames based on wildcard patterns that should not be compressed when pulling files from the daemon (no analogous parameter exists to govern the pushing of files to a daemon). Compression can be expensive in terms of CPU usage, so it is usually good to not try to compress files that won't compress well, such as already compressed files.

The "dont compress" parameter takes a space-separated list of case-insensitive wildcard patterns. Any source filename matching one of the patterns will be compressed as little as possible during the transfer. If the compression algorithm has an "off" level (such as zlib/zlibx) then no compression occurs for those files. Other algorithms have the level minimized to reduce the CPU usage as much as possible.

See the **--skip-compress** parameter in the **rsync(1)** manpage for the list of file suffixes that are not compressed by default. Specifying a value for the "dont compress" parameter changes the default when the daemon is the sender.

early exec, pre-xfer exec, post-xfer exec

You may specify a command to be run in the early stages of the connection, or right before and/or after the transfer. If the **early exec** or **pre-xfer exec** command returns an error code, the transfer is aborted before it begins. Any output from the **pre-xfer exec** command on stdout (up to several KB) will be displayed to the user when aborting, but is *not* displayed if the script returns success. The other programs cannot send any text to the user. All output except for the **pre-xfer exec** stdout goes to the corresponding daemon's stdout/stderr, which is typically discarded. See the **--no-detach** option for a way to see the daemon's output, which can assist with debugging.

Note that the **early exec** command runs before any part of the transfer request is known except for the module name. This helper script can be used to setup a disk mount or decrypt some data into a module dir, but you may need to use **lock file** and **max connections** to avoid concurrency issues. If the client rsync specified the **--early-input=FILE** option, it can send up to about 5K of data to the stdin of the early script. The stdin will otherwise be empty.

Note that the **post-xfer exec** command is still run even if one of the other scripts returns an error code. The **pre-xfer exec** command will *not* be run, however, if the **early exec** command fails.

The following environment variables will be set, though some are specific to the pre-xfer or the post-xfer environment:

- o **RSYNC_MODULE_NAME**: The name of the module being accessed.
- o **RSYNC_MODULE_PATH**: The path configured for the module.
- o **RSYNC_HOST_ADDR**: The accessing host's IP address.
- o **RSYNC_HOST_NAME**: The accessing host's name.
- o **RSYNC_USER_NAME**: The accessing user's name (empty if no user).

- o **RSYNC_PID**: A unique number for this transfer.
- o **RSYNC_REQUEST**: (pre-xfer only) The module/path info specified by the user. Note that the user can specify multiple source files, so the request can be something like "mod/path1 mod/path2", etc.
- o **RSYNC_ARG#**: (pre-xfer only) The pre-request arguments are set in these numbered values. RSYNC_ARG0 is always "rsyncd", followed by the options that were used in RSYNC_ARG1, and so on. There will be a value of "." indicating that the options are done and the path args are beginning -- these contain similar information to RSYNC_REQUEST, but with values separated and the module name stripped off.
- o **RSYNC_EXIT_STATUS**: (post-xfer only) the server side's exit value. This will be 0 for a successful run, a positive value for an error that the server generated, or a -1 if rsync failed to exit properly. Note that an error that occurs on the client side does not currently get sent to the server side, so this is not the final exit status for the whole transfer.
- o **RSYNC_RAW_STATUS**: (post-xfer only) the raw exit value from `waitpid()`.

Even though the commands can be associated with a particular module, they are run using the permissions of the user that started the daemon (not the module's uid/gid setting) without any chroot restrictions.

These settings honor 2 environment variables: use RSYNC_SHELL to set a shell to use when running the command (which otherwise uses your `system()` call's default shell), and use RSYNC_NO_XFER_EXEC to disable both options completely.

CONFIG DIRECTIVES

There are currently two config directives available that allow a config file to incorporate the contents of other files: **&include** and **&merge**. Both allow a reference to either a file or a directory. They differ in how segregated the file's contents are considered to be.

The **&include** directive treats each file as more distinct, with each one inheriting the defaults of the parent file, starting the parameter parsing as globals/defaults, and leaving the defaults unchanged for the parsing of the rest of the parent file.

The **&merge** directive, on the other hand, treats the file's contents as if it were simply inserted in place of the directive, and thus it can set parameters in a module started in another file, can affect the defaults for other files, etc.

When an **&include** or **&merge** directive refers to a directory, it will read in all the `*.conf` or `*.inc` files (respectively) that are contained inside that directory (without any recursive scanning), with the files sorted into alpha order. So, if you have a directory named "rsyncd.d" with the files "foo.conf", "bar.conf", and "baz.conf" inside it, this directive:

```
&include /path/rsyncd.d
```

would be the same as this set of directives:

```
&include /path/rsyncd.d/bar.conf
&include /path/rsyncd.d/baz.conf
&include /path/rsyncd.d/foo.conf
```

except that it adjusts as files are added and removed from the directory.

The advantage of the **&include** directive is that you can define one or more modules in a separate file without worrying about unintended side-effects between the self-contained module files.

The advantage of the **&merge** directive is that you can load config snippets that can be included into multiple module definitions, and you can also set global values that will affect connections (such as **motd file**), or globals that will affect other include files.

For example, this is a useful `/etc/rsyncd.conf` file:

```
port = 873
```

```
log file = /var/log/rsync.log
pid file = /var/lock/rsync.lock
```

```
&merge /etc/rsyncd.d
&include /etc/rsyncd.d
```

This would merge any **/etc/rsyncd.d/*.inc** files (for global values that should stay in effect), and then include any **/etc/rsyncd.d/*.conf** files (defining modules without any global-value cross-talk).

AUTHENTICATION STRENGTH

The authentication protocol used in rsync is a 128 bit MD4 based challenge response system. This is fairly weak protection, though (with at least one brute-force hash-finding algorithm publicly available), so if you want really top-quality security, then I recommend that you run rsync over ssh. (Yes, a future version of rsync will switch over to a stronger hashing method.)

Also note that the rsync daemon protocol does not currently provide any encryption of the data that is transferred over the connection. Only authentication is provided. Use ssh as the transport if you want encryption.

You can also make use of SSL/TLS encryption if you put rsync behind an SSL proxy.

SSL/TLS Daemon Setup

When setting up an rsync daemon for access via SSL/TLS, you will need to configure a proxy (such as haproxy or nginx) as the front-end that handles the encryption.

- o You should limit the access to the backend-rsyncd port to only allow the proxy to connect. If it is on the same host as the proxy, then configuring it to only listen on localhost is a good idea.
- o You should consider turning on the **proxy protocol** parameter if your proxy supports sending that information. The examples below assume that this is enabled.

An example haproxy setup is as follows:

```
frontend fe_rsync-ssl
    bind :::874 ssl crt /etc/letsencrypt/example.com/combined.pem
    mode tcp
    use_backend be_rsync

backend be_rsync
    mode tcp
    server local-rsync 127.0.0.1:873 check send-proxy
```

An example nginx proxy setup is as follows:

```
stream {
    server {
        listen 874 ssl;
        listen [::]:874 ssl;

        ssl_certificate /etc/letsencrypt/example.com/fullchain.pem;
        ssl_certificate_key /etc/letsencrypt/example.com/privkey.pem;

        proxy_pass localhost:873;
        proxy_protocol on; # Requires "proxy protocol = true"
        proxy_timeout 1m;
        proxy_connect_timeout 5s;
    }
}
```

EXAMPLES

A simple rsyncd.conf file that allow anonymous rsync to a ftp area at **/home/ftp** would be:

```
[ftp]
```

```
path = /home/ftp
comment = ftp export area
```

A more sophisticated example would be:

```
uid = nobody
gid = nobody
use chroot = yes
max connections = 4
syslog facility = local5
pid file = /var/run/rsyncd.pid
```

```
[ftp]
path = /var/ftp./pub
comment = whole ftp area (approx 6.1 GB)
```

```
[sambaftp]
path = /var/ftp./pub/samba
comment = Samba ftp area (approx 300 MB)
```

```
[rsyncftp]
path = /var/ftp./pub/rsync
comment = rsync ftp area (approx 6 MB)
```

```
[sambawww]
path = /public_html/samba
comment = Samba WWW pages (approx 240 MB)
```

```
[cvs]
path = /data/cvs
comment = CVS repository (requires authentication)
auth users = tridge, susan
secrets file = /etc/rsyncd.secrets
```

The /etc/rsyncd.secrets file would look something like this:

```
tridge:mypass
susan:herpass
```

FILES

/etc/rsyncd.conf or rsyncd.conf

rsync(1), rsync-ssl(1)

BUGS

Please report bugs! The rsync bug tracking system is online at <https://rsync.samba.org/>.

VERSION

This man page is current for version 3.2.3 of rsync.

CREDITS

rsync is distributed under the GNU General Public License. See the file COPYING for details.

The primary ftp site for rsync is <ftp://rsync.samba.org/pub/rsync>

A web site is available at <https://rsync.samba.org/>.

We would be delighted to hear from you if you like this program.

This program uses the zlib compression library written by Jean-loup Gailly and Mark Adler.

THANKS

Thanks to Warren Stanley for his original idea and patch for the rsync daemon. Thanks to Karsten Thygesen for his many suggestions and documentation!

AUTHOR

rsync was written by Andrew Tridgell and Paul Mackerras. Many people have later contributed to it.

Mailing lists for support and development are available at <https://lists.samba.org/>.

samba(7) - Linux man page

Name

samba - A Windows SMB/CIFS fileserver for UNIX

Synopsis

samba

Description

The Samba software suite is a collection of programs that implements the Server Message Block (commonly abbreviated as SMB) protocol for UNIX systems. This protocol is sometimes also referred to as the Common Internet File System (CIFS). For a more thorough description, see <http://www.ubiqx.org/cifs/>. Samba also implements the NetBIOS protocol in nmbd.

smbd(8)

The smbd daemon provides the file and print services to SMB clients, such as Windows 95/98, Windows NT, Windows for Workgroups or LanManager. The configuration file for this daemon is described in **smb.conf(5)**

nmbd(8)

The nmbd daemon provides NetBIOS nameservice and browsing support. The configuration file for this daemon is described in **smb.conf(5)**

smbclient(1)

The smbclient program implements a simple ftp-like client. This is useful for accessing SMB shares on other compatible servers (such as Windows NT), and can also be used to allow a UNIX box to print to a printer attached to any SMB server (such as a PC running Windows NT).

testparm(1)

The testparm utility is a simple syntax checker for Samba's **smb.conf(5)** configuration file.

smbstatus(1)

The smbstatus tool provides access to information about the current connections to smbd.

nmblookup(1)

The nmblookup tools allows NetBIOS name queries to be made from a UNIX host.

smbpasswd(8)

The smbpasswd command is a tool for changing LanMan and Windows NT password hashes on Samba and Windows NT servers.

smbcacls(1)

The smbcacls command is a tool to set ACL's on remote CIFS servers.

smbtree(1)

The smbtree command is a text-based network neighborhood tool.

smbtar(1)

The smbtar can make backups of data on CIFS/SMB servers.

smbspool(8)

smbspool is a helper utility for printing on printers connected to CIFS servers.

smbcontrol(1)

smbcontrol is a utility that can change the behaviour of running samba daemons.

rpcclient(1)

rpcclient is a utility that can be used to execute RPC commands on remote CIFS servers.

pdbedit(8)

The pdbedit command can be used to maintain the local user database on a samba server.

findsmb(1)

The findsmb command can be used to find SMB servers on the local network.

net(8)

The net command is supposed to work similar to the DOS/Windows NET.EXE command.

swat(8)

swat is a web-based interface to configuring smb.conf.

winbindd(8)

winbindd is a daemon that is used for integrating authentication and the user database into unix.

wbinfo(1)

wbinfo is a utility that retrieves and stores information related to winbind.

profiles(1)

profiles is a command-line utility that can be used to replace all occurrences of a certain SID with another SID.

log2pcap(1)

log2pcap is a utility for generating pcap trace files from Samba log files.

vfstest(1)

vfstest is a utility that can be used to test vfs modules.

ntlm_auth(1)

ntlm_auth is a helper-utility for external programs wanting to do NTLM-authentication.

smbcquotas(1)

smbcquotas is a tool that can set remote QUOTA's on server with NTFS 5.

Components

The Samba suite is made up of several components. Each component is described in a separate manual page. It is strongly recommended that you read the documentation that comes with Samba and the manual pages of those components that you use. If the manual

pages and documents aren't clear enough then please visit <http://devel.samba.org> for information on how to file a bug report or submit a patch.

If you require help, visit the Samba webpage at <http://www.samba.org/> and explore the many option available to you.

Availability

The Samba software suite is licensed under the GNU Public License(GPL). A copy of that license should have come with the package in the file COPYING. You are encouraged to distribute copies of the Samba suite, but please obey the terms of this license.

The latest version of the Samba suite can be obtained via anonymous ftp from samba.org in the directory pub/samba/. It is also available on several mirror sites worldwide.

You may also find useful information about Samba on the newsgroup comp.protocol.smb and the Samba mailing list. Details on how to join the mailing list are given in the README file that comes with Samba.

If you have access to a WWW viewer (such as Mozilla or Konqueror) then you will also find lots of useful information, including back issues of the Samba mailing list, at <http://lists.samba.org>.

Version

This man page is correct for version 3 of the Samba suite.

Contributions

If you wish to contribute to the Samba project, then I suggest you join the Samba mailing list at <http://lists.samba.org>.

If you have patches to submit, visit <http://devel.samba.org/> for information on how to do it properly. We prefer patches in diff -u format.

Contributors

Contributors to the project are now too numerous to mention here but all deserve the thanks of all Samba users. To see a full list, look at the change-log in the source package for the pre-CVS changes and at <http://cvs.samba.org/> for the contributors to Samba post-CVS. CVS is the Open Source source code control system used by the Samba Team to develop Samba. The project would have been unmanageable without it.

Author

The original Samba software and related utilities were created by Andrew Tridgell. Samba is now developed by the Samba Team as an Open Source project similar to the way the

Linux kernel is developed.

The original Samba man pages were written by Karl Auer. The man page sources were converted to YODL format (another excellent piece of Open Source software, available at <ftp://ftp.icce.rug.nl/pub/unix/>) and updated for the Samba 2.0 release by Jeremy Allison. The conversion to DocBook for Samba 2.2 was done by Gerald Carter. The conversion to DocBook XML 4.2 for Samba 3.0 was done by Alexander Bokovoy.

NAME

scp — OpenSSH secure file copy

SYNOPSIS

```
scp [ -346ABCOpqRrsTv ] [-c cipher] [-D sftp_server_path] [-F ssh_config]
[ -i identity_file ] [-J destination] [-l limit] [-o ssh_option] [-P port]
[ -S program] source ... target
```

DESCRIPTION

scp copies files between hosts on a network.

It uses **ssh(1)** for data transfer, and uses the same authentication and provides the same security as a login session.

scp will ask for passwords or passphrases if they are needed for authentication.

The *source* and *target* may be specified as a local pathname, a remote host with optional path in the form `[user@]host:[path]`, or a URI in the form `scp://[user@]host[:port][/path]`. Local file names can be made explicit using absolute or relative pathnames to avoid **scp** treating file names containing ‘`:`’ as host specifiers.

When copying between two remote hosts, if the URI format is used, a *port* cannot be specified on the *target* if the **-R** option is used.

The options are as follows:

- 3** Copies between two remote hosts are transferred through the local host. Without this option the data is copied directly between the two remote hosts. Note that, when using the original SCP protocol (the default), this option selects batch mode for the second host as **scp** cannot ask for passwords or passphrases for both hosts. This mode is the default.
- 4** Forces **scp** to use IPv4 addresses only.
- 6** Forces **scp** to use IPv6 addresses only.
- A** Allows forwarding of **ssh-agent(1)** to the remote system. The default is not to forward an authentication agent.
- B** Selects batch mode (prevents asking for passwords or passphrases).
- C** Compression enable. Passes the **-C** flag to **ssh(1)** to enable compression.
- c cipher**
Selects the cipher to use for encrypting the data transfer. This option is directly passed to **ssh(1)**.
- D sftp_server_path**
When using the SFTP protocol support via **-s**, connect directly to a local SFTP server program rather than a remote one via **ssh(1)**. This option may be useful in debugging the client and server.
- F ssh_config**
Specifies an alternative per-user configuration file for **ssh**. This option is directly passed to **ssh(1)**.
- i identity_file**
Selects the file from which the identity (private key) for public key authentication is read. This option is directly passed to **ssh(1)**.
- J destination**
Connect to the target host by first making an **scp** connection to the jump host described by *destination* and then establishing a TCP forwarding to the ultimate destination from there. Multiple jump hops may be specified separated by comma characters. This is a shortcut to specify a

ProxyJump configuration directive. This option is directly passed to **ssh(1)**.

-l *limit*

Limits the used bandwidth, specified in Kbit/s.

- o** Use the original SCP protocol for file transfers instead of the SFTP protocol. Forcing the use of the SCP protocol may be necessary for servers that do not implement SFTP, for backwards-compatibility for particular filename wildcard patterns and for expanding paths with a ‘~’ prefix for older SFTP servers. This mode is the default.

-o *ssh_option*

Can be used to pass options to **ssh** in the format used in **ssh_config(5)**. This is useful for specifying options for which there is no separate **scp** command-line flag. For full details of the options listed below, and their possible values, see **ssh_config(5)**.

-P *port*

Specifies the port to connect to on the remote host. Note that this option is written with a capital ‘P’, because **-p** is already reserved for preserving the times and mode bits of the file.

-p Preserves modification times, access times, and file mode bits from the source file.

-q Quiet mode: disables the progress meter as well as warning and diagnostic messages from **ssh(1)**.

-R Copies between two remote hosts are performed by connecting to the origin host and executing **scp** there. This requires that **scp** running on the origin host can authenticate to the destination host without requiring a password.

-r Recursively copy entire directories. Note that **scp** follows symbolic links encountered in the tree traversal.

-s *program*

Name of *program* to use for the encrypted connection. The program must understand **ssh(1)** options.

-s Use the SFTP protocol for transfers rather than the original scp protocol.

-T Disable strict filename checking. By default when copying files from a remote host to a local directory **scp** checks that the received filenames match those requested on the command-line to prevent the remote end from sending unexpected or unwanted files. Because of differences in how various operating systems and shells interpret filename wildcards, these checks may cause wanted files to be rejected. This option disables these checks at the expense of fully trusting that the server will not send unexpected filenames.

-v Verbose mode. Causes **scp** and **ssh(1)** to print debugging messages about their progress. This is helpful in debugging connection, authentication, and configuration problems.

EXIT STATUS

The **scp** utility exits 0 on success, and >0 if an error occurs.

CAVEATS

The original SCP protocol (used by default) requires execution of the remote user's shell to perform **glob(3)** pattern matching. This requires careful quoting of any characters that have special meaning to the remote shell, such as quote characters.

NAME

sed – stream editor for filtering and transforming text

SYNOPSIS

sed [*OPTION*]... {*script-only-if-no-other-script*} [*input-file*]...

DESCRIPTION

Sed is a stream editor. A stream editor is used to perform basic text transformations on an input stream (a file or input from a pipeline). While in some ways similar to an editor which permits scripted edits (such as *ed*), *sed* works by making only one pass over the input(s), and is consequently more efficient. But it is *sed*'s ability to filter text in a pipeline which particularly distinguishes it from other types of editors.

-n, --quiet, --silent

suppress automatic printing of pattern space

--debug

annotate program execution

-e script, --expression=script

add the script to the commands to be executed

-f script-file, --file=script-file

add the contents of script-file to the commands to be executed

--follow-symlinks

follow symlinks when processing in place

-i[SUFFIX], --in-place[=SUFFIX]

edit files in place (makes backup if SUFFIX supplied)

-l N, --line-length=N

specify the desired line-wrap length for the 'l' command

--posix

disable all GNU extensions.

-E, -r, --regexp-extended

use extended regular expressions in the script (for portability use POSIX -E).

-s, --separate

consider files as separate rather than as a single, continuous long stream.

--sandbox

operate in sandbox mode (disable e/r/w commands).

-u, --unbuffered

load minimal amounts of data from the input files and flush the output buffers more often

-z, --null-data

separate lines by NUL characters

--help

display this help and exit

--version

output version information and exit

If no **-e**, **--expression**, **-f**, or **--file** option is given, then the first non-option argument is taken as the *sed* script to interpret. All remaining arguments are names of input files; if no input files are specified, then the standard input is read.

GNU sed home page: <<https://www.gnu.org/software/sed/>>. General help using GNU software: <<https://www.gnu.org/gethelp/>>. E-mail bug reports to: <bug-sed@gnu.org>.

COMMAND SYNOPSIS

This is just a brief synopsis of *sed* commands to serve as a reminder to those who already know *sed*; other documentation (such as the texinfo document) must be consulted for fuller descriptions.

Zero-address “commands”

:label Label for **b** and **t** commands.

#comment

The comment extends until the next newline (or the end of a **-e** script fragment).

} The closing bracket of a { } block.

Zero- or One- address commands

= Print the current line number.

**a **

text Append *text*, which has each embedded newline preceded by a backslash.

**i **

text Insert *text*, which has each embedded newline preceded by a backslash.

q [exit-code]

Immediately quit the *sed* script without processing any more input, except that if auto-print is not disabled the current pattern space will be printed. The exit code argument is a GNU extension.

Q [exit-code]

Immediately quit the *sed* script without processing any more input. This is a GNU extension.

r filename

Append text read from *filename*.

R filename

Append a line read from *filename*. Each invocation of the command reads a line from the file. This is a GNU extension.

Commands which accept address ranges

{ Begin a block of commands (end with a **}**).

b label Branch to *label*; if *label* is omitted, branch to end of script.

**c **

text Replace the selected lines with *text*, which has each embedded newline preceded by a backslash.

d Delete pattern space. Start next cycle.

D If pattern space contains no newline, start a normal new cycle as if the **d** command was issued. Otherwise, delete text in the pattern space up to the first newline, and restart cycle with the resultant pattern space, without reading a new line of input.

h H Copy/append pattern space to hold space.

g G Copy/append hold space to pattern space.

l List out the current line in a “visually unambiguous” form.

l width List out the current line in a “visually unambiguous” form, breaking it at *width* characters. This is a GNU extension.

n N Read/append the next line of input into the pattern space.

p Print the current pattern space.

P Print up to the first embedded newline of the current pattern space.

s/regexp/replacement/

Attempt to match *regexp* against the pattern space. If successful, replace that portion matched with *replacement*. The *replacement* may contain the special character **&** to refer to that portion of the pattern space which matched, and the special escapes **\1** through **\9** to refer to the corresponding matching sub-expressions in the *regexp*.

t label If a **s///** has done a successful substitution since the last input line was read and since the last **t** or **T** command, then branch to *label*; if *label* is omitted, branch to end of script.

T label If no **s///** has done a successful substitution since the last input line was read and since the last **t** or **T** command, then branch to *label*; if *label* is omitted, branch to end of script. This is a GNU extension.

w filename

Write the current pattern space to *filename*.

W filename

Write the first line of the current pattern space to *filename*. This is a GNU extension.

x Exchange the contents of the hold and pattern spaces.

y/source/dest/

Transliterate the characters in the pattern space which appear in *source* to the corresponding character in *dest*.

Addresses

Sed commands can be given with no addresses, in which case the command will be executed for all input lines; with one address, in which case the command will only be executed for input lines which match that address; or with two addresses, in which case the command will be executed for all input lines which match the inclusive range of lines starting from the first address and continuing to the second address. Three things to note about address ranges: the syntax is *addr1,addr2* (i.e., the addresses are separated by a comma); the line which *addr1* matched will always be accepted, even if *addr2* selects an earlier line; and if *addr2* is a *regexp*, it will not be tested against the line that *addr1* matched.

After the address (or address-range), and before the command, a **!** may be inserted, which specifies that the command shall only be executed if the address (or address-range) does **not** match.

The following address types are supported:

number

Match only the specified line *number* (which increments cumulatively across files, unless the **-s** option is specified on the command line).

first~step

Match every *step*'th line starting with line *first*. For example, “*sed -n 1~2p*” will print all the odd-numbered lines in the input stream, and the address *2~5* will match every fifth line, starting with the second. *first* can be zero; in this case, *sed* operates as if it were equal to *step*. (This is an extension.)

\$ Match the last line.

/regexp/

Match lines matching the regular expression *regexp*. Matching is performed on the current pattern space, which can be modified with commands such as “**s///**”.

\cregexp\c

Match lines matching the regular expression *regexp*. The **c** may be an **y** character.

GNU *sed* also supports some special 2-address forms:

0,addr2

Start out in "matched first address" state, until *addr2* is found. This is similar to *1,addr2*, except that if *addr2* matches the very first line of input the *0,addr2* form will be at the end of its range, whereas the *1,addr2* form will still be at the beginning of its range. This works only when *addr2*

is a regular expression.

addr1,+N

Will match *addr1* and the *N* lines following *addr1*.

addr1,~N

Will match *addr1* and the lines following *addr1* until the next line whose input line number is a multiple of *N*.

REGULAR EXPRESSIONS

POSIX.2 BREs *should* be supported, but they aren't completely because of performance problems. The **\n** sequence in a regular expression matches the newline character, and similarly for **\a**, **\t**, and other sequences. The **-E** option switches to using extended regular expressions instead; it has been supported for years by GNU sed, and is now included in POSIX.

BUGS

E-mail bug reports to bug-sed@gnu.org. Also, please include the output of “sed --version” in the body of your report if at all possible.

NAME

service – run a System V init script

SYNOPSIS

service *SCRIPT COMMAND [OPTIONS]*

service --status-all

service --help | -h | --version

DESCRIPTION

service runs a System V init script or systemd unit in as predictable an environment as possible, removing most environment variables and with the current working directory set to */*.

The *SCRIPT* parameter specifies a System V init script, located in */etc/init.d/SCRIPT*, or the name of a systemd unit. The existence of a systemd unit of the same name as a script in */etc/init.d* will cause the unit to take precedence over the init.d script. The supported values of *COMMAND* depend on the invoked script. **service** passes *COMMAND* and *OPTIONS* to the init script unmodified. For systemd units, start, stop, status, and reload are passed through to their systemctl/initctl equivalents.

All scripts should support at least the **start** and **stop** commands. As a special case, if *COMMAND* is **--full-restart**, the script is run twice, first with the **stop** command, then with the **start** command. Note, that unlike **update-rc.d(8)**, **service** does not check */usr/sbin/policy-rc.d*.

service --status-all runs all init scripts, in alphabetical order, with the **status** command. The status is [+] for running services, [-] for stopped services and [?] for services without **astatus** command. This option only calls status for sysvinit jobs.

EXIT CODES

service calls the init script and returns the status returned by it.

FILES

/etc/init.d

The directory containing System V init scripts.

{lib,run,etc}/systemd/system

The directories containing systemd units.

ENVIRONMENT

LANG, LANGUAGE, LC_CTYPE, LC_NUMERIC, LC_TIME, LC_COLLATE, LC_MONETARY, LC_MESSAGES, LC_PAPER, LC_NAME, LC_ADDRESS, LC_TELEPHONE, LC_MEASUREMENT, LC_IDENTIFICATION, LC_ALL, TERM, PATH

The only environment variables passed to the init scripts.

SERVICE(8)

System Manager's Manual

SERVICE(8)

NAME

services – Internet network services list

DESCRIPTION

services is a plain ASCII file providing a mapping between human-friendly textual names for internet services, and their underlying assigned port numbers and protocol types. Every networking program should look into this file to get the port number (and protocol) for its service. The C library routines **getservent(3)**, **getservbyname(3)**, **getservbyport(3)**, **setservent(3)**, and **endservent(3)** support querying this file from programs.

Port numbers are assigned by the IANA (Internet Assigned Numbers Authority), and their current policy is to assign both TCP and UDP protocols when assigning a port number. Therefore, most entries will have two entries, even for TCP-only services.

Port numbers below 1024 (so-called "low numbered" ports) can be bound to only by root (see **bind(2)**, **tcp(7)**, and **udp(7)**). This is so clients connecting to low numbered ports can trust that the service running on the port is the standard implementation, and not a rogue service run by a user of the machine. Well-known port numbers specified by the IANA are normally located in this root-only space.

The presence of an entry for a service in the **services** file does not necessarily mean that the service is currently running on the machine. See **inetd.conf(5)** for the configuration of Internet services offered. Note that not all networking services are started by **inetd(8)**, and so won't appear in **inetd.conf(5)**. In particular, news (NNTP) and mail (SMTP) servers are often initialized from the system boot scripts.

The location of the **services** file is defined by **_PATH_SERVICES** in **<netdb.h>**. This is usually set to **/etc/services**.

Each line describes one service, and is of the form:

```
service-name port/protocol [aliases ...]
```

where:

service-name

is the friendly name the service is known by and looked up under. It is case sensitive. Often, the client program is named after the *service-name*.

port is the port number (in decimal) to use for this service.

protocol

is the type of protocol to be used. This field should match an entry in the **protocols(5)** file. Typical values include **tcp** and **udp**.

aliases is an optional space or tab separated list of other names for this service. Again, the names are case sensitive.

Either spaces or tabs may be used to separate the fields.

Comments are started by the hash sign (#) and continue until the end of the line. Blank lines are skipped.

The *service-name* should begin in the first column of the file, since leading spaces are not stripped. *service-names* can be any printable characters excluding space and tab. However, a conservative choice of characters should be used to minimize compatibility problems. For example, a–z, 0–9, and hyphen (–) would seem a sensible choice.

Lines not matching this format should not be present in the file. (Currently, they are silently skipped by **getservent(3)**, **getservbyname(3)**, and **getservbyport(3)**. However, this behavior should not be relied on.)

This file might be distributed over a network using a network-wide naming service like Yellow Pages/NIS or BIND/Hesiod.

A sample **services** file might look like this:

netstat	15/tcp	
qotd	17/tcp	quote
msp	18/tcp	# message send protocol

```
msp          18/udp      # message send protocol
chargen     19/tcp       ttytst source
chargen     19/udp      ttytst source
ftp          21/tcp
# 22 - unassigned
telnet      23/tcp
```

FILES

/etc/services

NAME

setfacl – set file access control lists

SYNOPSIS

```
setfacl [-bkndRLPvh] [{-m|-x} acl_spec] [{-M|-X} acl_file] file ...  
setfacl --restore={file|-}
```

DESCRIPTION

This utility sets Access Control Lists (ACLs) of files and directories. On the command line, a sequence of commands is followed by a sequence of files (which in turn can be followed by another sequence of commands, ...).

The *-m* and *-x* options expect an ACL on the command line. Multiple ACL entries are separated by comma characters (','). The *-M* and *-X* options read an ACL from a file or from standard input. The ACL entry format is described in Section ACL ENTRIES.

The *--set* and *--set-file* options set the ACL of a file or a directory. The previous ACL is replaced. ACL entries for this operation must include permissions.

The *-m* (*--modify*) and *-M* (*--modify-file*) options modify the ACL of a file or directory. ACL entries for this operation must include permissions.

The *-x* (*--remove*) and *-X* (*--remove-file*) options remove ACL entries. It is not an error to remove an entry which does not exist. Only ACL entries without the *perms* field are accepted as parameters, unless *POSIXLY_CORRECT* is defined.

When reading from files using the *-M* and *-X* options, *setf acl* accepts the output *getfacl* produces. There is at most one ACL entry per line. After a Pound sign ('#'), everything up to the end of the line is treated as a comment.

If *setfacl* is used on a file system which does not support ACLs, *setfacl* operates on the file mode permission bits. If the ACL does not fit completely in the permission bits, *setfacl* modifies the file mode permission bits to reflect the ACL as closely as possible, writes an error message to standard error, and returns with an exit status greater than 0.

PERMISSIONS

The file owner and processes capable of *CAP_FOWNER* are granted the right to modify ACLs of a file. This is analogous to the permissions required for accessing the file mode. (On current Linux systems, root is the only user with the *CAP_FOWNER* capability.)

OPTIONS

- b, --remove-all*
Remove all extended ACL entries. The base ACL entries of the owner, group and others are retained.
- k, --remove-default*
Remove the Default ACL. If no Default ACL exists, no warnings are issued.
- n, --no-mask*
Do not recalculate the effective rights mask. The default behavior of *setfacl* is to recalculate the ACL mask entry, unless a mask entry was explicitly given. The mask entry is set to the union of all permissions of the owning group, and all named user and group entries. (These are exactly the entries affected by the mask entry).

--mask

Do recalculate the effective rights mask, even if an ACL mask entry was explicitly given. (See the **-n** option.)

-d, --default

All operations apply to the Default ACL. Regular ACL entries in the input set are promoted to Default ACL entries. Default ACL entries in the input set are discarded. (A warning is issued if that happens).

--restore={file}/-

Restore a permission backup created by ‘getfacl -R’ or similar. All permissions of a complete directory subtree are restored using this mechanism. If the input contains owner comments or group comments, setfacl attempts to restore the owner and owning group. If the input contains flags comments (which define the setuid, setgid, and sticky bits), setfacl sets those three bits accordingly; otherwise, it clears them. This option cannot be mixed with other options except ‘--test’. If the file specified is ‘-’, then it will be read from standard input.

--test

Test mode. Instead of changing the ACLs of any files, the resulting ACLs are listed.

-R, --recursive

Apply operations to all files and directories recursively. This option cannot be mixed with ‘--restore’.

-L, --logical

Logical walk, follow symbolic links to directories. The default behavior is to follow symbolic link arguments, and skip symbolic links encountered in subdirectories. Only effective in combination with **-R**. This option cannot be mixed with ‘--restore’.

-P, --physical

Physical walk, do not follow symbolic links to directories. This also skips symbolic link arguments. Only effective in combination with **-R**. This option cannot be mixed with ‘--restore’.

-v, --version

Print the version of setfacl and exit.

-h, --help

Print help explaining the command line options.

-- End of command line options. All remaining parameters are interpreted as file names, even if they start with a dash.

– If the file name parameter is a single dash, setfacl reads a list of files from standard input.

ACL ENTRIES

The setfacl utility recognizes the following ACL entry formats (blanks inserted for clarity):

[d[efault]:] [u[ser]:]uid [:perms]

Permissions of a named user. Permissions of the file owner if *uid* is empty.

[d[efault]:] g[roup]:gid [:perms]

Permissions of a named group. Permissions of the owning group if *gid* is empty.

[d[efault]:] m[ask][:] [:perms]

Effective rights mask

[d[efault]:] o[ther][:] [:perms]

Permissions of others.

Whitespace between delimiter characters and non-delimiter characters is ignored.

Proper ACL entries including permissions are used in modify and set operations. (options **-m**, **-M**, **--set** and **--set-file**). Entries without the *perms* field are used for *deletion* of entries (options **-x** and **-X**).

For *uid* and *gid* you can specify either a name or a number. Character literals may be specified with a

backslash followed by the 3-digit octal digits corresponding to the ASCII code for the character (e.g., \101 for 'A'). If the name contains a literal backslash followed by 3 digits, the backslash must be escaped (i.e., \\).

The *perms* field is a combination of characters that indicate the read (*r*), write (*w*), execute (*x*) permissions. Dash characters in the *perms* field (–) are ignored. The character *X* stands for the execute permission if the file is a directory or already has execute permission for some user. Alternatively, the *perms* field can define the permissions numerically, as a bit-wise combination of read (4), write (2), and execute (1). Zero *perms* fields or *perms* fields that only consist of dashes indicate no permissions.

AUTOMATICALLY CREATED ENTRIES

Initially, files and directories contain only the three base ACL entries for the owner, the group, and others. There are some rules that need to be satisfied in order for an ACL to be valid:

- * The three base entries cannot be removed. There must be exactly one entry of each of these base entry types.
- * Whenever an ACL contains named user entries or named group objects, it must also contain an effective rights mask.
- * Whenever an ACL contains any Default ACL entries, the three Default ACL base entries (default owner, default group, and default others) must also exist.
- * Whenever a Default ACL contains named user entries or named group objects, it must also contain a default effective rights mask.

To help the user ensure these rules, setfac1 creates entries from existing entries under the following conditions:

- * If an ACL contains named user or named group entries, and no mask entry exists, a mask entry containing the same permissions as the group entry is created. Unless the *-n* option is given, the permissions of the mask entry are further adjusted to include the union of all permissions affected by the mask entry. (See the *-n* option description).
- * If a Default ACL entry is created, and the Default ACL contains no owner, owning group, or others entry, a copy of the ACL owner, owning group, or others entry is added to the Default ACL.
- * If a Default ACL contains named user entries or named group entries, and no mask entry exists, a mask entry containing the same permissions as the default Default ACL's group entry is added. Unless the *-n* option is given, the permissions of the mask entry are further adjusted to include the union of all permissions affected by the mask entry. (See the *-n* option description).

EXAMPLES

Granting an additional user read access

```
setfac1 -m u:lisa:r file
```

Revoking write access from all groups and all named users (using the effective rights mask)

```
setfac1 -m m:::rx file
```

Removing a named group entry from a file's ACL

```
setfac1 -x g:staff file
```

Copying the ACL of one file to another

```
getfac1 file1 | setfac1 --set-file=- file2
```

Copying the access ACL into the Default ACL

```
getfac1 --access dir | setfac1 -d -M- dir
```

CONFORMANCE TO POSIX 1003.1e DRAFT STANDARD 17

If the environment variable `POSIXLY_CORRECT` is defined, the default behavior of `setfac1` changes as follows: All non-standard options are disabled. The "default:" prefix is disabled. The `-x` and `-X` options also accept permission fields (and ignore them).

NAME

setfattr – set extended attributes of filesystem objects

SYNOPSIS

```
setfattr [-h] -n name [-v value] pathname...
setfattr [-h] -x name pathname...
setfattr [-h] --restore=file
```

DESCRIPTION

The **setfattr** command associates a new *value* with an extended attribute *name* for each specified file.

OPTIONS

-n *name*, **--name**=*name*

Specifies the name of the extended attribute to set.

-v *value*, **--value**=*value*

Specifies the new value of the extended attribute. There are three methods available for encoding the value. If the given string is enclosed in double quotes, the inner string is treated as text. In that case, backslashes and double quotes have special meanings and need to be escaped by a preceding backslash. Any control characters can be encoded as a backslash followed by three digits as its ASCII code in octal. If the given string begins with 0x or 0X, it expresses a hexadecimal number. If the given string begins with 0s or 0S, base64 encoding is expected. Also see the **--encoding** option of **getattr(1)**.

-x *name*, **--remove**=*name*

Remove the named extended attribute entirely.

-h, **--no-dereference**

Do not follow symlinks. If *pathname* is a symbolic link, it is not followed, but is instead itself the inode being modified.

--restore=*file*

Restores extended attributes from file. The file must be in the format generated by the **getattr** command with the **--dump** option. If a dash (–) is given as the file name, **setfattr** reads from standard input.

--raw

Do not decode the attribute value. Can be used to set values obtained with **getattr --only-values**.

--version

Print the version of **setfattr** and exit.

--help

Print help explaining the command line options.

-- End of command line options. All remaining parameters are interpreted as file names, even if they start with a dash character.

EXAMPLES

Add extended attribute to user namespace:

```
$ setfattr -n user.foo -v bar file.txt
```

To add md5sum of the file as an extended attribute:

```
# setfattr -n trusted.md5sum -v d41d8cd98f00b204e00998ecf8427e file.txt
```

NAME

`gethostname`, `sethostname` – get/set hostname

LIBRARY

Standard C library (`libc`, `-lc`)

SYNOPSIS

```
#include <unistd.h>
int gethostname(char *name, size_t len);
int sethostname(const char *name, size_t len);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros**(7)):

```
gethostname():
_XOPEN_SOURCE >= 500 || _POSIX_C_SOURCE >= 200112L
|| /* glibc 2.19 and earlier */ _BSD_SOURCE

sethostname():
Since glibc 2.21:
_DEFAULT_SOURCE
In glibc 2.19 and 2.20:
_DEFAULT_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
Up to and including glibc 2.19:
_BSD_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
```

DESCRIPTION

These system calls are used to access or to change the system hostname. More precisely, they operate on the hostname associated with the calling process's UTS namespace.

sethostname() sets the hostname to the value given in the character array *name*. The *len* argument specifies the number of bytes in *name*. (Thus, *name* does not require a terminating null byte.)

gethostname() returns the null-terminated hostname in the character array *name*, which has a length of *len* bytes. If the null-terminated hostname is too large to fit, then the name is truncated, and no error is returned (but see NOTES below). POSIX.1 says that if such truncation occurs, then it is unspecified whether the returned buffer includes a terminating null byte.

RETURN VALUE

On success, zero is returned. On error, `-1` is returned, and *errno* is set to indicate the error.

ERRORS**FAULT**

name is an invalid address.

EINVAL

len is negative or, for **sethostname**(*len*), *len* is larger than the maximum allowed size.

ENAMETOOLONG

(glibc **gethostname**(*len*) *len* is smaller than the actual size. (Before glibc 2.1, glibc uses **EINVAL** for this case.)

EPERM

For **sethostname**(*len*), the caller did not have the **CAP_SYS_ADMIN** capability in the user namespace associated with its UTS namespace (see **namespaces**(7)).

STANDARDS

SVr4, 4.4BSD (these interfaces first appeared in 4.2BSD). POSIX.1-2001 and POSIX.1-2008 specify **gethostname**(*len*) but not **sethostname**(*len*).

NOTES

SUSv2 guarantees that "Host names are limited to 255 bytes". POSIX.1 guarantees that "Host names (not including the terminating null byte) are limited to **HOST_NAME_MAX** bytes". On Linux, **HOST_NAME_MAX** is defined with the value 64, which has been the limit since Linux 1.0 (earlier

kernels imposed a limit of 8 bytes).

C library/kernel differences

The GNU C library does not employ the **gethostname()** system call; instead, it implements **gethostname()** as a library function that calls **uname(2)** and copies up to *len* bytes from the returned *nodename* field into *name*. Having performed the copy, the function then checks if the length of the *nodename* was greater than or equal to *len*, and if it is, then the function returns -1 with *errno* set to **ENAMETOOLONG**; in this case, a terminating null byte is not included in the returned *name*.

Versions of glibc before glibc 2.2 handle the case where the length of the *nodename* was greater than or equal to *len* differently: nothing is copied into *name* and the function returns -1 with *errno* set to **ENAME-TOOLONG**.

NAME

`setxattr`, `lsetxattr`, `fsetxattr` – set an extended attribute value

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/xattr.h>

int setxattr(const char *path, const char *name,
             const void value[.size], size_t size, int flags);
int lsetxattr(const char *path, const char *name,
              const void value[.size], size_t size, int flags);
int fsetxattr(int fd, const char *name,
              const void value[.size], size_t size, int flags);
```

DESCRIPTION

Extended attributes are *name:value* pairs associated with inodes (files, directories, symbolic links, etc.). They are extensions to the normal attributes which are associated with all inodes in the system (i.e., the `stat(2)` data). A complete overview of extended attributes concepts can be found in **xattr(7)**.

setxattr() sets the *value* of the extended attribute identified by *name* and associated with the given *path* in the filesystem. The *size* argument specifies the size (in bytes) of *value*; a zero-length value is permitted.

lsetxattr() is identical to **setxattr()**, except in the case of a symbolic link, where the extended attribute is set on the link itself, not the file that it refers to.

fsetxattr() is identical to **setxattr()**, only the extended attribute is set on the open file referred to by *fd* (as returned by `open(2)`) in place of *path*.

An extended attribute name is a null-terminated string. The *name* includes a namespace prefix; there may be several, disjoint namespaces associated with an individual inode. The *value* of an extended attribute is a chunk of arbitrary textual or binary data of specified length.

By default (i.e., *flags* is zero), the extended attribute will be created if it does not exist, or the value will be replaced if the attribute already exists. To modify these semantics, one of the following values can be specified in *flags*:

XATTR_CREATE

Perform a pure create, which fails if the named attribute exists already.

XATTR_REPLACE

Perform a pure replace operation, which fails if the named attribute does not already exist.

RETURN VALUE

On success, zero is returned. On failure, -1 is returned and *errno* is set to indicate the error.

ERRORS**EDQUOT**

Disk quota limits meant that there is insufficient space remaining to store the extended attribute.

EEXIST

XATTR_CREATE was specified, and the attribute exists already.

ENODATA

XATTR_REPLACE was specified, and the attribute does not exist.

ENOSPC

There is insufficient space remaining to store the extended attribute.

ENOTSUP

The namespace prefix of *name* is not valid.

ENOTSUP

Extended attributes are not supported by the filesystem, or are disabled,

EPERM

The file is marked immutable or append-only. (See [ioctl_iflags\(2\)](#).)

In addition, the errors documented in [stat\(2\)](#) can also occur.

ERANGE

The size of *name* or *value* exceeds a filesystem-specific limit.

VERSIONS

These system calls have been available since Linux 2.4; glibc support is provided since glibc 2.3.

STANDARDS

These system calls are Linux-specific.

NAME

sfdisk – display or manipulate a disk partition table

SYNOPSIS

sfdisk [options] *device* [-N *partition-number*]

sfdisk [options] *command*

DESCRIPTION

sfdisk is a script-oriented tool for partitioning any block device. It runs in interactive mode if executed on a terminal (stdin refers to a terminal).

Since version 2.26 **sfdisk** supports MBR (DOS), GPT, SUN and SGI disk labels, but no longer provides any functionality for CHS (Cylinder–Head–Sector) addressing. CHS has never been important for Linux, and this addressing concept does not make any sense for new devices.

sfdisk protects the first disk sector when create a new disk label. The option **--wipe always** disables this protection. Note that **fdisk(8)** and **cfdisk(8)** completely erase this area by default.

sfdisk (since version 2.26) **aligns the start and end of partitions** to block-device I/O limits when relative sizes are specified, when the default values are used or when multiplicative suffixes (e.g., MiB) are used for sizes. It is possible that partition size will be optimized (reduced or enlarged) due to alignment if the start offset is specified exactly in sectors and partition size relative or by multiplicative suffixes.

The recommended way is not to specify start offsets at all and specify partition size in MiB, GiB (or so). In this case **sfdisk** aligns all partitions to block-device I/O limits (or when I/O limits are too small then to megabyte boundary to keep disk layout portable). If this default behaviour is unwanted (usually for very small partitions) then specify offsets and sizes in sectors. In this case **sfdisk** entirely follows specified numbers without any optimization.

sfdisk does not create the standard system partitions for SGI and SUN disk labels like **fdisk(8)** does. It is necessary to explicitly create all partitions including whole-disk system partitions.

sfdisk uses **BLKRRPART** (reread partition table) ioctl to make sure that the device is not used by system or other tools (see also **--no-reread**). It's possible that this feature or another **sfdisk** activity races with **systemd-udevd(8)**. The recommended way how to avoid possible collisions is to use **--lock** option. The exclusive lock will cause **systemd-udevd** to skip the event handling on the device.

The **sfdisk** prompt is only a hint for users and a displayed partition number does not mean that the same partition table entry will be created (if **-N** not specified), especially for tables with gaps.

COMMANDS

The commands are mutually exclusive.

[**-N** *partition-number*] *device*

The default **sfdisk** command is to read the specification for the desired partitioning of *device* from standard input, and then create a partition table according to the specification. See below for the description of the input format. If standard input is a terminal, then **sfdisk** starts an interactive session.

If the option **-N** is specified, then the changes are applied to the partition addressed by *partition-number*. The unspecified fields of the partition are not modified.

Note that it's possible to address an unused partition with **-N**. For example, an MBR always contains 4 partitions, but the number of used partitions may be smaller. In this case **sfdisk** follows the default values from the partition table and does not use built-in defaults for the unused partition given with **-N**. See also **--append**.

-A, --activate device [partition-number...]

Switch on the bootable flag for the specified partitions and switch off the bootable flag on all unspecified partitions. The special placeholder '-' may be used instead of the partition numbers to switch off the bootable flag on all partitions.

The activation command is supported for MBR and PMBR only. If a GPT label is detected, then **sfdisk** prints warning and automatically enters PMBR.

If no *partition-number* is specified, then list the partitions with an enabled flag.

--backup-pt-sectors device

Back up the current partition table sectors in binary format and exit. See the **BACKING UP THE PARTITION TABLE** section.

--delete device [partition-number...]

Delete all or the specified partitions.

-d, --dump device

Dump the partitions of a device in a format that is usable as input to **sfdisk**. See the **BACKING UP THE PARTITION TABLE** section.

-g, --show-geometry [device...]

List the geometry of all or the specified devices. For backward compatibility the deprecated option **--show-pt-geometry** have the same meaning as this one.

-J, --json device

Dump the partitions of a device in JSON format. Note that **sfdisk** is not able to use JSON as input format.

-l, --list [device...]

List the partitions of all or the specified devices. This command can be used together with **--verify**.

-F, --list-free [device...]

List the free unpartitioned areas on all or the specified devices.

--part-attrs device partition-number [attributes]

Change the GPT partition attribute bits. If *attributes* is not specified, then print the current partition settings. The *attributes* argument is a comma- or space-delimited list of bits numbers or bit names. For example, the string "RequiredPartition,50,51" sets three bits. The currently supported attribute bits are:

Bit 0 (RequiredPartition)

If this bit is set, the partition is required for the platform to function. The creator of the partition indicates that deletion or modification of the contents can result in loss of platform features or failure for the platform to boot or operate. The system cannot function normally if this partition is removed, and it should be considered part of the hardware of the system.

Bit 1 (NoBlockIOProtocol)

EFI firmware should ignore the content of the partition and not try to read from it.

Bit 2 (LegacyBIOSBootable)

The partition may be bootable by legacy BIOS firmware.

Bits 3–47

Undefined and must be zero. Reserved for expansion by future versions of the UEFI specification.

Bits 48–63

Reserved for GUID specific use. The use of these bits will vary depending on the partition type. For example Microsoft uses bit 60 to indicate read-only, 61 for shadow copy of another partition, 62 for hidden partitions and 63 to disable automount.

--part-label *device partition-number [label]*

Change the GPT partition name (label). If *label* is not specified, then print the current partition label.

--part-type *device partition-number [type]*

Change the partition type. If *type* is not specified, then print the current partition type.

The *type* argument is hexadecimal for MBR, GUID for GPT, type alias (e.g. "linux") or type shortcut (e.g. 'L'). For backward compatibility the options **-c** and **--id** have the same meaning as this one.

--part-uuid *device partition-number [uuid]*

Change the GPT partition UUID. If *uuid* is not specified, then print the current partition UUID.

--disk-id *device [id]*

Change the disk identifier. If *id* is not specified, then print the current identifier. The identifier is UUID for GPT or unsigned integer for MBR.

-r, --reorder *device*

Renumber the partitions, ordering them by their start offset.

-s, --show-size [*device...*]

List the sizes of all or the specified devices in units of 1024 byte size. This command is DEPRECATED in favour of **blockdev(8)**.

-T, --list-types

Print all supported types for the current disk label or the label specified by **--label**.

-V, --verify [*device...*]

Test whether the partition table and partitions seem correct.

--relocate *oper device*

Relocate partition table header. This command is currently supported for GPT header only. The argument *oper* can be:

gpt-bak-std

Move GPT backup header to the standard location at the end of the device.

gpt-bak-mini

Move GPT backup header behind the last partition. Note that UEFI standard requires the backup header at the end of the device and partitioning tools can automatically relocate the header to follow the standard.

OPTIONS

-a, --append

Don't create a new partition table, but only append the specified partitions.

Note that unused partition maybe be re-used in this case although it is not the last partition in the partition table. See also **-N** to specify entry in the partition table.

-b, --backup

Back up the current partition table sectors before starting the partitioning. The default backup file name is `/sfdisk-<device>-<offset>.bak`; to use another name see option **-O, --backup-file**. See section **BACKING UP THE PARTITION TABLE** for more details.

--color[=when]

Colorize the output. The optional argument *when* can be **auto**, **never** or **always**. If the *when* argument is omitted, it defaults to **auto**. The colors can be disabled; for the current built-in default see the **--help** output. See also the **COLORS** section.

-f, --force

Disable all consistency checking.

--Linux

Deprecated and ignored option. Partitioning that is compatible with Linux (and other modern operating systems) is the default.

--lock[=mode]

Use exclusive BSD lock for device or file it operates. The optional argument *mode* can be **yes**, **no** (or 1 and 0) or **nonblock**. If the *mode* argument is omitted, it defaults to **yes**. This option overwrites environment variable `$LOCK_BLOCK_DEVICE`. The default is not to use any lock at all, but it's recommended to avoid collisions with **systemd-udevd(8)** or other tools.

-n, --no-act

Do everything except writing to the device.

--no-reread

Do not check through the re-read-partition-table ioctl whether the device is in use.

--no-tell-kernel

Don't tell the kernel about partition changes. This option is recommended together with **--no-reread** to modify a partition on used disk. The modified partition should not be used (e.g., mounted).

-O, --backup-file path

Override the default backup file name. Note that the device name and offset are always appended to the file name.

--move-data[=path]

Move data after partition relocation, for example when moving the beginning of a partition to another place on the disk. The size of the partition has to remain the same, the new and old location may overlap. This option requires option **-N** in order to be processed on one specific partition only.

The optional *path* specifies log file name. The log file contains information about all read/write operations on the partition data. The word "@default" as a *path* forces **sfdisk** to use `/sfdisk-<devname>.move` for the log. The log is optional since v2.35.

Note that this operation is risky and not atomic. **Don't forget to backup your data!**

See also **--move-use-fsync**.

In the example below, the first command creates a 100MiB free area before the first partition and moves the data it contains (e.g., a filesystem), the next command creates a new partition from the free space (at offset 2048), and the last command reorders partitions to match disk order (the original sdc1 will become sdc2).

```
echo '+100M,' | sfdisk --move-data /dev/sdc -N 1 echo '2048,' | sfdisk /dev/sdc --append sfdisk /dev/sdc --reorder
```

--move-use-fsync

Use the **fsync**(2) system call after each write when moving data to a new location by **--move-data**.

-o, --output list

Specify which output columns to print. Use **--help** to get a list of all supported columns.

The default list of columns may be extended if *list* is specified in the format *+list* (e.g., **-o +UUID**).

-q, --quiet

Suppress extra info messages.

-u, --unit S

Deprecated option. Only the sector unit is supported. This option is not supported when using the **--show-size** command.

-X, --label type

Specify the disk label type (e.g., **dos**, **gpt**, ...). If this option is not given, then **sfdisk** defaults to the existing label, but if there is no label on the device yet, then the type defaults to **dos**. The default or the current label may be overwritten by the "label: <name>" script header line. The option **--label** does not force **sfdisk** to create empty disk label (see the **EMPTY DISK LABEL** section below).

-Y, --label-nested type

Force editing of a nested disk label. The primary disk label has to exist already. This option allows editing for example a hybrid/protective MBR on devices with GPT.

-w, --wipe when

Wipe filesystem, RAID and partition-table signatures from the device, in order to avoid possible collisions. The argument *when* can be **auto**, **never** or **always**. When this option is not given, the default is **auto**, in which case signatures are wiped only when in interactive mode; except the old partition-table signatures which are always wiped before create a new partition-table if the argument *when* is not **never**. The **auto** mode also does not wipe the first sector (boot sector), it is necessary to use the **always** mode to wipe this area. In all cases detected signatures are reported by warning messages before a new partition table is created. See also the **wipefs(8)** command.

-W, --wipe-partitions when

Wipe filesystem, RAID and partition-table signatures from a newly created partition, in order to avoid possible collisions. The argument *when* can be **auto**, **never** or **always**. When this option is not given, the default is **auto**, in which case signatures are wiped only when in interactive mode and after confirmation by user. In all cases detected signatures are reported by warning messages after a new partition is created. See also **wipefs(8)** command.

-v, --version

Display version information and exit.

-h, --help

Display help text and exit.

INPUT FORMATS

sfdisk supports two input formats and generic header lines.

Header lines

The optional header lines specify generic information that apply to the partition table. The header-line format is:

<name>: <value>

The currently recognized headers are:

unit

Specify the partitioning unit. The only supported unit is **sectors**.

label

Specify the partition table type. For example **dos** or **gpt**.

label-id

Specify the partition table identifier. It should be a hexadecimal number (with a 0x prefix) for MBR and a UUID for GPT.

first-lba

Specify the first usable sector for GPT partitions.

last-lba

Specify the last usable sector for GPT partitions.

table-length

Specify the maximal number of GPT partitions.

grain

Specify minimal size in bytes used to calculate partitions alignment. The default is 1MiB and it's strongly recommended to use the default. Do not modify this variable if you're not sure.

sector-size

Specify sector size. This header is informative only and it is not used when **sfdisk** creates a new partition table, in this case the real device specific value is always used and sector size from the dump is ignored.

Note that it is only possible to use header lines before the first partition is specified in the input.

Unnamed-fields format

start size type bootable

where each line fills one partition descriptor.

Fields are separated by whitespace, comma (recommended) or semicolon possibly followed by whitespace; initial and trailing whitespace is ignored. Numbers can be octal, decimal or hexadecimal; decimal is the default. When a field is absent, empty or specified as '-' a default value is used. But when the **-N** option (change a single partition) is given, the default for each field is its previous value.

The default value of *start* is the first non-assigned sector aligned according to device I/O limits. The default start offset for the first partition is 1 MiB. If the offset is followed by the multiplicative suffixes (KiB, MiB, GiB, TiB, PiB, EiB, ZiB and YiB), then the number is interpreted as offset in bytes. Since v2.38 when the **-N** option (change a single partition) is given, a '+' can be used to enlarge partition by move start of the partition if there is a free space before the partition.

The default value of *size* indicates "as much as possible"; i.e., until the next partition or end-of-device. A numerical argument is by default interpreted as a number of sectors, however if the size is followed by one of the multiplicative suffixes (KiB, MiB, GiB, TiB, PiB, EiB, ZiB and YiB) then the number is interpreted as the size of the partition in bytes and it is then aligned according to the device I/O limits. A '+' can be used instead of a number to enlarge the partition as much as possible. Note '+' is equivalent to the default

behaviour for a new partition; existing partitions will be resized as required.

The partition *type* is given in hex for MBR (DOS) where 0x prefix is optional; a GUID string for GPT; a shortcut or an alias. It's recommended to use two letters for MBR hex codes to avoid collision between deprecated shortcut 'E' and '0E' MBR hex code. For backward compatibility **sfdisk** tries to interpret *type* as a shortcut as a first possibility in partitioning scripts although on other places (e.g. **--part-type** command) it tries shortcuts as the last possibility.

Since v2.36 libfdisk supports partition type aliases as extension to shortcuts. The alias is a simple human readable word (e.g. "linux").

Since v2.37 libfdisk supports partition type names on input, ignoring the case of the characters and all non-alphanumeric and non-digit characters in the name (e.g. "Linux /usr x86" is the same as "linux usr-x86").

Supported shortcuts and aliases:

L – alias 'linux'

Linux; means 83 for MBR and 0FC63DAF-8483-4772-8E79-3D69D8477DE4 for GPT.

S – alias 'swap'

swap area; means 82 for MBR and 0657FD6D-A4AB-43C4-84E5-0933C84B4F4F for GPT

Ex – alias 'extended'

MBR extended partition; means 05 for MBR. The original shortcut 'E' is deprecated due to collision with 0x0E MBR partition type.

H – alias 'home'

home partition; means 933AC7E1-2EB4-4F13-B844-0E14E2AEF915 for GPT

U – alias 'uefi'

EFI System partition, means EF for MBR and C12A7328-F81F-11D2-BA4B-00A0C93EC93B for GPT

R – alias 'raid'

Linux RAID; means FD for MBR and A19D880F-05FC-4D3B-A006-743F0F84911E for GPT

V – alias 'lvm'

LVM; means 8E for MBR and E6D6D379-F507-44C2-A23C-238F2A3DF928 for GPT

The default *type* value is *linux*.

The shortcut 'X' for Linux extended partition (85) is deprecated in favour of 'Ex'.

bootable is specified as [*|–], with as default not-bootable. The value of this field is irrelevant for Linux – when Linux runs it has been booted already – but it might play a role for certain boot loaders and for other operating systems.

Named-fields format

This format is more readable, robust, extensible and allows specifying additional information (e.g., a UUID). It is recommended to use this format to keep your scripts more readable.

[*device* :] *name*[=*value*], ...

The *device* field is optional. **sfdisk** extracts the partition number from the device name. It allows specifying

the partitions in random order. This functionality is mostly used by **--dump**. Don't use it if you are not sure.

The *value* can be between quotation marks (e.g., name="This is partition name"). The fields **start=** and **size=** support '+' and '-' in the same way as **Unnamed-fields format**.

The currently supported fields are:

start=number

The first non-assigned sector aligned according to device I/O limits. The default start offset for the first partition is 1 MiB. If the offset is followed by the multiplicative suffixes (KiB, MiB, GiB, TiB, PiB, EiB, ZiB and YiB), then the number is interpreted as offset in bytes.

size=number

Specify the partition size in sectors. The number may be followed by the multiplicative suffixes (KiB, MiB, GiB, TiB, PiB, EiB, ZiB and YiB), then it's interpreted as size in bytes and the size is aligned according to device I/O limits.

bootable

Mark the partition as bootable.

attrs=string

Partition attributes, usually GPT partition attribute bits. See **--part-attrs** for more details about the GPT-bits string format.

uuid=string

GPT partition UUID.

name=string

GPT partition name.

type=code

A hexadecimal number (without 0x) for an MBR partition, a GUID for a GPT partition, a shortcut as for unnamed-fields format or a type name (e.g. type="Linux /usr (x86)"). See above the section about the unnamed-fields format for more details. For backward compatibility the **Id=** field has the same meaning.

EMPTY DISK LABEL

sfdisk does not create partition table without partitions by default. The lines with partitions are expected in the script by default. The empty partition table has to be explicitly requested by "label: <name>" script header line without any partitions lines. For example:

```
echo 'label: gpt' | sfdisk /dev/sdb
```

creates empty GPT partition table. Note that the **--append** disables this feature.

BACKING UP THE PARTITION TABLE

It is recommended to save the layout of your devices. **sfdisk** supports two ways.

Dump in sfdisk compatible format

Use the **--dump** command to save a description of the device layout to a text file. The dump format is suitable for later **sfdisk** input. For example:

```
sfdisk --dump /dev/sda > sda.dump
```

This can later be restored by:

```
sfdisk /dev/sda < sda.dump
```

Full binary backup

If you want to do a full binary backup of all sectors where the partition table is stored, then use the **--backup-pt-sectors** command. It writes the sectors to `~/sfdisk-<device>-<offset>.bak` files. The default name of the backup file can be changed with the **--backup-file** option. The backup files contain only raw data from the *device*. For example:

```
sfdisk --backup-pt-sectors /dev/sda
```

The GPT header can later be restored by:

```
dd if=~/sfdisk-sda-0x00000200.bak of=/dev/sda seek=$((0x00000200)) bs=1  
conv=notrunc
```

It's also possible to use the **--backup** option to create the same backup immediately after startup for other **sfdisk** commands. For example, backup partition table before deleting all partitions from partition table:

```
sfdisk --backup --delete /dev/sda
```

The same concept of backup files is used by **wipefs(8)**.

Note that **sfdisk** since version 2.26 no longer provides the **-I** option to restore sectors. **dd(1)** provides all necessary functionality.

COLORS

The output colorization is implemented by **terminal-colors.d(5)** functionality. Implicit coloring can be disabled by an empty file

```
/etc/terminal-colors.d/sfdisk.disable
```

for the **sfdisk** command or for all tools by

```
/etc/terminal-colors.d/disable
```

The user-specific `$XDG_CONFIG_HOME/terminal-colors.d` or `$HOME/.config/terminal-colors.d` overrides the global setting.

Note that the output colorization may be enabled by default, and in this case `terminal-colors.d` directories do not have to exist yet.

The logical color names supported by **sfdisk** are:

header

The header of the output tables.

warn

The warning messages.

welcome

The welcome message.

ENVIRONMENT

SFDISK_DEBUG=all

enables **sfdisk** debug output.

LIBFDISK_DEBUG=all
enables libfdisk debug output.

LIBBLKID_DEBUG=all
enables libblkid debug output.

LIBSMARTCOLS_DEBUG=all
enables libsmartcols debug output.

LOCK_BLOCK_DEVICE=<mode>
use exclusive BSD lock. The mode is "1" or "0". See **--lock** for more details.

NOTES

Since version 2.26 **sfdisk** no longer provides the **-R** or **--re-read** option to force the kernel to reread the partition table. Use **blockdev --rereadpt** instead.

Since version 2.26 **sfdisk** does not provide the **--DOS**, **--IBM**, **--DOS-extended**, **--unhide**, **--show-extended**, **--cylinders**, **--heads**, **--sectors**, **--inside-outer**, **--not-inside-outer** options.

EXAMPLES

sfdisk --list --label-nested=mbr /dev/sda
Print protective MBR on device with GPT disk label.

echo -e ',10M,L\n,10M,L\n,+,\n' | sfdisk /dev/sdc
Create three Linux partitions, with the default start, the size of the first two partitions is 10MiB, and the last partition fills all available space on the device.

echo -e 'size=10M, type=L\n size=10M, type=L\n size=+\n' | sfdisk /dev/sdc
The same as the previous example, but in named-fields format.

echo -e 'type=swap' | sfdisk -N 3 /dev/sdc
Set type of the 3rd partition to 'swap'.

sfdisk --part-type /dev/sdc 3 swap
The same as the previous example, but without script use.

sfdisk --delete /dev/sdc 2
Delete 2nd partition.

echo "," | sfdisk -N 3 --move-data /dev/sdc
Enlarge 3rd partition in both directions, move start to use free space before the partition and enlarge the size to use all free space after to the partition, and move partition data too.

AUTHORS

Karel Zak <kzak@redhat.com>

The current **sfdisk** implementation is based on the original **sfdisk** from Andries E. Brouwer.

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **sfdisk** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](#) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME**sftp-server** — OpenSSH SFTP server subsystem**SYNOPSIS**

```
sftp-server [-ehR] [-d start_directory] [-f log_facility] [-l log_level]
            [-P denied_requests] [-p allowed_requests] [-u umask]
sftp-server -Q protocol_feature
```

DESCRIPTION

sftp-server is a program that speaks the server side of SFTP protocol to stdout and expects client requests from stdin. **sftp-server** is not intended to be called directly, but from sshd(8) using the **Subsystem** option.

Command-line flags to **sftp-server** should be specified in the **Subsystem** declaration. See sshd_config(5) for more information.

Valid options are:

-d start_directory

Specifies an alternate starting directory for users. The pathname may contain the following tokens that are expanded at runtime: %% is replaced by a literal '%', %d is replaced by the home directory of the user being authenticated, and %u is replaced by the username of that user. The default is to use the user's home directory. This option is useful in conjunction with the sshd_config(5) **ChrootDirectory** option.

-e Causes **sftp-server** to print logging information to stderr instead of syslog for debugging.

-f log_facility

Specifies the facility code that is used when logging messages from **sftp-server**. The possible values are: DAEMON, USER, AUTH, LOCAL0, LOCAL1, LOCAL2, LOCAL3, LOCAL4, LOCAL5, LOCAL6, LOCAL7. The default is AUTH.

-h Displays **sftp-server** usage information.

-l log_level

Specifies which messages will be logged by **sftp-server**. The possible values are: QUIET, FATAL, ERROR, INFO, VERBOSE, DEBUG, DEBUG1, DEBUG2, and DEBUG3. INFO and VERBOSE log transactions that **sftp-server** performs on behalf of the client. DEBUG and DEBUG1 are equivalent. DEBUG2 and DEBUG3 each specify higher levels of debugging output. The default is ERROR.

-P denied_requests

Specifies a comma-separated list of SFTP protocol requests that are banned by the server. **sftp-server** will reply to any denied request with a failure. The **-Q** flag can be used to determine the supported request types. If both denied and allowed lists are specified, then the denied list is applied before the allowed list.

-p allowed_requests

Specifies a comma-separated list of SFTP protocol requests that are permitted by the server. All request types that are not on the allowed list will be logged and replied to with a failure message.

Care must be taken when using this feature to ensure that requests made implicitly by SFTP clients are permitted.

-Q protocol_feature

Queries protocol features supported by **sftp-server**. At present the only feature that may be queried is "requests", which may be used to deny or allow specific requests (flags **-P** and **-p** re-

spectively).

-R Places this instance of **sftp-server** into a read-only mode. Attempts to open files for writing, as well as other operations that change the state of the filesystem, will be denied.

-u umask

Sets an explicit umask(2) to be applied to newly-created files and directories, instead of the user's default mask.

On some systems, **sftp-server** must be able to access /dev/log for logging to work, and use of **sftp-server** in a chroot configuration therefore requires that **syslogd(8)** establish a logging socket inside the chroot directory.

NAME

sftp — OpenSSH secure file transfer

SYNOPSIS

```
sftp [-46AaCfNpqrv] [-B buffer_size] [-b batchfile] [-c cipher]
      [-D sftp_server_path] [-F ssh_config] [-i identity_file]
      [-J destination] [-l limit] [-o ssh_option] [-P port] [-R num_requests]
      [-s program] [-s subsystem | sftp_server] destination
```

DESCRIPTION

sftp is a file transfer program, similar to **ftp(1)**, which performs all operations over an encrypted **ssh(1)** transport. It may also use many features of **ssh**, such as public key authentication and compression.

The *destination* may be specified either as [user@]host[:path] or as a URI in the form sftp://[user@]host[:port][/path].

If the *destination* includes a *path* and it is not a directory, **sftp** will retrieve files automatically if a non-interactive authentication method is used; otherwise it will do so after successful interactive authentication.

If no *path* is specified, or if the *path* is a directory, **sftp** will log in to the specified *host* and enter interactive command mode, changing to the remote directory if one was specified. An optional trailing slash can be used to force the *path* to be interpreted as a directory.

Since the destination formats use colon characters to delimit host names from path names or port numbers, IPv6 addresses must be enclosed in square brackets to avoid ambiguity.

The options are as follows:

-4 Forces **sftp** to use IPv4 addresses only.

-6 Forces **sftp** to use IPv6 addresses only.

-A Allows forwarding of **ssh-agent(1)** to the remote system. The default is not to forward an authentication agent.

-a Attempt to continue interrupted transfers rather than overwriting existing partial or complete copies of files. If the partial contents differ from those being transferred, then the resultant file is likely to be corrupt.

-B *buffer_size*

Specify the size of the buffer that **sftp** uses when transferring files. Larger buffers require fewer round trips at the cost of higher memory consumption. The default is 32768 bytes.

-b *batchfile*

Batch mode reads a series of commands from an input *batchfile* instead of *stdin*. Since it lacks user interaction it should be used in conjunction with non-interactive authentication to obviate the need to enter a password at connection time (see **sshd(8)** and **ssh-keygen(1)** for details).

A *batchfile* of ‘-’ may be used to indicate standard input. **sftp** will abort if any of the following commands fail: **get**, **put**, **reget**, **reput**, **rename**, **ln**, **rm**, **mkdir**, **chdir**, **ls**, **lchdir**, **chmod**, **chown**, **chgrp**, **lpwd**, **df**, **symlink**, and **lmdir**.

Termination on error can be suppressed on a command by command basis by prefixing the command with a ‘-’ character (for example, **-rm /tmp/blah***). Echo of the command may be suppressed by prefixing the command with a ‘@’ character. These two prefixes may be combined in any order, for example **-@ls /bsd**.

- C** Enables compression (via ssh's **-C** flag).
- c cipher** Selects the cipher to use for encrypting the data transfers. This option is directly passed to ssh(1).
- D sftp_server_path** Connect directly to a local sftp server (rather than via ssh(1)). This option may be useful in debugging the client and server.
- F ssh_config** Specifies an alternative per-user configuration file for ssh(1). This option is directly passed to ssh(1).
- f** Requests that files be flushed to disk immediately after transfer. When uploading files, this feature is only enabled if the server implements the "fsync@openssh.com" extension.
- i identity_file** Selects the file from which the identity (private key) for public key authentication is read. This option is directly passed to ssh(1).
- J destination** Connect to the target host by first making an **sftp** connection to the jump host described by *destination* and then establishing a TCP forwarding to the ultimate destination from there. Multiple jump hops may be specified separated by comma characters. This is a shortcut to specify a **ProxyJump** configuration directive. This option is directly passed to ssh(1).
- l limit** Limits the used bandwidth, specified in Kbit/s.
- N** Disables quiet mode, e.g. to override the implicit quiet mode set by the **-b** flag.
- o ssh_option** Can be used to pass options to **ssh** in the format used in **ssh_config(5)**. This is useful for specifying options for which there is no separate **sftp** command-line flag. For example, to specify an alternate port use: **sftp -oPort=24**. For full details of the options listed below, and their possible values, see **ssh_config(5)**.
 - AddressFamily
 - BatchMode
 - BindAddress
 - BindInterface

-P port

Specifies the port to connect to on the remote host.

-p Preserves modification times, access times, and modes from the original files transferred.

-q Quiet mode: disables the progress meter as well as warning and diagnostic messages from ssh(1).

-R num_requests

Specify how many requests may be outstanding at any one time. Increasing this may slightly improve file transfer speed but will increase memory usage. The default is 64 outstanding requests.

- r** Recursively copy entire directories when uploading and downloading. Note that **sftp** does not follow symbolic links encountered in the tree traversal.
- s program** Name of the *program* to use for the encrypted connection. The program must understand **ssh(1)** options.
- s subsystem | sftp_server** Specifies the SSH2 subsystem or the path for an sftp server on the remote host. A path is useful when the remote **sshd(8)** does not have an sftp subsystem configured.
- v** Raise logging level. This option is also passed to **ssh**.

INTERACTIVE COMMANDS

Once in interactive mode, **sftp** understands a set of commands similar to those of **f tp(1)**. Commands are case insensitive. Pathnames that contain spaces must be enclosed in quotes. Any special characters contained within pathnames that are recognized by **glob(3)** must be escaped with backslashes ('\'').

bye Quit **sftp**.

cd [path]

Change remote directory to *path*. If *path* is not specified, then change directory to the one the session started in.

chgrp [-h] grp path

Change group of file *path* to *grp*. *path* may contain **glob(7)** characters and may match multiple files. *grp* must be a numeric GID.

If the **-h** flag is specified, then symlinks will not be followed. Note that this is only supported by servers that implement the "lsetstat@openssh.com" extension.

chmod [-h] mode path

Change permissions of file *path* to *mode*. *path* may contain **glob(7)** characters and may match multiple files.

If the **-h** flag is specified, then symlinks will not be followed. Note that this is only supported by servers that implement the "lsetstat@openssh.com" extension.

chown [-h] own path

Change owner of file *path* to *own*. *path* may contain **glob(7)** characters and may match multiple files. *own* must be a numeric UID.

If the **-h** flag is specified, then symlinks will not be followed. Note that this is only supported by servers that implement the "lsetstat@openssh.com" extension.

df [-hi] [path]

Display usage information for the filesystem holding the current directory (or *path* if specified). If the **-h** flag is specified, the capacity information will be displayed using "human-readable" suffixes.

The **-i** flag requests display of inode information in addition to capacity information. This command is only supported on servers that implement the "statvfs@openssh.com" extension.

exit Quit **sftp**.

get [-afpR] remote-path [local-path]

Retrieve the *remote-path* and store it on the local machine. If the local path name is not specified, it is given the same name it has on the remote machine. *remote-path* may contain **glob(7)** characters and may match multiple files. If it does and *local-path* is specified, then *local-path* must specify a directory.

If the **-a** flag is specified, then attempt to resume partial transfers of existing files. Note that resumption assumes that any partial copy of the local file matches the remote copy. If the remote file contents differ from the partial local copy then the resultant file is likely to be corrupt.

If the **-f** flag is specified, then `fsync(2)` will be called after the file transfer has completed to flush the file to disk.

If the **-p** flag is specified, then full file permissions and access times are copied too.

If the **-R** flag is specified then directories will be copied recursively. Note that **sftp** does not follow symbolic links when performing recursive transfers.

help Display help text.

lcd [*path*]

Change local directory to *path*. If *path* is not specified, then change directory to the local user's home directory.

l1s [*ls-options* [*path*]]

Display local directory listing of either *path* or current directory if *path* is not specified. *ls-options* may contain any flags supported by the local system's `ls(1)` command. *path* may contain `glob(7)` characters and may match multiple files.

lmkdir *path*

Create local directory specified by *path*.

ln [**-s**] *oldpath newpath*

Create a link from *oldpath* to *newpath*. If the **-s** flag is specified the created link is a symbolic link, otherwise it is a hard link.

lpwd Print local working directory.

ls [**-1afhlnrst**] [*path*]

Display a remote directory listing of either *path* or the current directory if *path* is not specified. *path* may contain `glob(7)` characters and may match multiple files.

The following flags are recognized and alter the behaviour of **ls** accordingly:

-1 Produce single columnar output.

-a List files beginning with a dot ('.') .

-f Do not sort the listing. The default sort order is lexicographical.

-h When used with a long format option, use unit suffixes: Byte, Kilobyte, Megabyte, Gigabyte, Terabyte, Petabyte, and Exabyte in order to reduce the number of digits to four or fewer using powers of 2 for sizes (K=1024, M=1048576, etc.).

-1 Display additional details including permissions and ownership information.

-n Produce a long listing with user and group information presented numerically.

-r Reverse the sort order of the listing.

-s Sort the listing by file size.

-t Sort the listing by last modification time.

lumask *umask*

Set local umask to *umask*.

mkdir *path*

Create remote directory specified by *path*.

progress

Toggle display of progress meter.

put [**-afpR**] *local-path* [*remote-path*]

Upload *local-path* and store it on the remote machine. If the remote path name is not specified, it is given the same name it has on the local machine. *local-path* may contain glob(7) characters and may match multiple files. If it does and *remote-path* is specified, then *remote-path* must specify a directory.

If the **-a** flag is specified, then attempt to resume partial transfers of existing files. Note that resumption assumes that any partial copy of the remote file matches the local copy. If the local file contents differ from the remote local copy then the resultant file is likely to be corrupt.

If the **-f** flag is specified, then a request will be sent to the server to call fsync(2) after the file has been transferred. Note that this is only supported by servers that implement the "fsync@openssh.com" extension.

If the **-p** flag is specified, then full file permissions and access times are copied too.

If the **-R** flag is specified then directories will be copied recursively. Note that **sftp** does not follow symbolic links when performing recursive transfers.

pwd Display remote working directory.**quit** Quit **sftp**.**reget** [**-fpR**] *remote-path* [*local-path*]

Resume download of *remote-path*. Equivalent to **get** with the **-a** flag set.

reput [**-fpR**] *local-path* [*remote-path*]

Resume upload of *local-path*. Equivalent to **put** with the **-a** flag set.

rename *oldpath newpath*

Rename remote file from *oldpath* to *newpath*.

rm *path*

Delete remote file specified by *path*.

rmdir *path*

Remove remote directory specified by *path*.

symlink *oldpath newpath*

Create a symbolic link from *oldpath* to *newpath*.

version

Display the **sftp** protocol version.

!command

Execute *command* in local shell.

!

Escape to local shell.

?

Synonym for help.

NAME

dash — command interpreter (shell)

SYNOPSIS

```
dash [-aCefnuvxIimqVEbp] [+aCefnuvxIimqVEbp] [-o option_name]
      [+o option_name] [command_file [argument ...]]
dash -c[-aCefnuvxIimqVEbp] [+aCefnuvxIimqVEbp] [-o option_name]
      [+o option_name] command_string [command_name [argument ...]]
dash -s[-aCefnuvxIimqVEbp] [+aCefnuvxIimqVEbp] [-o option_name]
      [+o option_name] [argument ...]
```

DESCRIPTION

dash is the standard command interpreter for the system. The current version of **dash** is in the process of being changed to conform with the POSIX 1003.2 and 1003.2a specifications for the shell. This version has many features which make it appear similar in some respects to the Korn shell, but it is not a Korn shell clone (see **ksh(1)**). Only features designated by POSIX, plus a few Berkeley extensions, are being incorporated into this shell. This man page is not intended to be a tutorial or a complete specification of the shell.

Overview

The shell is a command that reads lines from either a file or the terminal, interprets them, and generally executes other commands. It is the program that is running when a user logs into the system (although a user can select a different shell with the **chsh(1)** command). The shell implements a language that has flow control constructs, a macro facility that provides a variety of features in addition to data storage, along with built in history and line editing capabilities. It incorporates many features to aid interactive use and has the advantage that the interpretative language is common to both interactive and non-interactive use (shell scripts). That is, commands can be typed directly to the running shell or can be put into a file and the file can be executed directly by the shell.

Invocation

If no args are present and if the standard input of the shell is connected to a terminal (or if the **-i** flag is set), and the **-c** option is not present, the shell is considered an interactive shell. An interactive shell generally prompts before each command and handles programming and command errors differently (as described below). When first starting, the shell inspects argument 0, and if it begins with a dash ‘-’, the shell is also considered a login shell. This is normally done automatically by the system when the user first logs in. A login shell first reads commands from the files **/etc/profile** and **.profile** if they exist. If the environment variable **ENV** is set on entry to an interactive shell, or is set in the **.profile** of a login shell, the shell next reads commands from the file named in **ENV**. Therefore, a user should place commands that are to be executed only at login time in the **.profile** file, and commands that are executed for every interactive shell inside the **ENV** file. To set the **ENV** variable to some file, place the following line in your **.profile** of your home directory

```
ENV=$HOME/.shinit; export ENV
```

substituting for “**.shinit**” any filename you wish.

If command line arguments besides the options have been specified, then the shell treats the first argument as the name of a file from which to read commands (a shell script), and the remaining arguments are set as the positional parameters of the shell (**\$1**, **\$2**, etc). Otherwise, the shell reads commands from its standard input.

Argument List Processing

All of the single letter options that have a corresponding name can be used as an argument to the **-o** option. The set **-o** name is provided next to the single letter option in the description below. Specifying a dash “-” turns the option on, while using a plus “+” disables the option. The following options can be set from the

command line or with the **set** builtin (described later).

-a <i>alllexport</i>	Export all variables assigned to.
-c	Read commands from the <i>command_string</i> operand instead of from the standard input. Special parameter 0 will be set from the <i>command_name</i> operand and the positional parameters (\$1, \$2, etc.) set from the remaining argument operands.
-C <i>noclobber</i>	Don't overwrite existing files with ">".
-e <i>errexit</i>	If not interactive, exit immediately if any untested command fails. The exit status of a command is considered to be explicitly tested if the command is used to control an if , elif , while , or until ; or if the command is the left hand operand of an “&&” or “ ” operator.
-f <i>noglob</i>	Disable pathname expansion.
-n <i>noexec</i>	If not interactive, read commands but do not execute them. This is useful for checking the syntax of shell scripts.
-u <i>nounset</i>	Write a message to standard error when attempting to expand a variable that is not set, and if the shell is not interactive, exit immediately.
-v <i>verbose</i>	The shell writes its input to standard error as it is read. Useful for debugging.
-x <i>xtrace</i>	Write each command to standard error (preceded by a ‘+’) before it is executed. Useful for debugging.
-I <i>ignoreeof</i>	Ignore EOF's from input when interactive.
-i <i>interactive</i>	Force the shell to behave interactively.
-l	Make dash act as if it had been invoked as a login shell.
-m <i>monitor</i>	Turn on job control (set automatically when interactive).
-s <i>stdin</i>	Read commands from standard input (set automatically if no file arguments are present). This option has no effect when the shell has already started running (i.e. with set).
-v <i>vi</i>	Enable the built-in vi (1) command line editor (disables -E if it has been set).
-E <i>emacs</i>	Enable the built-in emacs (1) command line editor (disables -v if it has been set).
-b <i>notify</i>	Enable asynchronous notification of background job completion. (UNIMPLEMENTED for 4.4alpha)
-p <i>privileged</i>	Do not attempt to reset effective uid if it does not match uid. This is not set by default to help avoid incorrect usage by setuid root programs via system (3) or popen (3).

Lexical Structure

The shell reads input in terms of lines from a file and breaks it up into words at whitespace (blanks and tabs), and at certain sequences of characters that are special to the shell called “operators”. There are two types of operators: control operators and redirection operators (their meaning is discussed later). Following is a list of operators:

Control operators:

```
& && ( ) ; ; | || <newline>
```

Redirection operators:

```
< > >| << >> <& >& <<- >>
```

Quoting

Quoting is used to remove the special meaning of certain characters or words to the shell, such as operators, whitespace, or keywords. There are three types of quoting: matched single quotes, matched double quotes, and backslash.

Backslash

A backslash preserves the literal meaning of the following character, with the exception of `<newline>`. A backslash preceding a `<newline>` is treated as a line continuation.

Single Quotes

Enclosing characters in single quotes preserves the literal meaning of all the characters (except single quotes, making it impossible to put single-quotes in a single-quoted string).

Double Quotes

Enclosing characters within double quotes preserves the literal meaning of all characters except dollarsign (\$), backquote (`), and backslash (\). The backslash inside double quotes is historically weird, and serves to quote only the following characters:

```
$ ` " \ <newline>
```

Otherwise it remains literal.

Reserved Words

Reserved words are words that have special meaning to the shell and are recognized at the beginning of a line and after a control operator. The following are reserved words:

```
!      elif    fi      while  case
else   for     then    {       }
do     done    until   if     esac
```

Their meaning is discussed later.

Aliases

An alias is a name and corresponding value set using the `alias(1)` builtin command. Whenever a reserved word may occur (see above), and after checking for reserved words, the shell checks the word to see if it matches an alias. If it does, it replaces it in the input stream with its value. For example, if there is an alias called “`lf`” with the value “`ls -F`”, then the input:

```
lf foobar <return>
```

would become

```
ls -F foobar <return>
```

Aliases provide a convenient way for naive users to create shorthands for commands without having to learn how to create functions with arguments. They can also be used to create lexically obscure code. This use is discouraged.

Commands

The shell interprets the words it reads according to a language, the specification of which is outside the scope of this man page (refer to the BNF in the POSIX 1003.2 document). Essentially though, a line is read and if

the first word of the line (or after a control operator) is not a reserved word, then the shell has recognized a simple command. Otherwise, a complex command or some other special construct may have been recognized.

Simple Commands

If a simple command has been recognized, the shell performs the following actions:

1. Leading words of the form “name=value” are stripped off and assigned to the environment of the simple command. Redirection operators and their arguments (as described below) are stripped off and saved for processing.
2. The remaining words are expanded as described in the section called “Expansions”, and the first remaining word is considered the command name and the command is located. The remaining words are considered the arguments of the command. If no command name resulted, then the “name=value” variable assignments recognized in item 1 affect the current shell.
3. Redirections are performed as described in the next section.

Redirections

Redirections are used to change where a command reads its input or sends its output. In general, redirections open, close, or duplicate an existing reference to a file. The overall format used for redirection is:

`[n] redir-op file`

where *redir-op* is one of the redirection operators mentioned previously. Following is a list of the possible redirections. The [n] is an optional number between 0 and 9, as in ‘3’ (not ‘[3]’), that refers to a file descriptor.

<code>[n]> file</code>	Redirect standard output (or n) to file.
<code>[n]> file</code>	Same, but override the -C option.
<code>[n]>> file</code>	Append standard output (or n) to file.
<code>[n]< file</code>	Redirect standard input (or n) from file.
<code>[n]<&n2</code>	Copy file descriptor n2 as stdout (or fd n1). fd n2.
<code>[n]<&-</code>	Close standard input (or n).
<code>[n]>&n2</code>	Copy file descriptor n2 as stdin (or fd n1). fd n2.
<code>[n]>&-</code>	Close standard output (or n).
<code>[n]<> file</code>	Open file for reading and writing on standard input (or n).

The following redirection is often called a “here-document”.

```
[n]<< delimiter
    here-doc-text ...
delimiter
```

All the text on successive lines up to the delimiter is saved away and made available to the command on standard input, or file descriptor n if it is specified. If the delimiter as specified on the initial line is quoted, then the here-doc-text is treated literally, otherwise the text is subjected to parameter expansion, command substitution, and arithmetic expansion (as described in the section on “Expansions”). If the operator is “<<-” instead of “<<”, then leading tabs in the here-doc-text are stripped.

Search and Execution

There are three types of commands: shell functions, builtin commands, and normal programs – and the command is searched for (by name) in that order. They each are executed in a different way.

When a shell function is executed, all of the shell positional parameters (except \$0, which remains unchanged) are set to the arguments of the shell function. The variables which are explicitly placed in the environment of the command (by placing assignments to them before the function name) are made local to the function and are set to the values given. Then the command given in the function definition is executed. The positional parameters are restored to their original values when the command completes. This all occurs within the current shell.

Shell builtins are executed internally to the shell, without spawning a new process.

Otherwise, if the command name doesn't match a function or builtin, the command is searched for as a normal program in the file system (as described in the next section). When a normal program is executed, the shell runs the program, passing the arguments and the environment to the program. If the program is not a normal executable file (i.e., if it does not begin with the "magic number" whose ASCII representation is "#!", so `execve(2)` returns `ENOEXEC` then) the shell will interpret the program in a subshell. The child shell will reinitialize itself in this case, so that the effect will be as if a new shell had been invoked to handle the ad-hoc shell script, except that the location of hashed commands located in the parent shell will be remembered by the child.

Note that previous versions of this document and the source code itself misleadingly and sporadically refer to a shell script without a magic number as a "shell procedure".

Path Search

When locating a command, the shell first looks to see if it has a shell function by that name. Then it looks for a builtin command by that name. If a builtin command is not found, one of two things happen:

1. Command names containing a slash are simply executed without performing any searches.
2. The shell searches each entry in `PATH` in turn for the command. The value of the `PATH` variable should be a series of entries separated by colons. Each entry consists of a directory name. The current directory may be indicated implicitly by an empty directory name, or explicitly by a single period.

Command Exit Status

Each command has an exit status that can influence the behaviour of other shell commands. The paradigm is that a command exits with zero for normal or success, and non-zero for failure, error, or a false indication. The man page for each command should indicate the various exit codes and what they mean. Additionally, the builtin commands return exit codes, as does an executed shell function.

If a command consists entirely of variable assignments then the exit status of the command is that of the last command substitution if any, otherwise 0.

Complex Commands

Complex commands are combinations of simple commands with control operators or reserved words, together creating a larger complex command. More generally, a command is one of the following:

- simple command
- pipeline
- list or compound-list
- compound command

- function definition

Unless otherwise stated, the exit status of a command is that of the last simple command executed by the command.

Pipelines

A pipeline is a sequence of one or more commands separated by the control operator `|`. The standard output of all but the last command is connected to the standard input of the next command. The standard output of the last command is inherited from the shell, as usual.

The format for a pipeline is:

```
[ ! ] command1 [| command2 ... ]
```

The standard output of `command1` is connected to the standard input of `command2`. The standard input, standard output, or both of a command is considered to be assigned by the pipeline before any redirection specified by redirection operators that are part of the command.

If the pipeline is not in the background (discussed later), the shell waits for all commands to complete.

If the reserved word `!` does not precede the pipeline, the exit status is the exit status of the last command specified in the pipeline. Otherwise, the exit status is the logical NOT of the exit status of the last command. That is, if the last command returns zero, the exit status is 1; if the last command returns greater than zero, the exit status is zero.

Because pipeline assignment of standard input or standard output or both takes place before redirection, it can be modified by redirection. For example:

```
$ command1 2>&1 | command2
```

sends both the standard output and standard error of `command1` to the standard input of `command2`.

`A ;` or `<newline>` terminator causes the preceding AND-OR-list (described next) to be executed sequentially; a `&` causes asynchronous execution of the preceding AND-OR-list.

Note that unlike some other shells, each process in the pipeline is a child of the invoking shell (unless it is a shell builtin, in which case it executes in the current shell – but any effect it has on the environment is wiped).

Background Commands – &

If a command is terminated by the control operator ampersand (`&`), the shell executes the command asynchronously – that is, the shell does not wait for the command to finish before executing the next command.

The format for running a command in background is:

```
command1 & [ command2 & ... ]
```

If the shell is not interactive, the standard input of an asynchronous command is set to `/dev/null`.

Lists – Generally Speaking

A list is a sequence of zero or more commands separated by newlines, semicolons, or ampersands, and optionally terminated by one of these three characters. The commands in a list are executed in the order they are written. If command is followed by an ampersand, the shell starts the command and immediately proceeds onto the next command; otherwise it waits for the command to terminate before proceeding to the next one.

Short-Circuit List Operators

“`&&`” and “`||`” are AND-OR list operators. “`&&`” executes the first command, and then executes the second command if and only if the exit status of the first command is zero. “`||`” is similar, but executes the second command if and only if the exit status of the first command is nonzero. “`&&`” and “`||`” both have the same priority.

Flow-Control Constructs – if, while, for, case

The syntax of the if command is

```
if list
then list
[ elif list
then    list ] ...
[ else list ]
fi
```

The syntax of the while command is

```
while list
do    list
done
```

The two lists are executed repeatedly while the exit status of the first list is zero. The until command is similar, but has the word until in place of while, which causes it to repeat until the exit status of the first list is zero.

The syntax of the for command is

```
for variable [ in [ word ... ] ]
do    list
done
```

The words following in are expanded, and then the list is executed repeatedly with the variable set to each word in turn. Omitting in word ... is equivalent to in “`$@`”.

The syntax of the break and continue command is

```
break [ num ]
continue [ num ]
```

Break terminates the num innermost for or while loops. Continue continues with the next iteration of the innermost loop. These are implemented as builtin commands.

The syntax of the case command is

```
case word in
[ ( ]pattern) list ;;
...
esac
```

The pattern can actually be one or more patterns (see **Shell Patterns** described later), separated by “`|`” characters. The “`(`” character before the pattern is optional.

Grouping Commands Together

Commands may be grouped by writing either

```
(list)
```

or

```
{ list; }
```

The first of these executes the commands in a subshell. Builtin commands grouped into a (list) will not affect the current shell. The second form does not fork another shell so is slightly more efficient. Grouping commands together this way allows you to redirect their output as though they were one program:

```
{ printf " hello " ; printf " world\n" ; } > greeting
```

Note that “}” must follow a control operator (here, “;”) so that it is recognized as a reserved word and not as another command argument.

Functions

The syntax of a function definition is

```
name () command
```

A function definition is an executable statement; when executed it installs a function named name and returns an exit status of zero. The command is normally a list enclosed between “{” and “}”.

Variables may be declared to be local to a function by using a local command. This should appear as the first statement of a function, and the syntax is

```
local [variable | -] . . .
```

Local is implemented as a builtin command.

When a variable is made local, it inherits the initial value and exported and readonly flags from the variable with the same name in the surrounding scope, if there is one. Otherwise, the variable is initially unset. The shell uses dynamic scoping, so that if you make the variable x local to function f, which then calls function g, references to the variable x made inside g will refer to the variable x declared inside f, not to the global variable named x.

The only special parameter that can be made local is “-”. Making “-” local any shell options that are changed via the set command inside the function to be restored to their original values when the function returns.

The syntax of the return command is

```
return [exitstatus]
```

It terminates the currently executing function. Return is implemented as a builtin command.

Variables and Parameters

The shell maintains a set of parameters. A parameter denoted by a name is called a variable. When starting up, the shell turns all the environment variables into shell variables. New variables can be set using the form

```
name=value
```

Variables set by the user must have a name consisting solely of alphabets, numerics, and underscores - the first of which must not be numeric. A parameter can also be denoted by a number or a special character as explained below.

Positional Parameters

A positional parameter is a parameter denoted by a number ($n > 0$). The shell sets these initially to the values of its command line arguments that follow the name of the shell script. The **set** builtin can also be used to set or reset them.

Special Parameters

A special parameter is a parameter denoted by one of the following special characters. The value of the parameter is listed next to its character.

*	Expands to the positional parameters, starting from one. When the expansion occurs within a double-quoted string it expands to a single field with the value of each parameter separated by the first character of the <code>IFS</code> variable, or by a <code>(space)</code> if <code>IFS</code> is unset.
@	Expands to the positional parameters, starting from one. When the expansion occurs within double-quotes, each positional parameter expands as a separate argument. If there are no positional parameters, the expansion of @ generates zero arguments, even when @ is double-quoted. What this basically means, for example, is if \$1 is "abc" and \$2 is "def ghi", then "\$@" expands to the two arguments:
	"abc" "def ghi"
#	Expands to the number of positional parameters.
?	Expands to the exit status of the most recent pipeline.
- (Hyphen.)	Expands to the current option flags (the single-letter option names concatenated into a string) as specified on invocation, by the set builtin command, or implicitly by the shell.
\$	Expands to the process ID of the invoked shell. A subshell retains the same value of \$ as its parent.
!	Expands to the process ID of the most recent background command executed from the current shell. For a pipeline, the process ID is that of the last command in the pipeline.
0 (Zero.)	Expands to the name of the shell or shell script.

Word Expansions

This clause describes the various expansions that are performed on words. Not all expansions are performed on every word, as explained later.

Tilde expansions, parameter expansions, command substitutions, arithmetic expansions, and quote removals that occur within a single word expand to a single field. It is only field splitting or pathname expansion that can create multiple fields from a single word. The single exception to this rule is the expansion of the special parameter @ within double-quotes, as was described above.

The order of word expansion is:

1. Tilde Expansion, Parameter Expansion, Command Substitution, Arithmetic Expansion (these all occur at the same time).
2. Field Splitting is performed on fields generated by step (1) unless the `IFS` variable is null.
3. Pathname Expansion (unless set `-f` is in effect).
4. Quote Removal.

The \$ character is used to introduce parameter expansion, command substitution, or arithmetic evaluation.

Tilde Expansion (substituting a user's home directory)

A word beginning with an unquoted tilde character (~) is subjected to tilde expansion. All the characters up to a slash (/) or the end of the word are treated as a username and are replaced with the user's home directory. If the username is missing (as in ~ /foobar), the tilde is replaced with the value of the `HOME` variable (the current user's home directory).

Parameter Expansion

The format for parameter expansion is as follows:

```
$ {expression}
```

where expression consists of all characters until the matching “}”. Any “}” escaped by a backslash or within a quoted string, and characters in embedded arithmetic expansions, command substitutions, and variable expansions, are not examined in determining the matching “}”.

The simplest form for parameter expansion is:

```
$ {parameter}
```

The value, if any, of parameter is substituted.

The parameter name or symbol can be enclosed in braces, which are optional except for positional parameters with more than one digit or when parameter is followed by a character that could be interpreted as part of the name. If a parameter expansion occurs inside double-quotes:

1. Pathname expansion is not performed on the results of the expansion.
2. Field splitting is not performed on the results of the expansion, with the exception of @.

In addition, a parameter expansion can be modified by using one of the following formats.

<code>\${parameter:-word}</code>	Use Default Values. If parameter is unset or null, the expansion of word is substituted; otherwise, the value of parameter is substituted.
<code>\${parameter:=word}</code>	Assign Default Values. If parameter is unset or null, the expansion of word is assigned to parameter. In all cases, the final value of parameter is substituted. Only variables, not positional parameters or special parameters, can be assigned in this way.
<code>\${parameter:?word}</code>	Indicate Error if Null or Unset. If parameter is unset or null, the expansion of word (or a message indicating it is unset if word is omitted) is written to standard error and the shell exits with a nonzero exit status. Otherwise, the value of parameter is substituted. An interactive shell need not exit.
<code>\${parameter:+word}</code>	Use Alternative Value. If parameter is unset or null, null is substituted; otherwise, the expansion of word is substituted.

In the parameter expansions shown previously, use of the colon in the format results in a test for a parameter that is unset or null; omission of the colon results in a test for a parameter that is only unset.

<code>\$#parameter</code>	String Length. The length in characters of the value of parameter.
---------------------------	--

The following four varieties of parameter expansion provide for substring processing. In each case, pattern matching notation (see **Shell Patterns**), rather than regular expression notation, is used to evaluate the patterns. If parameter is* or @, the result of the expansion is unspecified. Enclosing the full parameter expansion string in double-quotes does not cause the following four varieties of pattern characters to be quoted, whereas quoting characters within the braces has this effect.

<code>\$parameter%word</code>	Remove Smallest Suffix Pattern. The word is expanded to produce a pattern. The parameter expansion then results in parameter, with the smallest portion of the suffix matched by the pattern deleted.
<code>\$parameter%%word</code>	Remove Largest Suffix Pattern. The word is expanded to produce a pattern. The parameter expansion then results in parameter, with the largest portion of the suffix matched by the pattern deleted.

<code>\$(parameter#word}</code>	Remove Smallest Prefix Pattern. The word is expanded to produce a pattern. The parameter expansion then results in parameter, with the smallest portion of the prefix matched by the pattern deleted.
<code>\$(parameter##word}</code>	Remove Largest Prefix Pattern. The word is expanded to produce a pattern. The parameter expansion then results in parameter, with the largest portion of the prefix matched by the pattern deleted.

Command Substitution

Command substitution allows the output of a command to be substituted in place of the command name itself. Command substitution occurs when the command is enclosed as follows:

```
$ ( command )
```

or (“backquoted” version):

```
' command '
```

The shell expands the command substitution by executing command in a subshell environment and replacing the command substitution with the standard output of the command, removing sequences of one or more `\n`s at the end of the substitution. (Embedded `\n`s before the end of the output are not removed; however, during field splitting, they may be translated into s, depending on the value of `IFS` and quoting that is in effect.)

Arithmetic Expansion

Arithmetic expansion provides a mechanism for evaluating an arithmetic expression and substituting its value. The format for arithmetic expansion is as follows:

```
$ ( ( expression ) )
```

The expression is treated as if it were in double-quotes, except that a double-quote inside the expression is not treated specially. The shell expands all tokens in the expression for parameter expansion, command substitution, and quote removal.

Next, the shell treats this as an arithmetic expression and substitutes the value of the expression.

White Space Splitting (Field Splitting)

After parameter expansion, command substitution, and arithmetic expansion the shell scans the results of expansions and substitutions that did not occur in double-quotes for field splitting and multiple fields can result.

The shell treats each character of the `IFS` as a delimiter and uses the delimiters to split the results of parameter expansion and command substitution into fields.

Pathname Expansion (File Name Generation)

Unless the `-f` flag is set, file name generation is performed after word splitting is complete. Each word is viewed as a series of patterns, separated by slashes. The process of expansion replaces the word with the names of all existing files whose names can be formed by replacing each pattern with a string that matches the specified pattern. There are two restrictions on this: first, a pattern cannot match a string containing a slash, and second, a pattern cannot match a string starting with a period unless the first character of the pattern is a period. The next section describes the patterns used for both Pathname Expansion and the `case` command.

Shell Patterns

A pattern consists of normal characters, which match themselves, and meta-characters. The meta-characters are “!”, “*”, “?”, and “[”. These characters lose their special meanings if they are quoted. When command or variable substitution is performed and the dollar sign or back quotes are not double quoted, the value of

the variable or the output of the command is scanned for these characters and they are turned into meta-characters.

An asterisk (“*”) matches any string of characters. A question mark matches any single character. A left bracket (“[”) introduces a character class. The end of the character class is indicated by a (“]”); if the “]” is missing then the “[” matches a “[” rather than introducing a character class. A character class matches any of the characters between the square brackets. A range of characters may be specified using a minus sign. The character class may be complemented by making an exclamation point the first character of the character class.

To include a “[” in a character class, make it the first character listed (after the “!”, if any). To include a minus sign, make it the first or last character listed.

Builtins

This section lists the builtin commands which are builtin because they need to perform some operation that can't be performed by a separate process. In addition to these, there are several other commands that may be builtin for efficiency (e.g. `printf(1)`, `echo(1)`, `test(1)`, etc).

:

`true` A null command that returns a 0 (true) exit value.

`. file` The commands in the specified file are read and executed by the shell.

`alias [name[=string ...]]`

If `name=string` is specified, the shell defines the alias `name` with value `string`. If `justname` is specified, the value of the alias `name` is printed. With no arguments, the `alias` builtin prints the names and values of all defined aliases (see `unalias`).

`bg [job] ...`

Continue the specified jobs (or the current job if no jobs are given) in the background.

`command [-p] [-v] [-V] command [arg ...]`

Execute the specified command but ignore shell functions when searching for it. (This is useful when you have a shell function with the same name as a builtin command.)

`-p` search for command using a PATH that guarantees to find all the standard utilities.

`-v` Do not execute the command but search for the command and print the resolution of the command search. This is the same as the type builtin.

`-V` Do not execute the command but search for the command and print the absolute pathname of utilities, the name for builtins or the expansion of aliases.

`cd -`

`cd [-LP] [directory]`

Switch to the specified directory (default HOME). If an entry for CDPATH appears in the environment of the `cd` command or the shell variable CDPATH is set and the directory name does not begin with a slash, then the directories listed in CDPATH will be searched for the specified directory. The format of CDPATH is the same as that of PATH. If a single dash is specified as the argument, it will be replaced by the value of OLDPWD. The `cd` command will print out the name of the directory that it actually switched to if this is different from the name that the user gave. These may be different either because the CDPATH mechanism was used or because the argument is a single dash. The `-P` option causes the physical directory structure to be used, that is, all symbolic links are resolved to their respective values. The `-L` option turns off the effect of any preceding `-P` options.

echo [**-n**] *args...*

Print the arguments on the standard output, separated by spaces. Unless the **-n** option is present, a newline is output following the arguments.

If any of the following sequences of characters is encountered during output, the sequence is not output. Instead, the specified action is performed:

- \b A backspace character is output.
- \c Subsequent output is suppressed. This is normally used at the end of the last argument to suppress the trailing newline that **echo** would otherwise output.
- \e Outputs an escape character (ESC).
- \f Output a form feed.
- \n Output a newline character.
- \r Output a carriage return.
- \t Output a (horizontal) tab character.
- \v Output a vertical tab.

\0*digits*

Output the character whose value is given by zero to three octal digits. If there are zero digits, a nul character is output.

- \\\ Output a backslash.

All other backslash sequences elicit undefined behaviour.

eval *string* . . .

Concatenate all the arguments with spaces. Then re-parse and execute the command.

exec [*command arg* . . .]

Unless *command* is omitted, the shell process is replaced with the specified program (which must be a real program, not a shell builtin or function). Any redirections on the **exec** command are marked as permanent, so that they are not undone when the **exec** command finishes.

exit [*exitstatus*]

Terminate the shell process. If *exitstatus* is given it is used as the exit status of the shell; otherwise the exit status of the preceding command is used.

export *name* . . .**export -p**

The specified names are exported so that they will appear in the environment of subsequent commands. The only way to un-export a variable is to unset it. The shell allows the value of a variable to be set at the same time it is exported by writing

```
export name=value
```

With no arguments the export command lists the names of all exported variables. With the **-p** option specified the output will be formatted suitably for non-interactive use.

fc [**-e** *editor*] [*first [last]*]**fc -l** [**-nr**] [*first [last]*]**fc -s** [*old=new*] [*first*]

The **fc** builtin lists, or edits and re-executes, commands previously entered to an interactive shell.

-e editor

Use the editor named by editor to edit the commands. The editor string is a command name, subject to search via the PATH variable. The value in the FCEDIT variable is used as a default when **-e** is not specified. If FCEDIT is null or unset, the value of the EDITOR variable is used. If EDITOR is null or unset, ed(1) is used as the editor.

-l (ell)

List the commands rather than invoking an editor on them. The commands are written in the sequence indicated by the first and last operands, as affected by **-r**, with each command preceded by the command number.

-n Suppress command numbers when listing with **-l**.**-r** Reverse the order of the commands listed (with **-l**) or edited (with neither **-l** nor **-s**).**-s** Re-execute the command without invoking an editor.

first

last Select the commands to list or edit. The number of previous commands that can be accessed are determined by the value of the HISTSIZE variable. The value of first or last or both are one of the following:

[+]number

A positive number representing a command number; command numbers can be displayed with the **-l** option.

-number

A negative decimal number representing the command that was executed number of commands previously. For example, **-1** is the immediately previous command.

string A string indicating the most recently entered command that begins with that string. If the old=new operand is not also specified with **-s**, the string form of the first operand cannot contain an embedded equal sign.

The following environment variables affect the execution of fc:

FCEDIT Name of the editor to use.

HISTSIZE The number of previous commands that are accessible.

fg [job]

Move the specified job or the current job to the foreground.

getopts optstring var

The POSIX **getopts** command, not to be confused with the *Bell Labs* -derived getopt(1).

The first argument should be a series of letters, each of which may be optionally followed by a colon to indicate that the option requires an argument. The variable specified is set to the parsed option.

The **getopts** command deprecates the older getopt(1) utility due to its handling of arguments containing whitespace.

The **getopts** builtin may be used to obtain options and their arguments from a list of parameters. When invoked, **getopts** places the value of the next option from the option string in the list in the shell variable specified by *var* and its index in the shell variable OPTIND. When the shell is invoked, OPTIND is initialized to 1. For each option that requires an argument, the **getopts** builtin will place it in the shell variable OPTARG. If an option is not allowed for in the *optstring*, then OPTARG will be unset.

optstring is a string of recognized option letters (see `getopt(3)`). If a letter is followed by a colon, the option is expected to have an argument which may or may not be separated from it by white space. If an option character is not found where expected, `getopts` will set the variable *var* to a “?”; `getopts` will then unset OPTARG and write output to standard error. By specifying a colon as the first character of *optstring* all errors will be ignored.

After the last option `getopts` will return a non-zero value and set *var* to “?”.

The following code fragment shows how one might process the arguments for a command that can take the options [a] and [b], and the option [c], which requires an argument.

```
while getopts abc: f
do
    case $f in
        a | b) flag=$f;;
        c)      carg=$OPTARG;;
        \?)     echo $USAGE; exit 1;;
    esac
done
shift `expr $OPTIND - 1`
```

This code will accept any of the following as equivalent:

```
cmd -acarg file file
cmd -a -c arg file file
cmd -carg -a file file
cmd -a -carg -- file file
```

`hash -rv command . . .`

The shell maintains a hash table which remembers the locations of commands. With no arguments whatsoever, the `hash` command prints out the contents of this table. Entries which have not been looked at since the last `cd` command are marked with an asterisk; it is possible for these entries to be invalid.

With arguments, the `hash` command removes the specified commands from the hash table (unless they are functions) and then locates them. With the `-v` option, `hash` prints the locations of the commands as it finds them. The `-r` option causes the `hash` command to delete all the entries in the hash table except for functions.

`pwd [-LP]`

builtin command remembers what the current directory is rather than recomputing it each time. This makes it faster. However, if the current directory is renamed, the builtin version of `pwd` will continue to print the old name for the directory. The `-P` option causes the physical value of the current working directory to be shown, that is, all symbolic links are resolved to their respective values. The `-L` option turns off the effect of any preceding `-P` options.

`read [-p prompt] [-r] variable [. . .]`

The prompt is printed if the `-p` option is specified and the standard input is a terminal. Then a line is read from the standard input. The trailing newline is deleted from the line and the line is split as described in the section on word splitting above, and the pieces are assigned to the variables in order. At least one variable must be specified. If there are more pieces than variables, the remaining pieces (along with the characters in IFS that separated them) are assigned to the last variable. If there are more variables than pieces, the remaining variables are assigned the null string. The `read` builtin will indicate success unless EOF is encountered on input, in which case failure is returned.

By default, unless the **-r** option is specified, the backslash “\” acts as an escape character, causing the following character to be treated literally. If a backslash is followed by a newline, the backslash and the newline will be deleted.

`readonly name . . .`

`readonly -p`

The specified names are marked as read only, so that they cannot be subsequently modified or unset. The shell allows the value of a variable to be set at the same time it is marked read only by writing

`readonly name=value`

With no arguments the `readonly` command lists the names of all read only variables. With the **-p** option specified the output will be formatted suitably for non-interactive use.

`printf format [arguments . . .]`

`printf` formats and prints its arguments, after the first, under control of the *format*. The *format* is a character string which contains three types of objects: plain characters, which are simply copied to standard output, character escape sequences which are converted and copied to the standard output, and format specifications, each of which causes printing of the next successive *argument*.

The *arguments* after the first are treated as strings if the corresponding format is either **b**, **c** or **s**; otherwise it is evaluated as a C constant, with the following extensions:

- A leading plus or minus sign is allowed.
- If the leading character is a single or double quote, the value is the ASCII code of the next character.

The format string is reused as often as necessary to satisfy the *arguments*. Any extra format specifications are evaluated with zero or the null string.

Character escape sequences are in backslash notation as defined in ANSI X3.159-1989 (“ANSI C89”). The characters and their meanings are as follows:

<code>\a</code>	Write a <bell> character.
<code>\b</code>	Write a <backspace> character.
<code>\e</code>	Write an <escape> (ESC) character.
<code>\f</code>	Write a <form-feed> character.
<code>\n</code>	Write a <new-line> character.
<code>\r</code>	Write a <carriage return> character.
<code>\t</code>	Write a <tab> character.
<code>\v</code>	Write a <vertical tab> character.
<code>\\\</code>	Write a backslash character.
<code>\num</code>	Write an 8-bit character whose ASCII value is the 1-, 2-, or 3-digit octal number <i>num</i> .

Each format specification is introduced by the percent character (“%”). The remainder of the format specification includes, in the following order:

Zero or more of the following flags:

- # A '#' character specifying that the value should be printed in an “alternative form”. For **b**, **c**, **d**, and **s** formats, this option has no effect. For the **o** format the precision of the number is increased to force the first character of the output string to a zero.

For the **x** (**X**) format, a non-zero result has the string 0x (0X) prepended to it. For **e**, **E**, **f**, **g**, and **G** formats, the result will always contain a decimal point, even if no digits follow the point (normally, a decimal point only appears in the results of those formats if a digit follows the decimal point). For **g** and **G** formats, trailing zeros are not removed from the result as they would otherwise be.

- A minus sign ‘-’ which specifies *left adjustment* of the output in the indicated field;
- + A ‘+’ character specifying that there should always be a sign placed before the number when using signed formats.
- ‘ ’ A space specifying that a blank should be left before a positive number for a signed format. A ‘+’ overrides a space if both are used;
- 0 A zero ‘0’ character indicating that zero-padding should be used rather than blank-padding. A ‘-’ overrides a ‘0’ if both are used;

Field Width:

An optional digit string specifying a *field width*; if the output string has fewer characters than the field width it will be blank-padded on the left (or right, if the left-adjustment indicator has been given) to make up the field width (note that a leading zero is a flag, but an embedded zero is part of a field width);

Precision:

An optional period, ‘.’, followed by an optional digit string giving a *precision* which specifies the number of digits to appear after the decimal point, for **e** and **f** formats, or the maximum number of bytes to be printed from a string (**b** and **s** formats); if the digit string is missing, the precision is treated as zero;

Format:

A character which indicates the type of format to use (one of **d****i****o****u****x****X****f****w****E****g****G****b****c****s**).

A field width or precision may be ‘*’ instead of a digit string. In this case an argument supplies the field width or precision.

The format characters and their meanings are:

- d****i****o****u****x****x** The argument is printed as a signed decimal (d or i), unsigned octal, unsigned decimal, or unsigned hexadecimal (X or x), respectively.
 - f** The argument is printed in the style [-]ddd.ddd where the number of d's after the decimal point is equal to the precision specification for the argument. If the precision is missing, 6 digits are given; if the precision is explicitly 0, no digits and no decimal point are printed.
 - e****E** The argument is printed in the style [-]d.ddde±dd where there is one digit before the decimal point and the number after is equal to the precision specification for the argument; when the precision is missing, 6 digits are produced. An upper-case E is used for an ‘E’ format.
 - g****G** The argument is printed in style **f** or in style **e** (**E**) whichever gives full precision in minimum space.
 - b** Characters from the string argument are printed with backslash-escape sequences expanded.
- The following additional backslash-escape sequences are supported:

- \c Causes **dash** to ignore any remaining characters in the string operand containing it, any remaining string operands, and any additional characters in the format operand.
- \0*num* Write an 8-bit character whose ASCII value is the 1-, 2-, or 3-digit octal number *num*.
- c The first character of *argument* is printed.
- s Characters from the string *argument* are printed until the end is reached or until the number of bytes indicated by the precision specification is reached; if the precision is omitted, all characters in the string are printed.
- % Print a ‘%’; no argument is used.

In no case does a non-existent or small field width cause truncation of a field; padding takes place only if the specified field width exceeds the actual width.

set [{ -options | +options | -- }] *arg* . . .

The **set** command performs three different functions.

With no arguments, it lists the values of all shell variables.

If options are given, it sets the specified option flags, or clears them as described in the section called **Argument List Processing**. As a special case, if the option is -o or +o and no argument is supplied, the shell prints the settings of all its options. If the option is -o, the settings are printed in a human-readable format; if the option is +o, the settings are printed in a format suitable for reinput to the shell to affect the same option settings.

The third use of the set command is to set the values of the shell’s positional parameters to the specified args. To change the positional parameters without changing any options, use “--” as the first argument to set. If no args are present, the set command will clear all the positional parameters (equivalent to executing “shift \$#”).

shift [*n*]

Shift the positional parameters *n* times. A **shift** sets the value of \$1 to the value of \$2, the value of \$2 to the value of \$3, and so on, decreasing the value of \$# by one. If *n* is greater than the number of positional parameters, **shift** will issue an error message, and exit with return status 2.

test *expression*

[*expression*]

The **test** utility evaluates the expression and, if it evaluates to true, returns a zero (true) exit status; otherwise it returns 1 (false). If there is no expression, test also returns 1 (false).

All operators and flags are separate arguments to the **test** utility.

The following primaries are used to construct expression:

- b *file* True if *file* exists and is a block special file.
- c *file* True if *file* exists and is a character special file.
- d *file* True if *file* exists and is a directory.
- e *file* True if *file* exists (regardless of type).
- f *file* True if *file* exists and is a regular file.
- g *file* True if *file* exists and its set group ID flag is set.

-h file True if *file* exists and is a symbolic link.

-k file True if *file* exists and its sticky bit is set.

-n string True if the length of *string* is nonzero.

-p file True if *file* is a named pipe (FIFO).

-r file True if *file* exists and is readable.

-s file True if *file* exists and has a size greater than zero.

-t file_descriptor True if the file whose file descriptor number is *file_descriptor* is open and is associated with a terminal.

-u file True if *file* exists and its set user ID flag is set.

-w file True if *file* exists and is writable. True indicates only that the write flag is on. The file is not writable on a read-only file system even if this test indicates true.

-x file True if *file* exists and is executable. True indicates only that the execute flag is on. If *file* is a directory, true indicates that *file* can be searched.

-z string True if the length of *string* is zero.

-L file True if *file* exists and is a symbolic link. This operator is retained for compatibility with previous versions of this program. Do not rely on its existence; use **-h** instead.

-o file True if *file* exists and its owner matches the effective user id of this process.

-G file True if *file* exists and its group matches the effective group id of this process.

-s file True if *file* exists and is a socket.

file1 -nt file2 True if *file1* and *file2* exist and *file1* is newer than *file2*.

file1 -ot file2 True if *file1* and *file2* exist and *file1* is older than *file2*.

file1 -ef file2 True if *file1* and *file2* exist and refer to the same file.

string True if *string* is not the null string.

s1 = s2 True if the strings *s1* and *s2* are identical.

s1 != s2 True if the strings *s1* and *s2* are not identical.

s1 < s2 True if string *s1* comes before *s2* based on the ASCII value of their characters.

s1 > s2 True if string *s1* comes after *s2* based on the ASCII value of their characters.

n1 -eq n2 True if the integers *n1* and *n2* are algebraically equal.

n1 -ne n2 True if the integers *n1* and *n2* are not algebraically equal.

n1 -gt n2 True if the integer *n1* is algebraically greater than the integer *n2*.

n1 -ge n2 True if the integer *n1* is algebraically greater than or equal to the integer *n2*.

n1 -lt n2 True if the integer *n1* is algebraically less than the integer *n2*.

n1 -le n2 True if the integer *n1* is algebraically less than or equal to the integer *n2*.

These primaries can be combined with the following operators:

! *expression*
True if *expression* is false.

expression1 -a expression2
True if both *expression1* and *expression2* are true.

expression1 -o expression2
True if either *expression1* or *expression2* are true.

(*expression***)**
True if *expression* is true.

The **-a** operator has higher precedence than the **-o** operator.

times Print the accumulated user and system times for the shell and for processes run from the shell. The return status is 0.

trap [*action signal . . .*]

Cause the shell to parse and execute action when any of the specified signals are received. The signals are specified by signal number or as the name of the signal. If *signal* is 0 or EXIT, the action is executed when the shell exits. *action* may be empty (''), which causes the specified signals to be ignored. With *action* omitted or set to '-' the specified signals are set to their default action. When the shell forks off a subshell, it resets trapped (but not ignored) signals to the default action. The **trap** command has no effect on signals that were ignored on entry to the shell. **trap** without any arguments cause it to write a list of signals and their associated action to the standard output in a format that is suitable as an input to the shell that achieves the same trapping results.

Examples:

trap

List trapped signals and their corresponding action

trap '' INT QUIT tstop 30

Ignore signals INT QUIT TSTOP USR1

trap date INT

Print date upon receiving signal INT

type [*name . . .*]

Interpret each name as a command and print the resolution of the command search. Possible resolutions are: shell keyword, alias, shell builtin, command, tracked alias and not found. For aliases the alias expansion is printed; for commands and tracked aliases the complete pathname of the command is printed.

ulimit [**-H** | **-S**] [**-a** | **-tfdscmlpnv** [*value*]]

Inquire about or set the hard or soft limits on processes or set new limits. The choice between hard limit (which no process is allowed to violate, and which may not be raised once it has been lowered) and soft limit (which causes processes to be signaled but not necessarily killed, and which may be raised) is made with these flags:

- H** set or inquire about hard limits
- S** set or inquire about soft limits. If neither **-H** nor **-S** is specified, the soft limit is displayed or both limits are set. If both are specified, the last one wins.

The limit to be interrogated or set, then, is chosen by specifying any one of these flags:

- a** show all the current limits
- t** show or set the limit on CPU time (in seconds)
- f** show or set the limit on the largest file that can be created (in 512-byte blocks)
- d** show or set the limit on the data segment size of a process (in kilobytes)
- s** show or set the limit on the stack size of a process (in kilobytes)
- c** show or set the limit on the largest core dump size that can be produced (in 512-byte blocks)
- m** show or set the limit on the total physical memory that can be in use by a process (in kilobytes)
- l** show or set the limit on how much memory a process can lock with `mlock(2)` (in kilobytes)
- p** show or set the limit on the number of processes this user can have at one time
- n** show or set the limit on the number files a process can have open at once
- v** show or set the limit on the total virtual memory that can be in use by a process (in kilobytes)
- r** show or set the limit on the real-time scheduling priority of a process

If none of these is specified, it is the limit on file size that is shown or set. If value is specified, the limit is set to that number; otherwise the current limit is displayed.

Limits of an arbitrary process can be displayed or set using the `sysctl(8)` utility.

umask [*mask*]

Set the value of umask (see `umask(2)`) to the specified octal value. If the argument is omitted, the umask value is printed.

unalias [-a] [*name*]

If *name* is specified, the shell removes that alias. If **-a** is specified, all aliases are removed.

unset [-fv] [*name* . . .]

The specified variables and functions are unset and unexported. If **-f** or **-v** is specified, the corresponding function or variable is unset, respectively. If a given name corresponds to both a variable and a function, and no options are given, only the variable is unset.

wait [*job*]

Wait for the specified job to complete and return the exit status of the last process in the job. If the argument is omitted, wait for all jobs to complete and return an exit status of zero.

Command Line Editing

When `dash` is being used interactively from a terminal, the current command and the command history (see `fc` in **Builtins**) can be edited using vi-mode command-line editing. This mode uses commands, described below, similar to a subset of those described in the vi man page. The command `set -o vi` enables vi-mode editing and places sh into vi insert mode. With vi-mode enabled, sh can be switched between insert mode and command mode. It is similar to vi: typing `<ESC>` enters vi command mode. Hitting `<return>` while

in command mode will pass the line to the shell.

EXIT STATUS

Errors that are detected by the shell, such as a syntax error, will cause the shell to exit with a non-zero exit status. If the shell is not an interactive shell, the execution of the shell file will be aborted. Otherwise the shell will return the exit status of the last command executed, or if the exit builtin is used with a numeric argument, it will return the argument.

ENVIRONMENT

HOME	Set automatically by <code>login(1)</code> from the user's login directory in the password file (<code>passwd(4)</code>). This environment variable also functions as the default argument for the <code>cd</code> builtin.
PATH	The default search path for executables. See the above section Path Search .
CDPATH	The search path used with the <code>cd</code> builtin.
MAIL	The name of a mail file, that will be checked for the arrival of new mail. Overridden by <code>MAILPATH</code> .
MAILCHECK	The frequency in seconds that the shell checks for the arrival of mail in the files specified by the <code>MAILPATH</code> or the <code>MAIL</code> file. If set to 0, the check will occur at each prompt.
MAILPATH	A colon ":" separated list of file names, for the shell to check for incoming mail. This environment setting overrides the <code>MAIL</code> setting. There is a maximum of 10 mailboxes that can be monitored at once.
PS1	The primary prompt string, which defaults to "\$ ", unless you are the superuser, in which case it defaults to "# ".
PS2	The secondary prompt string, which defaults to ">".
PS4	Output before each line when execution trace (set -x) is enabled, defaults to "+".
IFS	Input Field Separators. This is normally set to <space>, <tab>, and <newline>. See the White Space Splitting section for more details.
TERM	The default terminal setting for the shell. This is inherited by children of the shell, and is used in the history editing modes.
HISTSIZE	The number of lines in the history buffer for the shell.
PWD	The logical value of the current working directory. This is set by the <code>cd</code> command.
OLDPWD	The previous logical value of the current working directory. This is set by the <code>cd</code> command.
PPID	The process ID of the parent process of the shell.

FILES

`$HOME/.profile`
`/etc/profile`

SEE ALSO

`csh(1)`, `echo(1)`, `getopt(1)`, `ksh(1)`, `login(1)`, `printf(1)`, `test(1)`, `getopt(3)`, `passwd(5)`, `environ(7)`, `sysctl(8)`

HISTORY

dash is a POSIX-compliant implementation of /bin/sh that aims to be as small as possible. **dash** is a direct descendant of the NetBSD version of ash (the Almquist SHell), ported to Linux in early 1997. It was renamed to **dash** in 2002.

BUGS

Setuid shell scripts should be avoided at all costs, as they are a significant security risk.

PS1, PS2, and PS4 should be subject to parameter expansion before being displayed.

NAME

sha1sum – compute and check SHA1 message digest

SYNOPSIS

sha1sum [*OPTION*]... [*FILE*]...

DESCRIPTION

Print or check SHA1 (160-bit) checksums.

With no FILE, or when FILE is `-`, read standard input.

-b, --binary

read in binary mode

-c, --check

read SHA1 sums from the FILEs and check them

--tag create a BSD-style checksum

-t, --text

read in text mode (default)

-z, --zero

end each output line with NUL, not newline, and disable file name escaping

The following five options are useful only when verifying checksums:

--ignore-missing

don't fail or report status for missing files

--quiet

don't print OK for each successfully verified file

--status

don't output anything, status code shows success

--strict

exit non-zero for improperly formatted checksum lines

-w, --warn

warn about improperly formatted checksum lines

--help display this help and exit

--version

output version information and exit

The sums are computed as described in FIPS-180-1. When checking, the input should be a former output of this program. The default mode is to print a line with checksum, a space, a character indicating input mode ('*' for binary, ' ' for text or where binary is insignificant), and name for each FILE.

Note: There is no difference between binary mode and text mode on GNU systems.

BUGS

Do not use the SHA-1 algorithm for security related purposes. Instead, use an SHA-2 algorithm, implemented in the programs sha224sum(1), sha256sum(1), sha384sum(1), sha512sum(1), or the BLAKE2 algorithm, implemented in b2sum(1)

NAME

sha224sum – compute and check SHA224 message digest

SYNOPSIS

sha224sum [*OPTION*]... [*FILE*]...

DESCRIPTION

Print or check SHA224 (224-bit) checksums.

With no FILE, or when FILE is `-`, read standard input.

-b, --binary

read in binary mode

-c, --check

read SHA224 sums from the FILES and check them

--tag create a BSD-style checksum

-t, --text

read in text mode (default)

-z, --zero

end each output line with NUL, not newline, and disable file name escaping

The following five options are useful only when verifying checksums:

--ignore-missing

don't fail or report status for missing files

--quiet

don't print OK for each successfully verified file

--status

don't output anything, status code shows success

--strict

exit non-zero for improperly formatted checksum lines

-w, --warn

warn about improperly formatted checksum lines

--help display this help and exit

--version

output version information and exit

The sums are computed as described in RFC 3874. When checking, the input should be a former output of this program. The default mode is to print a line with checksum, a space, a character indicating input mode ('*' for binary, ' ' for text or where binary is insignificant), and name for each FILE.

Note: There is no difference between binary mode and text mode on GNU systems.

NAME

sha256sum – compute and check SHA256 message digest

SYNOPSIS

sha256sum [*OPTION*]... [*FILE*]...

DESCRIPTION

Print or check SHA256 (256-bit) checksums.

With no FILE, or when FILE is `-`, read standard input.

-b, --binary

read in binary mode

-c, --check

read SHA256 sums from the FILES and check them

--tag create a BSD-style checksum

-t, --text

read in text mode (default)

-z, --zero

end each output line with NUL, not newline, and disable file name escaping

The following five options are useful only when verifying checksums:

NAME

shadow – shadowed password file

DESCRIPTION

shadow is a file which contains the password information for the system's accounts and optional aging information.

This file must not be readable by regular users if password security is to be maintained.

Each line of this file contains 9 fields, separated by colons (“：“), in the following order:

login name

It must be a valid account name, which exist on the system.

encrypted password

This field may be empty, in which case no passwords are required to authenticate as the specified login name. However, some applications which read the /etc/shadow file may decide not to permit any access at all if the password field is empty.

A password field which starts with an exclamation mark means that the password is locked. The remaining characters on the line represent the password field before the password was locked.

Refer to **crypt(3)** for details on how this string is interpreted.

If the password field contains some string that is not a valid result of **crypt(3)**, for instance ! or *, the user will not be able to use a unix password to log in (but the user may log in the system by other means).

date of last password change

The date of the last password change, expressed as the number of days since Jan 1, 1970.

The value 0 has a special meaning, which is that the user should change her password the next time she will log in the system.

An empty field means that password aging features are disabled.

minimum password age

The minimum password age is the number of days the user will have to wait before she will be allowed to change her password again.

An empty field and value 0 mean that there are no minimum password age.

maximum password age

The maximum password age is the number of days after which the user will have to change her password.

After this number of days is elapsed, the password may still be valid. The user should be asked to change her password the next time she will log in.

An empty field means that there are no maximum password age, no password warning period, and no password inactivity period (see below).

If the maximum password age is lower than the minimum password age, the user cannot change her password.

password warning period

The number of days before a password is going to expire (see the maximum password age above) during which the user should be warned.

An empty field and value 0 mean that there are no password warning period.

password inactivity period

The number of days after a password has expired (see the maximum password age above) during which the password should still be accepted (and the user should update her password during the next login).

After expiration of the password and this expiration period is elapsed, no login is possible using the current user's password. The user should contact her administrator.

An empty field means that there are no enforcement of an inactivity period.

account expiration date

The date of expiration of the account, expressed as the number of days since Jan 1, 1970.

Note that an account expiration differs from a password expiration. In case of an account expiration, the user shall not be allowed to login. In case of a password expiration, the user is not allowed to login using her password.

An empty field means that the account will never expire.

The value 0 should not be used as it is interpreted as either an account with no expiration, or as an expiration on Jan 1, 1970.

reserved field

This field is reserved for future use.

FILES

/etc/passwd

User account information.

/etc/shadow

Secure user account information.

/etc/shadow-

Backup file for /etc/shadow.

Note that this file is used by the tools of the shadow toolsuite, but not by all user and password management tools.

SEE ALSO

[chage\(1\)](#), [login\(1\)](#), [passwd\(1\)](#), [passwd\(5\)](#), [pwck\(8\)](#), [pwconv\(8\)](#), [pwunconv\(8\)](#), [su\(1\)](#), [sulogin\(8\)](#).

NAME

`shasum` – Print or Check SHA Checksums

SYNOPSIS

```
Usage: shasum [OPTION]... [FILE]...
Print or check SHA checksums.
With no FILE, or when FILE is -, read standard input.

-a, --algorithm    1 (default), 224, 256, 384, 512, 512224, 512256
-b, --binary       read in binary mode
-c, --check        read SHA sums from the FILES and check them
--tag              create a BSD-style checksum
-t, --text         read in text mode (default)
-U, --UNIVERSAL   read in Universal Newlines mode
                  produces same digest on Windows/Unix/Mac
-O, --01           read in BITS mode
                  ASCII '0' interpreted as 0-bit,
                  ASCII '1' interpreted as 1-bit,
                  all other characters ignored

The following five options are useful only when verifying checksums:
--ignore-missing  don't fail or report status for missing files
-q, --quiet        don't print OK for each successfully verified file
-s, --status       don't output anything, status code shows success
--strict          exit non-zero for improperly formatted checksum lines
-w, --warn         warn about improperly formatted checksum lines

-h, --help          display this help and exit
-v, --version      output version information and exit
```

When verifying SHA-512/224 or SHA-512/256 checksums, indicate the algorithm explicitly using the `-a` option, e.g.

```
shasum -a 512224 -c checksumfile
```

The sums are computed as described in FIPS PUB 180-4. When checking, the input should be a former output of this program. The default mode is to print a line with checksum, a character indicating type (`*` for binary, ` ` for text, `U` for UNIVERSAL, `^` for BITS), and name for each FILE. The line starts with a `\' character if the FILE name contains either newlines or backslashes, which are then replaced by the two-character sequences `\'n` and `\\` respectively.

Report `shasum` bugs to mshelor@cpan.org

DESCRIPTION

Running `shasum` is often the quickest way to compute SHA message digests. The user simply feeds data to the script through files or standard input, and then collects the results from standard output.

The following command shows how to compute digests for typical inputs such as the NIST test vector “abc”:

```
perl -e "print qq(abc)" | shasum
```

Or, if you want to use SHA-256 instead of the default SHA-1, simply say:

```
perl -e "print qq(abc)" | shasum -a 256
```

Since `shasum` mimics the behavior of the combined GNU `sha1sum`, `sha224sum`, `sha256sum`, `sha384sum`,

and *sha512sum* programs, you can install this script as a convenient drop-in replacement.

Unlike the GNU programs, *shasum* encompasses the full SHA standard by allowing partial-byte inputs. This is accomplished through the BITS option (*-0*). The following example computes the SHA-224 digest of the 7-bit message *0001100*:

```
perl -e "print qq(0001100)" | shasum -0 -a 224
```

SEE ALSO

shasum is implemented using the Perl module Digest::SHA.

NAME

shell-quote – quote arguments for safe use, unmodified in a shell command

SYNOPSIS

shell-quote [*switch*]... *arg*...

DESCRIPTION

shell-quote lets you pass arbitrary strings through the shell so that they won't be changed by the shell. This lets you process commands or files with embedded white space or shell globbing characters safely. Here are a few examples.

EXAMPLES**ssh preserving args**

When running a remote command with ssh, ssh doesn't preserve the separate arguments it receives. It just joins them with spaces and passes them to \$SHELL -c. This doesn't work as intended:

```
ssh host touch 'hi there'           # fails
```

It creates 2 files, *hi* and *there*. Instead, do this:

```
cmd='shell-quote touch \'hi there\'`  
ssh host "$cmd"
```

This gives you just 1 file, *hi there*.

process find output

It's not ordinarily possible to process an arbitrary list of files output by **find** with a shell script. Anything you put in \$IFS to split up the output could legitimately be in a file's name. Here's how you can do it using **shell-quote**:

```
eval set -- `find -type f -print0 | xargs -0 shell-quote --`
```

debug shell scripts

shell-quote is better than **echo** for debugging shell scripts.

```
debug() {  
    [ -z "$debug" ] || shell-quote "debug: \"\$@\""  
}
```

With **echo** you can't tell the difference between debug 'foo bar' and debug foo bar, but with **shell-quote** you can.

save a command for later

shell-quote can be used to build up a shell command to run later. Say you want the user to be able to give you switches for a command you're going to run. If you don't want the switches to be re-evaluated by the shell (which is usually a good idea, else there are things the user can't pass through), you can do something like this:

```
user_switches=  
while [ $# != 0 ]  
do  
    case x$1 in  
        x--pass-through)  
            [ $# -gt 1 ] || die "need an argument for $1"  
            user_switches="$user_switches `shell-quote -- \"$2\"`  
            shift;;  
        # process other switches  
    esac  
    shift  
done  
# later  
eval "shell-quote some-command $user_switches my args"
```

OPTIONS**--debug**

Turn debugging on.

--help

Show the usage message and die.

--version

Show the version number and exit.

AVAILABILITY

The code is licensed under the GNU GPL. Check <http://www.argon.org/~roderick/> or CPAN for updated versions.

NAME

shells – pathnames of valid login shells

DESCRIPTION

/etc/shells is a text file which contains the full pathnames of valid login shells. This file is consulted by **chsh(1)** and available to be queried by other programs.

Be aware that there are programs which consult this file to find out if a user is a normal user; for example, FTP daemons traditionally disallow access to users with shells not included in this file.

FILES

/etc/shells

EXAMPLES

/etc/shells may contain the following paths:

/bin/sh
/bin/bash
/bin/csh

SEE ALSO

chsh(1), **getusershell(3)**, **pam_shells(8)**

showmount(8) - Linux man page

Name

showmount - show mount information for an NFS server

Synopsis

```
showmount [ -adehv ] [ --all ] [ --directories ] [ --exports ] [ --help ] [ --version ]  
[ host ]
```

Description

showmount queries the mount daemon on a remote host for information about the state of the NFS server on that machine. With no options **showmount** lists the set of clients who are mounting from that host. The output from **showmount** is designed to appear as though it were processed through "sort -u".

Options

-a or **--all**

List both the client hostname or IP address and mounted directory in host:dir format. This info should not be considered reliable. See the notes on rmtab in [**rpc.mountd\(8\)**](#).

-d or **--directories**

List only the directories mounted by some client.

-e or **--exports**

Show the NFS server's export list.

-h or **--help**

Provide a short help summary.

-v or **--version**

Report the current version number of the program.

--no-headers

Suppress the descriptive headings from the output.

See Also

[**rpc.mountd\(8\)**](#), [**rpc.nfsd\(8\)**](#)

Bugs

The completeness and accuracy of the information that **showmount** displays varies according to the NFS server's implementation.

Because **showmount** sorts and unqs the output, it is impossible to determine from the output whether a client is mounting the same directory more than once.

NAME

skill, **snice** – send a signal or report process status

SYNOPSIS

skill [*signal*] [*options*] *expression*
snice [*new priority*] [*options*] *expression*

DESCRIPTION

These tools are obsolete and unportable. The command syntax is poorly defined. Consider using the killall, pkill, and pgrep commands instead.

The default signal for skill is TERM. Use -l or -L to list available signals. Particularly useful signals include HUP, INT, KILL, STOP, CONT, and 0. Alternate signals may be specified in three ways: -9 –SIGKILL –KILL.

The default priority for snice is +4. Priority numbers range from +20 (slowest) to -20 (fastest). Negative priority numbers are restricted to administrative users.

OPTIONS**-f, --fast**

Fast mode. This option has not been implemented.

-i, --interactive

Interactive use. You will be asked to approve each action.

-l, --list

List all signal names.

-L, --table

List all signal names in a nice table.

-n, --no-action

No action; perform a simulation of events that would occur but do not actually change the system.

-v, --verbose

Verbose; explain what is being done.

-w, --warnings

Enable warnings. This option has not been implemented.

-h, --help

Display help text and exit.

-V, --version

Display version information.

PROCESS SELECTION OPTIONS

Selection criteria can be: terminal, user, pid, command. The options below may be used to ensure correct interpretation.

-t, --tty *tty*

The next expression is a terminal (tty or pty).

-u, --user *user*

The next expression is a username.

-p, --pid *pid*

The next expression is a process ID number.

-c, --command *command*

The next expression is a command name.

--ns *pid*

Match the processes that belong to the same namespace as pid.

--nslist ns,...

list which namespaces will be considered for the --ns option. Available namespaces: ipc, mnt, net, pid, user, uts.

SIGNALS

The behavior of signals is explained in **signal(7)** manual page.

EXAMPLES

snice -c seti -c crack +7

Slow down seti and crack commands.

skill -KILL -t /dev/pts/*

Kill users on PTY devices.

skill -STOP -u viro -u lm -u davem

Stop three users.

SEE ALSO

kill(1), kill(2), killall(1), nice(1), pkill(1), renice(1), signal(7)

STANDARDS

No standards apply.

AUTHOR

Albert Cahalan <albert@users.sf.net> wrote skill and snice in 1999 as a replacement for a non-free version.

REPORTING BUGS

NAME

sort – sort lines of text files

SYNOPSIS

```
sort [OPTION]... [FILE]...
sort [OPTION]... --files0-from=F
```

DESCRIPTION

Write sorted concatenation of all FILE(s) to standard output.

With no FILE, or when FILE is **-**, read standard input.

Mandatory arguments to long options are mandatory for short options too. Ordering options:

-b, --ignore-leading-blanks

ignore leading blanks

-d, --dictionary-order

consider only blanks and alphanumeric characters

-f, --ignore-case

fold lower case to upper case characters

-g, --general-numeric-sort

compare according to general numerical value

-i, --ignore-nonprinting

consider only printable characters

-M, --month-sort

compare (unknown) < 'JAN' < ... < 'DEC'

-h, --human-numeric-sort

compare human readable numbers (e.g., 2K 1G)

-n, --numeric-sort

compare according to string numerical value

-R, --random-sort

shuffle, but group identical keys. See shuf(1)

--random-source=FILE

get random bytes from FILE

-r, --reverse

reverse the result of comparisons

--sort=WORD

sort according to WORD: general-numeric **-g**, human-numeric **-h**, month **-M**, numeric **-n**, random **-R**, version **-V**

-V, --version-sort

natural sort of (version) numbers within text

Other options:

--batch-size=NERGE

merge at most NERGE inputs at once; for more use temp files

-c, --check, --check=diagnose-first

check for sorted input; do not sort

-C, --check=quiet, --check=silent

like **-c**, but do not report first bad line

--compress-program=PROG

compress temporaries with PROG; decompress them with PROG **-d**

--debug
 annotate the part of the line used to sort, and warn about questionable usage to stderr

--files0-from=F
 read input from the files specified by NUL-terminated names in file F; If F is – then read names from standard input

-k, --key=KEYDEF
 sort via a key; KEYDEF gives location and type

-m, --merge
 merge already sorted files; do not sort

-o, --output=FILE
 write result to FILE instead of standard output

-s, --stable
 stabilize sort by disabling last-resort comparison

-S, --buffer-size=SIZE
 use SIZE for main memory buffer

-t, --field-separator=SEP
 use SEP instead of non-blank to blank transition

-T, --temporary-directory=DIR
 use DIR for temporaries, not \$TMPDIR or /tmp; multiple options specify multiple directories

--parallel=N
 change the number of sorts run concurrently to N

-u, --unique
 with -c, check for strict ordering; without -c, output only the first of an equal run

-z, --zero-terminated
 line delimiter is NUL, not newline

--help display this help and exit

--version
 output version information and exit

KEYDEF is F[.C][OPTS][,F[.C][OPTS]] for start and stop position, where F is a field number and C a character position in the field; both are origin 1, and the stop position defaults to the line's end. If neither -t nor -b is in effect, characters in a field are counted from the beginning of the preceding whitespace. OPTS is one or more single-letter ordering options [bdfgiMhnRrV], which override global ordering options for that key. If no key is given, use the entire line as the key. Use--deb ug to diagnose incorrect key usage.

SIZE may be followed by the following multiplicative suffixes: % 1% of memory, b 1, K 1024 (default), and so on for M, G, T, P, E, Z, Y.

*** WARNING *** The locale specified by the environment affects sort order. Set LC_ALL=C to get the traditional sort order that uses native byte values.

NAME

ss – another utility to investigate sockets

SYNOPSIS

ss [options] [FILTER]

DESCRIPTION

ss is used to dump socket statistics. It allows showing information similar to *netstat*. It can display more TCP and state information than other tools.

OPTIONS

When no option is used **ss** displays a list of open non-listening sockets (e.g. TCP/UNIX/UDP) that have established connection.

-h, --help

Show summary of options.

-V, --version

Output version information.

-H, --no-header

Suppress header line.

-O, --oneline

Print each socket's data on a single line.

-n, --numeric

Do not try to resolve service names. Show exact bandwidth values, instead of human-readable.

-r, --resolve

Try to resolve numeric address/ports.

-a, --all

Display both listening and non-listening (for TCP this means established connections) sockets.

-l, --listening

Display only listening sockets (these are omitted by default).

-o, --options

Show timer information. For TCP protocol, the output format is:

timer:(<timer_name>,<expire_time>,<retrans>)

<timer_name>

the name of the timer, there are five kind of timer names:

on : means one of these timers: TCP retrans timer, TCP early retrans timer and tail loss probe timer

keepalive: tcp keep alive timer

timewait: timewait stage timer

persist: zero window probe timer

unknown: none of the above timers

<expire_time>

how long time the timer will expire

<retrans>

how many times the retransmission occurred

-e, --extended

Show detailed socket information. The output format is:

uid:<uid_number> ino:<inode_number> sk:<cookie>

<uid_number>
 the user id the socket belongs to

<inode_number>
 the socket's inode number in VFS

<cookie>
 an uuid of the socket

-m, --memory
 Show socket memory usage. The output format is:
 skmem:(r<rmem_alloc>,rb<recv_buf>,t<wmem_alloc>,tb<snd_buf>,
 f<fwd_alloc>,w<wmem_queued>,o<opt_mem>,
 bl<back_log>,d<sock_drop>)

<rmem_alloc>
 the memory allocated for receiving packet

<recv_buf>
 the total memory can be allocated for receiving packet

<wmem_alloc>
 the memory used for sending packet (which has been sent to layer 3)

<snd_buf>
 the total memory can be allocated for sending packet

<fwd_alloc>
 the memory allocated by the socket as cache, but not used for receiving/sending packet yet. If need memory to send/receive packet, the memory in this cache will be used before allocate additional memory.

<wmem_queued>
 The memory allocated for sending packet (which has not been sent to layer 3)

<ropt_mem>
 The memory used for storing socket option, e.g., the key for TCP MD5 signature

<back_log>
 The memory used for the sk backlog queue. On a process context, if the process is receiving packet, and a new packet is received, it will be put into the sk backlog queue, so it can be received by the process immediately

<sock_drop>
 the number of packets dropped before they are de-multiplexed into the socket

-p, --processes
 Show process using socket.

-i, --info
 Show internal TCP information. Below fields may appear:
 ts show string "ts" if the timestamp option is set
 sack show string "sack" if the sack option is set
 ecn show string "ecn" if the explicit congestion notification option is set
 ecnseen show string "ecnseen" if the saw ecn flag is found in received packets
 fastopen show string "fastopen" if the fastopen option is set

cong_alg
the congestion algorithm name, the default congestion algorithm is "cubic"

wscale:<snd_wscale>:<rcv_wscale>
if window scale option is used, this field shows the send scale factor and receive scale factor

rto:<icsk_rto>
tcp re-transmission timeout value, the unit is millisecond

backoff:<icsk_backoff>
used for exponential backoff re-transmission, the actual re-transmission timeout value is iks_rto << iks_backoff

rtt:<rtt>/<rttvar>
rtt is the average round trip time, rttvar is the mean deviation of rtt, their units are millisecond

ato:<ato>
ack timeout, unit is millisecond, used for delay ack mode

mss:<mss>
max segment size

cwnd:<cwnd>
congestion window size

pmtu:<pmtu>
path MTU value

ssthresh:<ssthresh>
tcp congestion window slow start threshold

bytes_acked:<bytes_acked>
bytes acked

bytes_received:<bytes_received>
bytes received

segs_out:<segs_out>
segments sent out

segs_in:<segs_in>
segments received

send <send_bps>bps
egress bps

lastsnd:<lastsnd>
how long time since the last packet sent, the unit is millisecond

lastrecv:<lastrecv>
how long time since the last packet received, the unit is millisecond

lastack:<lastack>
how long time since the last ack received, the unit is millisecond

pacing_rate <pacing_rate>bps/<max_pacing_rate>bps
the pacing rate and max pacing rate

recv_space:<recv_space>
a helper variable for TCP internal auto tuning socket receive buffer

tcp-ulp-mptcp flags:[MmBbJjecv] token:<rem_token(rem_id)/loc_token(loc_id)> seq:<sn> sfseq:<ssn> ssnoff:<off> maplen:<maplen>
MPTCP subflow information

- tos** Show ToS and priority information. Below fields may appear:
- tos** IPv4 Type-of-Service byte
 - tclass** IPv6 Traffic Class byte
 - class_id**
Class id set by net_cls cgroup. If class is zero this shows priority set by SO_PRIORITY.
- cgroup**
Show cgroup information. Below fields may appear:
- cgroup** Cgroup v2 pathname. This pathname is relative to the mount point of the hierarchy.
- K, --kill**
Attempts to forcibly close sockets. This option displays sockets that are successfully closed and silently skips sockets that the kernel does not support closing. It supports IPv4 and IPv6 sockets only.
- s, --summary**
Print summary statistics. This option does not parse socket lists obtaining summary from various sources. It is useful when amount of sockets is so huge that parsing /proc/net/tcp is painful.
- E, --events**
Continually display sockets as they are destroyed
- Z, --context**
As the **-p** option but also shows process security context.
- For **netlink(7)** sockets the initiating process context is displayed as follows:
1. If valid pid show the process context.
 2. If destination is kernel (pid = 0) show kernel initial context.
 3. If a unique identifier has been allocated by the kernel or netlink user, show context as "unavailable". This will generally indicate that a process has more than one netlink socket active.
- z, --contexts**
As the **-Z** option but also shows the socket context. The socket context is taken from the associated inode and is not the actual socket context held by the kernel. Sockets are typically labeled with the context of the creating process, however the context shown will reflect any policy role, type and/or range transition rules applied, and is therefore a useful reference.
- N NSNAME, --net=NSNAME**
Switch to the specified network namespace name.
- b, --bpf**
Show socket classic BPF filters (only administrators are allowed to get these information).
- 4, --ipv4**
Display only IP version 4 sockets (alias for -f inet).
- 6, --ipv6**
Display only IP version 6 sockets (alias for -f inet6).
- 0, --packet**
Display PACKET sockets (alias for -f link).
- t, --tcp**
Display TCP sockets.
- u, --udp**
Display UDP sockets.

-d, --dccp
Display DCCP sockets.

-w, --raw
Display RAW sockets.

-x, --unix
Display Unix domain sockets (alias for -f unix).

-S, --sctp
Display SCTP sockets.

--vsock
Display vsock sockets (alias for -f vsock).

--xdp Display XDP sockets (alias for -f xdp).

--inet-sockopt
Display inet socket options.

-f FAMILY, --family=FAMILY
Display sockets of type FAMILY. Currently the following families are supported: unix, inet, inet6, link, netlink, vssock, xdp.

-A QUERY, --query=QUERY, --socket=QUERY
List of socket tables to dump, separated by commas. The following identifiers are understood: all, inet, tcp, udp, raw, unix, packet, netlink, unix_dgram, unix_stream, unix_seqpacket, packet_raw, packet_dgram, dccp, sctp, vsock_stream, vsock_dgram, xdp Any item in the list may optionally be prefixed by an exclamation mark (!) to exclude that socket table from being dumped.

-D FILE, --diag=FILE
Do not display anything, just dump raw information about TCP sockets to FILE after applying filters. If FILE is - stdout is used.

-F FILE, --filter=FILE
Read filter information from FILE. Each line of FILE is interpreted like single command line option. If FILE is - stdin is used.

FILTER := [state STATE-FILTER] [EXPRESSION]
Please take a look at the official documentation for details regarding filters.

STATE-FILTER

STATE-FILTER allows to construct arbitrary set of states to match. Its syntax is sequence of keywords state and exclude followed by identifier of state.

Available identifiers are:

All standard TCP states: **established**, **syn-sent**, **syn-recv**, **fin-wait-1**, **fin-wait-2**, **time-wait**, **closed**, **close-wait**, **last-ack**, **listening** and **closing**.

all - for all the states

connected - all the states except for **listening** and **closed**

synchronized - all the **connected** states except for **syn-sent**

bucket - states, which are maintained as minisockets, i.e. **time-wait** and **syn-recv**

big - opposite to **bucket**

EXPRESSION

EXPRESSION allows filtering based on specific criteria. **EXPRESSION** consists of a series of predicates combined by boolean operators. The possible operators in increasing order of precedence are **or** (or | or ||), **and** (or & or &&), and **not** (or !). If no operator is between consecutive predicates, an implicit **and** operator is assumed. Subexpressions can be grouped with "(" and ")".

The following predicates are supported:

{dst|src} [=] HOST

Test if the destination or source matches HOST. See HOST SYNTAX for details.

{dport|sport} [OP] [FAMILY:]PORT

Compare the destination or source port to PORT. OP can be any of "<", "<=", "=", "!=" or ">". Following normal arithmetic rules. FAMILY and PORT are as described in HOST SYNTAX below.

dev [=!=] DEVICE

Match based on the device the connection uses. DEVICE can either be a device name or the index of the interface.

fwmark [=!=] MASK

Matches based on the fwmark value for the connection. This can either be a specific mark value or a mark value followed by a "/" and a bitmask of which bits to use in the comparison. For example "fwmark = 0x01/0x03" would match if the two least significant bits of the fwmark were 0x01.

cgroup [=!=] PATH

Match if the connection is part of a cgroup at the given path.

autobound

Match if the port or path of the source address was automatically allocated (rather than explicitly specified).

Most operators have aliases. If no operator is supplied "=" is assumed. Each of the following groups of operators are all equivalent:

- == eq
- != ne neq
- > gt
- < lt
- >= ge geq
- <= le leq
- ! not
- | || or
- & && and

HOST SYNTAX

The general host syntax is [FAMILY:]ADDRESS[:PORT].

FAMILY must be one of the families supported by the -f option. If not given it defaults to the family given with the -f option, and if that is also missing, will assume either inet or inet6. Note that all host conditions in the expression should either all be the same family or be only inet and inet6. If there is some other mixture of families, the results will probably be unexpected.

The form of ADDRESS and PORT depends on the family used. "*" can be used as a wildcard for either the address or port. The details for each family are as follows:

unix ADDRESS is a glob pattern (see **fnmatch(3)**) that will be matched case-insensitively against the unix socket's address. Both path and abstract names are supported. Unix addresses do not support

a port, and "*" cannot be used as a wildcard.

link ADDRESS is the case-insensitive name of an Ethernet protocol to match. PORT is either a device name or a device index for the desired link device, as seen in the output of ip link.

netlink ADDRESS is a descriptor of the netlink family. Possible values come from /etc/iproute2/nl_protos. PORT is the port id of the socket, which is usually the same as the owning process id. The value "kernel" can be used to represent the kernel (port id of 0).

vsock ADDRESS is an integer representing the CID address, and PORT is the port.

inet and inet6

ADDRESS is an ip address (either v4 or v6 depending on the family) or a DNS hostname that resolves to an ip address of the required version. An ipv6 address must be enclosed in "[" and "]" to disambiguate the port separator. The address may additionally have a prefix length given in CIDR notation (a slash followed by the prefix length in bits). PORT is either the numerical socket port, or the service name for the port to match.

USAGE EXAMPLES

ss -t -a Display all TCP sockets.

ss -t -a -Z

Display all TCP sockets with process SELinux security contexts.

ss -u -a Display all UDP sockets.

ss -o state established '(dport = :ssh or sport = :ssh)'

Display all established ssh connections.

ss -x src /tmp/.X11-unix/*

Find all local processes connected to X server.

ss -o state fin-wait-1 '(sport = :http or sport = :https)' dst 193.233.7/24

List all the tcp sockets in state FIN-WAIT-1 for our apache to network 193.233.7/24 and look at their timers.

ss -a -A 'all,!tcp'

List sockets in all states from all socket tables but TCP.

NAME

ssh — OpenSSH remote login client

SYNOPSIS

```
ssh [-46AaCfGgKkMNnqsTtVvXxYy] [-B bind_interface] [-b bind_address]
     [-c cipher_spec] [-D [bind_address:]port] [-E log_file] [-e escape_char]
     [-F configfile] [-I pkcs11] [-i identity_file] [-J destination]
     [-L address] [-l login_name] [-m mac_spec] [-O ctl_cmd] [-o option]
     [-p port] [-Q query_option] [-R address] [-S ctl_path] [-W host:port]
     [-w local_tun[:remote_tun]] destination [command [argument ...]]
```

DESCRIPTION

ssh (SSH client) is a program for logging into a remote machine and for executing commands on a remote machine. It is intended to provide secure encrypted communications between two untrusted hosts over an insecure network. X11 connections, arbitrary TCP ports and UNIX-domain sockets can also be forwarded over the secure channel.

ssh connects and logs into the specified *destination*, which may be specified as either [user@]hostname or a URI of the form ssh://[user@]hostname[:port]. The user must prove their identity to the remote machine using one of several methods (see below).

If a *command* is specified, it will be executed on the remote host instead of a login shell. A complete command line may be specified as *command*, or it may have additional arguments. If supplied, the arguments will be appended to the command, separated by spaces, before it is sent to the server to be executed.

The options are as follows:

- 4** Forces **ssh** to use IPv4 addresses only.
- 6** Forces **ssh** to use IPv6 addresses only.
- A** Enables forwarding of connections from an authentication agent such as **ssh-agent(1)**. This can also be specified on a per-host basis in a configuration file.

Agent forwarding should be enabled with caution. Users with the ability to bypass file permissions on the remote host (for the agent's UNIX-domain socket) can access the local agent through the forwarded connection. An attacker cannot obtain key material from the agent, however they can perform operations on the keys that enable them to authenticate using the identities loaded into the agent. A safer alternative may be to use a jump host (see **-J**).

- a** Disables forwarding of the authentication agent connection.

-B bind_interface

Bind to the address of *bind_interface* before attempting to connect to the destination host. This is only useful on systems with more than one address.

-b bind_address

Use *bind_address* on the local machine as the source address of the connection. Only useful on systems with more than one address.

- C** Requests compression of all data (including stdin, stdout, stderr, and data for forwarded X11, TCP and UNIX-domain connections). The compression algorithm is the same used by **gzip(1)**. Compression is desirable on modem lines and other slow connections, but will only slow down things on fast networks. The default value can be set on a host-by-host basis in the configuration files; see the **Compression** option.

-c *cipher_spec*

Selects the cipher specification for encrypting the session. *cipher_spec* is a comma-separated list of ciphers listed in order of preference. See the **Ciphers** keyword in *ssh_config(5)* for more information.

-D [*bind_address*:]*port*

Specifies a local “dynamic” application-level port forwarding. This works by allocating a socket to listen to *port* on the local side, optionally bound to the specified *bind_address*. Whenever a connection is made to this port, the connection is forwarded over the secure channel, and the application protocol is then used to determine where to connect to from the remote machine. Currently the SOCKS4 and SOCKS5 protocols are supported, and **ssh** will act as a SOCKS server. Only root can forward privileged ports. Dynamic port forwardings can also be specified in the configuration file.

IPv6 addresses can be specified by enclosing the address in square brackets. Only the superuser can forward privileged ports. By default, the local port is bound in accordance with the **GatewayPorts** setting. However, an explicit *bind_address* may be used to bind the connection to a specific address. The *bind_address* of “localhost” indicates that the listening port be bound for local use only, while an empty address or ‘*’ indicates that the port should be available from all interfaces.

-E *log_file*

Append debug logs to *log_file* instead of standard error.

-e *escape_char*

Sets the escape character for sessions with a pty (default: ‘~’). The escape character is only recognized at the beginning of a line. The escape character followed by a dot (‘.’) closes the connection; followed by control-Z suspends the connection; and followed by itself sends the escape character once. Setting the character to “none” disables any escapes and makes the session fully transparent.

-F *configfile*

Specifies an alternative per-user configuration file. If a configuration file is given on the command line, the system-wide configuration file (*/etc/ssh/ssh_config*) will be ignored. The default for the per-user configuration file is *~/.ssh/config*. If set to “none”, no configuration files will be read.

-f Requests **ssh** to go to background just before command execution. This is useful if **ssh** is going to ask for passwords or passphrases, but the user wants it in the background. This implies **-n**. The recommended way to start X11 programs at a remote site is with something like **ssh -f host xterm**.

If the **ExitOnForwardFailure** configuration option is set to “yes”, then a client started with **-f** will wait for all remote port forwards to be successfully established before placing itself in the background. Refer to the description of **ForkAfterAuthentication** in *ssh_config(5)* for details.

-G Causes **ssh** to print its configuration after evaluating **Host** and **Match** blocks and exit.

-g Allows remote hosts to connect to local forwarded ports. If used on a multiplexed connection, then this option must be specified on the master process.

-I *pkcs11*

Specify the PKCS#11 shared library **ssh** should use to communicate with a PKCS#11 token providing keys for user authentication.

-i *identity_file*

Selects a file from which the identity (private key) for public key authentication is read. You can also specify a public key file to use the corresponding private key that is loaded in `ssh-agent(1)` when the private key file is not present locally. The default is `~/.ssh/id_rsa`, `~/.ssh/id_ecdsa`, `~/.ssh/id_ecdsa_sk`, `~/.ssh/id_ed25519`, `~/.ssh/id_ed25519_sk` and `~/.ssh/id_dsa`. Identity files may also be specified on a per-host basis in the configuration file. It is possible to have multiple **-i** options (and multiple identities specified in configuration files). If no certificates have been explicitly specified by the **CertificateFile** directive, **ssh** will also try to load certificate information from the filename obtained by appending `-cert.pub` to identity filenames.

-J *destination*

Connect to the target host by first making a **ssh** connection to the jump host described by *destination* and then establishing a TCP forwarding to the ultimate destination from there. Multiple jump hops may be specified separated by comma characters. This is a shortcut to specify a **ProxyJump** configuration directive. Note that configuration directives supplied on the command-line generally apply to the destination host and not any specified jump hosts. Use `~/.ssh/config` to specify configuration for jump hosts.

-K Enables GSSAPI-based authentication and forwarding (delegation) of GSSAPI credentials to the server.

-k Disables forwarding (delegation) of GSSAPI credentials to the server.

-L `[bind_address:]port:host:hostport`

-L `[bind_address:]port:remote_socket`

-L `local_socket:host:hostport`

-L `local_socket:remote_socket`

Specifies that connections to the given TCP port or Unix socket on the local (client) host are to be forwarded to the given host and port, or Unix socket, on the remote side. This works by allocating a socket to listen to either a TCP *port* on the local side, optionally bound to the specified *bind_address*, or to a Unix socket. Whenever a connection is made to the local port or socket, the connection is forwarded over the secure channel, and a connection is made to either *host* port *hostport*, or the Unix socket *remote_socket*, from the remote machine.

Port forwardings can also be specified in the configuration file. Only the superuser can forward privileged ports. IPv6 addresses can be specified by enclosing the address in square brackets.

By default, the local port is bound in accordance with the **GatewayPorts** setting. However, an explicit *bind_address* may be used to bind the connection to a specific address. The *bind_address* of “localhost” indicates that the listening port be bound for local use only, while an empty address or ‘*’ indicates that the port should be available from all interfaces.

-l *login_name*

Specifies the user to log in as on the remote machine. This also may be specified on a per-host basis in the configuration file.

-M Places the **ssh** client into “master” mode for connection sharing. Multiple **-M** options places **ssh** into “master” mode but with confirmation required using `ssh-askpass(1)` before each operation that changes the multiplexing state (e.g. opening a new session). Refer to the description of **ControlMaster** in `ssh_config(5)` for details.

-m *mac_spec*

A comma-separated list of MAC (message authentication code) algorithms, specified in order of preference. See the **MACs** keyword for more information.

- N Do not execute a remote command. This is useful for just forwarding ports. Refer to the description of **SessionType** in **ssh_config(5)** for details.
- n Redirects stdin from /dev/null (actually, prevents reading from stdin). This must be used when **ssh** is run in the background. A common trick is to use this to run X11 programs on a remote machine. For example, **ssh -n shadows.cs.hut.fi emacs &** will start an emacs on shadows.cs.hut.fi, and the X11 connection will be automatically forwarded over an encrypted channel. The **ssh** program will be put in the background. (This does not work if **ssh** needs to ask for a password or passphrase; see also the **-f** option.) Refer to the description of **StdinNull** in **ssh_config(5)** for details.
- o *ctl_cmd*
Control an active connection multiplexing master process. When the **-o** option is specified, the *ctl_cmd* argument is interpreted and passed to the master process. Valid commands are: “check” (check that the master process is running), “forward” (request forwardings without command execution), “cancel” (cancel forwardings), “exit” (request the master to exit), and “stop” (request the master to stop accepting further multiplexing requests).
- o *option*
Can be used to give options in the format used in the configuration file. This is useful for specifying options for which there is no separate command-line flag. For full details of the options listed below, and their possible values, see **ssh_config(5)**.
 - AddKeysToAgent
 - AddressFamily
 - BatchMode
 - BindAddress
 - CanonicalDomains
 - CanonicalizeFallbackLocal
 - CanonicalizeHostname
 - CanonicalizeMaxDots
 - CanonicalizePermittedCNAMEs
 - CASignatureAlgorithms

-p port

Port to connect to on the remote host. This can be specified on a per-host basis in the configuration file.

-Q query_option

Queries for the algorithms supported by one of the following features: *cipher* (supported symmetric ciphers), *cipher-auth* (supported symmetric ciphers that support authenticated encryption), *help* (supported query terms for use with the **-Q** flag), *mac* (supported message integrity codes), *kex* (key exchange algorithms), *kex-gss* (GSSAPI key exchange algorithms), *key* (key types), *key-cert* (certificate key types), *key-plain* (non-certificate key types), *key-sig* (all key types and signature algorithms), *protocol-version* (supported SSH protocol versions), and *sig* (supported signature algorithms). Alternatively, any keyword from *ssh_config(5)* or *sshd_config(5)* that takes an algorithm list may be used as an alias for the corresponding *query_option*.

-q Quiet mode. Causes most warning and diagnostic messages to be suppressed.

```
-R [bind_address:]port:host:hostport  
-R [bind_address:]port:local_socket  
-R remote_socket:host:hostport  
-R remote_socket:local_socket  
-R [bind_address:]port
```

Specifies that connections to the given TCP port or Unix socket on the remote (server) host are to be forwarded to the local side.

This works by allocating a socket to listen to either a TCP *port* or to a Unix socket on the remote side. Whenever a connection is made to this port or Unix socket, the connection is forwarded over the secure channel, and a connection is made from the local machine to either an explicit destination specified by *host* *port* *hostport*, or *local_socket*, or, if no explicit destination was specified, **ssh** will act as a SOCKS 4/5 proxy and forward connections to the destinations requested by the remote SOCKS client.

Port forwardings can also be specified in the configuration file. Privileged ports can be forwarded only when logging in as root on the remote machine. IPv6 addresses can be specified by enclosing the address in square brackets.

By default, TCP listening sockets on the server will be bound to the loopback interface only. This may be overridden by specifying a *bind_address*. An empty *bind_address*, or the address ‘*’, indicates that the remote socket should listen on all interfaces. Specifying a remote *bind_address* will only succeed if the server’s **GatewayPorts** option is enabled (see *sshd_config(5)*).

If the *port* argument is ‘0’, the listen port will be dynamically allocated on the server and reported to the client at run time. When used together with **-O forward** the allocated port will be printed to the standard output.

-s *ctl_path*

Specifies the location of a control socket for connection sharing, or the string “none” to disable connection sharing. Refer to the description of **ControlPath** and **ControlMaster** in *ssh_config(5)* for details.

-s May be used to request invocation of a subsystem on the remote system. Subsystems facilitate the use of SSH as a secure transport for other applications (e.g. *sftp(1)*). The subsystem is specified as the remote command. Refer to the description of **SessionType** in *ssh_config(5)* for details.

-T Disable pseudo-terminal allocation.

-t Force pseudo-terminal allocation. This can be used to execute arbitrary screen-based programs on a remote machine, which can be very useful, e.g. when implementing menu services. Multiple **-t** options force tty allocation, even if **ssh** has no local tty.

-v Display the version number and exit.

-v Verbose mode. Causes **ssh** to print debugging messages about its progress. This is helpful in debugging connection, authentication, and configuration problems. Multiple **-v** options increase the verbosity. The maximum is 3.

-W *host:port*

Requests that standard input and output on the client be forwarded to *host* on *port* over the secure channel. Implies **-N**, **-T**, **ExitOnForwardFailure** and **ClearAllForwardings**, though these can be overridden in the configuration file or using **-o** command line options.

-w *local_tun[:remote_tun]*

Requests tunnel device forwarding with the specified tun(4) devices between the client (*local_tun*) and the server (*remote_tun*).

The devices may be specified by numerical ID or the keyword “any”, which uses the next available tunnel device. If *remote_tun* is not specified, it defaults to “any”. See also the **Tunnel** and **TunnelDevice** directives in *ssh_config(5)*.

If the **Tunnel** directive is unset, it will be set to the default tunnel mode, which is “point-to-point”. If a different **Tunnel** forwarding mode is desired, then it should be specified before **-w**.

-x Enables X11 forwarding. This can also be specified on a per-host basis in a configuration file.

X11 forwarding should be enabled with caution. Users with the ability to bypass file permissions on the remote host (for the user’s X authorization database) can access the local X11 display through the forwarded connection. An attacker may then be able to perform activities such as keystroke monitoring.

For this reason, X11 forwarding is subjected to X11 SECURITY extension restrictions by default. Refer to the **ssh -Y** option and the **ForwardX11Trusted** directive in *ssh_config(5)* for more information.

(Debian-specific: X11 forwarding is not subjected to X11 SECURITY extension restrictions by default, because too many programs currently crash in this mode. Set the **ForwardX11Trusted** option to “no” to restore the upstream behaviour. This may change in future depending on client-side improvements.)

- x Disables X11 forwarding.
 - y Enables trusted X11 forwarding. Trusted X11 forwardings are not subjected to the X11 SECURITY extension controls.
- (Debian-specific: In the default configuration, this option is equivalent to -x, since **ForwardX11Trusted** defaults to “yes” as described above. Set the **ForwardX11Trusted** option to “no” to restore the upstream behaviour. This may change in future depending on client-side improvements.)
- y Send log information using the `syslog(3)` system module. By default this information is sent to stderr.

ssh may additionally obtain configuration data from a per-user configuration file and a system-wide configuration file. The file format and configuration options are described in `ssh_config(5)`.

AUTHENTICATION

The OpenSSH SSH client supports SSH protocol 2.

The methods available for authentication are: GSSAPI-based authentication, host-based authentication, public key authentication, keyboard-interactive authentication, and password authentication. Authentication methods are tried in the order specified above, though **PreferredAuthentications** can be used to change the default order.

Host-based authentication works as follows: If the machine the user logs in from is listed in `/etc/hosts.equiv` or `/etc/ssh/shosts.equiv` on the remote machine, the user is non-root and the user names are the same on both sides, or if the files `~/.rhosts` or `~/.shosts` exist in the user’s home directory on the remote machine and contain a line containing the name of the client machine and the name of the user on that machine, the user is considered for login. Additionally, the server *must* be able to verify the client’s host key (see the description of `/etc/ssh/ssh_known_hosts` and `~/.ssh/known_hosts`, below) for login to be permitted. This authentication method closes security holes due to IP spoofing, DNS spoofing, and routing spoofing. [Note to the administrator: `/etc/hosts.equiv`, `~/.rhosts`, and the rlogin/rsh protocol in general, are inherently insecure and should be disabled if security is desired.]

Public key authentication works as follows: The scheme is based on public-key cryptography, using cryptosystems where encryption and decryption are done using separate keys, and it is unfeasible to derive the decryption key from the encryption key. The idea is that each user creates a public/private key pair for authentication purposes. The server knows the public key, and only the user knows the private key. **ssh** implements public key authentication protocol automatically, using one of the DSA, ECDSA, Ed25519 or RSA algorithms. The HISTORY section of `ssl(8)` (on non-OpenBSD systems, see <http://www.openbsd.org/cgi-bin/man.cgi?query=ssl&sektion=8#HISTORY>) contains a brief discussion of the DSA and RSA algorithms.

The file `~/.ssh/authorized_keys` lists the public keys that are permitted for logging in. When the user logs in, the **ssh** program tells the server which key pair it would like to use for authentication. The client proves that it has access to the private key and the server checks that the corresponding public key is authorized to accept the account.

The server may inform the client of errors that prevented public key authentication from succeeding after authentication completes using a different method. These may be viewed by increasing the **LogLevel** to **DEBUG** or higher (e.g. by using the **-v** flag).

The user creates their key pair by running `ssh-keygen(1)`. This stores the private key in `~/.ssh/id_dsa` (DSA), `~/.ssh/id_ecdsa` (ECDSA), `~/.ssh/id_ecdsa_sk` (authenticator-hosted ECDSA), `~/.ssh/id_ed25519` (Ed25519), `~/.ssh/id_ed25519_sk` (authenticator-hosted Ed25519), or `~/.ssh/id_rsa` (RSA) and stores the public key in `~/.ssh/id_dsa.pub` (DSA), `~/.ssh/id_ecdsa.pub` (ECDSA), `~/.ssh/id_ecdsa_sk.pub` (authenticator-hosted ECDSA), `~/.ssh/id_ed25519.pub` (Ed25519), `~/.ssh/id_ed25519_sk.pub` (authenticator-hosted Ed25519), or `~/.ssh/id_rsa.pub` (RSA) in the user's home directory. The user should then copy the public key to `~/.ssh/authorized_keys` in their home directory on the remote machine. The `authorized_keys` file corresponds to the conventional `~/.rhosts` file, and has one key per line, though the lines can be very long. After this, the user can log in without giving the password.

A variation on public key authentication is available in the form of certificate authentication: instead of a set of public/private keys, signed certificates are used. This has the advantage that a single trusted certification authority can be used in place of many public/private keys. See the CERTIFICATES section of `ssh-keygen(1)` for more information.

The most convenient way to use public key or certificate authentication may be with an authentication agent. See `ssh-agent(1)` and (optionally) the **AddKeysToAgent** directive in `ssh_config(5)` for more information.

Keyboard-interactive authentication works as follows: The server sends an arbitrary "challenge" text and prompts for a response, possibly multiple times. Examples of keyboard-interactive authentication include BSD Authentication (see `login.conf(5)`) and PAM (some non-OpenBSD systems).

Finally, if other authentication methods fail, `ssh` prompts the user for a password. The password is sent to the remote host for checking; however, since all communications are encrypted, the password cannot be seen by someone listening on the network.

`ssh` automatically maintains and checks a database containing identification for all hosts it has ever been used with. Host keys are stored in `~/.ssh/known_hosts` in the user's home directory. Additionally, the file `/etc/ssh/ssh_known_hosts` is automatically checked for known hosts. Any new hosts are automatically added to the user's file. If a host's identification ever changes, `ssh` warns about this and disables password authentication to prevent server spoofing or man-in-the-middle attacks, which could otherwise be used to circumvent the encryption. The **StrictHostKeyChecking** option can be used to control logins to machines whose host key is not known or has changed.

When the user's identity has been accepted by the server, the server either executes the given command in a non-interactive session or, if no command has been specified, logs into the machine and gives the user a normal shell as an interactive session. All communication with the remote command or shell will be automatically encrypted.

If an interactive session is requested `ssh` by default will only request a pseudo-terminal (pty) for interactive sessions when the client has one. The flags **-T** and **-t** can be used to override this behaviour.

If a pseudo-terminal has been allocated the user may use the escape characters noted below.

If no pseudo-terminal has been allocated, the session is transparent and can be used to reliably transfer binary data. On most systems, setting the escape character to "none" will also make the session transparent even if a tty is used.

The session terminates when the command or shell on the remote machine exits and all X11 and TCP connections have been closed.

ESCAPE CHARACTERS

When a pseudo-terminal has been requested, `ssh` supports a number of functions through the use of an escape character.

A single tilde character can be sent as `~` or by following the tilde by a character other than those described below. The escape character must always follow a newline to be interpreted as special. The escape character can be changed in configuration files using the **EscapeChar** configuration directive or on the command line by the **-e** option.

The supported escapes (assuming the default `~`) are:

- ~.** Disconnect.
- ~~z** Background **ssh**.
- ~#** List forwarded connections.
- ~&** Background **ssh** at logout when waiting for forwarded connection / X11 sessions to terminate.
- ~?** Display a list of escape characters.
- ~B** Send a BREAK to the remote system (only useful if the peer supports it).
- ~C** Open command line. Currently this allows the addition of port forwardings using the **-L**, **-R** and **-D** options (see above). It also allows the cancellation of existing port-forwardings with **-KL[bind_address:]port** for local, **-KR[bind_address:]port** for remote and **-KD[bind_address:]port** for dynamic port-forwardings. **!command** allows the user to execute a local command if the **PermitLocalCommand** option is enabled in **ssh_config(5)**. Basic help is available, using the **-h** option.
- ~R** Request rekeying of the connection (only useful if the peer supports it).
- ~v** Decrease the verbosity (**LogLevel**) when errors are being written to stderr.
- ~v** Increase the verbosity (**LogLevel**) when errors are being written to stderr.

TCP FORWARDING

Forwarding of arbitrary TCP connections over a secure channel can be specified either on the command line or in a configuration file. One possible application of TCP forwarding is a secure connection to a mail server; another is going through firewalls.

In the example below, we look at encrypting communication for an IRC client, even though the IRC server it connects to does not directly support encrypted communication. This works as follows: the user connects to the remote host using **ssh**, specifying the ports to be used to forward the connection. After that it is possible to start the program locally, and **ssh** will encrypt and forward the connection to the remote server.

The following example tunnels an IRC session from the client to an IRC server at “server.example.com”, joining channel “#users”, nickname “pinky”, using the standard IRC port, 6667:

```
$ ssh -f -L 6667:localhost:6667 server.example.com sleep 10
$ irc -c '#users' pinky IRC/127.0.0.1
```

The **-f** option backgrounds **ssh** and the remote command “sleep 10” is specified to allow an amount of time (10 seconds, in the example) to start the program which is going to use the tunnel. If no connections are made within the time specified, **ssh** will exit.

X11 FORWARDING

If the **ForwardX11** variable is set to “yes” (or see the description of the **-X**, **-x**, and **-Y** options above) and the user is using X11 (the **DISPLAY** environment variable is set), the connection to the X11 display is automatically forwarded to the remote side in such a way that any X11 programs started from the shell (or command) will go through the encrypted channel, and the connection to the real X server will be made from the local machine. The user should not manually set **DISPLAY**. Forwarding of X11 connections can be configured on the command line or in configuration files.

The DISPLAY value set by **ssh** will point to the server machine, but with a display number greater than zero. This is normal, and happens because **ssh** creates a “proxy” X server on the server machine for forwarding the connections over the encrypted channel.

ssh will also automatically set up Xauthority data on the server machine. For this purpose, it will generate a random authorization cookie, store it in Xauthority on the server, and verify that any forwarded connections carry this cookie and replace it by the real cookie when the connection is opened. The real authentication cookie is never sent to the server machine (and no cookies are sent in the plain).

If the **ForwardAgent** variable is set to “yes” (or see the description of the **-A** and **-a** options above) and the user is using an authentication agent, the connection to the agent is automatically forwarded to the remote side.

VERIFYING HOST KEYS

When connecting to a server for the first time, a fingerprint of the server’s public key is presented to the user (unless the option **StrictHostKeyChecking** has been disabled). Fingerprints can be determined using **ssh-keygen(1)**:

```
$ ssh-keygen -l -f /etc/ssh/ssh_host_rsa_key
```

If the fingerprint is already known, it can be matched and the key can be accepted or rejected. If only legacy (MD5) fingerprints for the server are available, the **ssh-keygen(1)** **-E** option may be used to downgrade the fingerprint algorithm to match.

Because of the difficulty of comparing host keys just by looking at fingerprint strings, there is also support to compare host keys visually, using *random art*. By setting the **VisualHostKey** option to “yes”, a small ASCII graphic gets displayed on every login to a server, no matter if the session itself is interactive or not. By learning the pattern a known server produces, a user can easily find out that the host key has changed when a completely different pattern is displayed. Because these patterns are not unambiguous however, a pattern that looks similar to the pattern remembered only gives a good probability that the host key is the same, not guaranteed proof.

To get a listing of the fingerprints along with their random art for all known hosts, the following command line can be used:

```
$ ssh-keygen -lv -f ~/.ssh/known_hosts
```

If the fingerprint is unknown, an alternative method of verification is available: SSH fingerprints verified by DNS. An additional resource record (RR), SSHFP, is added to a zonefile and the connecting client is able to match the fingerprint with that of the key presented.

In this example, we are connecting a client to a server, “host.example.com”. The SSHFP resource records should first be added to the zonefile for host.example.com:

```
$ ssh-keygen -r host.example.com.
```

The output lines will have to be added to the zonefile. To check that the zone is answering fingerprint queries:

```
$ dig -t SSHFP host.example.com
```

Finally the client connects:

```
$ ssh -o "VerifyHostKeyDNS ask" host.example.com
[...]
Matching host key fingerprint found in DNS.
Are you sure you want to continue connecting (yes/no)?
```

See the **VerifyHostKeyDNS** option in **ssh_config(5)** for more information.

SSH-BASED VIRTUAL PRIVATE NETWORKS

ssh contains support for Virtual Private Network (VPN) tunnelling using the **tun(4)** network pseudo-device, allowing two networks to be joined securely. The **sshd_config(5)** configuration option **PermitTunnel** controls whether the server supports this, and at what level (layer 2 or 3 traffic).

The following example would connect client network 10.0.50.0/24 with remote network 10.0.99.0/24 using a point-to-point connection from 10.1.1.1 to 10.1.1.2, provided that the SSH server running on the gateway to the remote network, at 192.168.1.15, allows it.

On the client:

```
# ssh -f -w 0:1 192.168.1.15 true
# ifconfig tun0 10.1.1.1 10.1.1.2 netmask 255.255.255.252
# route add 10.0.99.0/24 10.1.1.2
```

On the server:

```
# ifconfig tun1 10.1.1.2 10.1.1.1 netmask 255.255.255.252
# route add 10.0.50.0/24 10.1.1.1
```

Client access may be more finely tuned via the **/root/.ssh/authorized_keys** file (see below) and the **PermitRootLogin** server option. The following entry would permit connections on **tun(4)** device 1 from user “jane” and on tun device 2 from user “john”, if **PermitRootLogin** is set to “forced-commands-only”:

```
tunnel="1",command="sh /etc/netstart tun1" ssh-rsa ... jane
tunnel="2",command="sh /etc/netstart tun2" ssh-rsa ... john
```

Since an SSH-based setup entails a fair amount of overhead, it may be more suited to temporary setups, such as for wireless VPNs. More permanent VPNs are better provided by tools such as **ipsecctl(8)** and **isakmpd(8)**.

ENVIRONMENT

ssh will normally set the following environment variables:

DISPLAY	The DISPLAY variable indicates the location of the X11 server. It is automatically set by ssh to point to a value of the form “hostname: <i>n</i> ”, where “hostname” indicates the host where the shell runs, and ‘ <i>n</i> ’ is an integer ≥ 1 . ssh uses this special value to forward X11 connections over the secure channel. The user should normally not set DISPLAY explicitly, as that will render the X11 connection insecure (and will require the user to manually copy any required authorization cookies).
HOME	Set to the path of the user’s home directory.
LOGNAME	Synonym for USER ; set for compatibility with systems that use this variable.
MAIL	Set to the path of the user’s mailbox.
PATH	Set to the default PATH , as specified when compiling ssh .
SSH_ASKPASS	If ssh needs a passphrase, it will read the passphrase from the current terminal if it was run from a terminal. If ssh does not have a terminal associated with it but DISPLAY and SSH_ASKPASS are set, it will execute the program specified by SSH_ASKPASS and open an X11 window to read the passphrase. This is particularly useful when calling ssh from a .xsession or related script. (Note that on some machines it may be neces-

	sary to redirect the input from <code>/dev/null</code> to make this work.)
<code>SSH_ASKPASS_REQUIRE</code>	Allows further control over the use of an askpass program. If this variable is set to “never” then ssh will never attempt to use one. If it is set to “prefer”, then ssh will prefer to use the askpass program instead of the TTY when requesting passwords. Finally, if the variable is set to “force”, then the askpass program will be used for all passphrase input regardless of whether <code>DISPLAY</code> is set.
<code>SSH_AUTH_SOCK</code>	Identifies the path of a UNIX-domain socket used to communicate with the agent.
<code>SSH_CONNECTION</code>	Identifies the client and server ends of the connection. The variable contains four space-separated values: client IP address, client port number, server IP address, and server port number.
<code>SSH_ORIGINAL_COMMAND</code>	This variable contains the original command line if a forced command is executed. It can be used to extract the original arguments.
<code>SSH_TTY</code>	This is set to the name of the tty (path to the device) associated with the current shell or command. If the current session has no tty, this variable is not set.
<code>SSH_TUNNEL</code>	Optionally set by <code>sshd(8)</code> to contain the interface names assigned if tunnel forwarding was requested by the client.
<code>SSH_USER_AUTH</code>	Optionally set by <code>sshd(8)</code> , this variable may contain a pathname to a file that lists the authentication methods successfully used when the session was established, including any public keys that were used.
<code>TZ</code>	This variable is set to indicate the present time zone if it was set when the daemon was started (i.e. the daemon passes the value on to new connections).
<code>USER</code>	Set to the name of the user logging in.

Additionally, **ssh** reads `~/.ssh/environment`, and adds lines of the format “`VARNAME=value`” to the environment if the file exists and users are allowed to change their environment. For more information, see the **PermitUserEnvironment** option in `sshd_config(5)`.

FILES

`~/.rhosts`

This file is used for host-based authentication (see above). On some machines this file may need to be world-readable if the user’s home directory is on an NFS partition, because `sshd(8)` reads it as root. Additionally, this file must be owned by the user, and must not have write permissions for anyone else. The recommended permission for most machines is read/write for the user, and not accessible by others.

`~/.shosts`

This file is used in exactly the same way as `.rhosts`, but allows host-based authentication without permitting login with rlogin/rsh.

`~/.ssh/`

This directory is the default location for all user-specific configuration and authentication information. There is no general requirement to keep the entire contents of this directory secret, but the recommended permissions are read/write/execute for the user, and not accessible by others.

`~/.ssh/authorized_keys`

Lists the public keys (DSA, ECDSA, Ed25519, RSA) that can be used for logging in as this user. The format of this file is described in the `sshd(8)` manual page. This file is not highly sensitive, but the recommended permissions are read/write for the user, and not accessible by others.

`~/.ssh/config`

This is the per-user configuration file. The file format and configuration options are described in `ssh_config(5)`. Because of the potential for abuse, this file must have strict permissions: read/write for the user, and not writable by others. It may be group-writable provided that the group in question contains only the user.

`~/.ssh/environment`

Contains additional definitions for environment variables; see **ENVIRONMENT**, above.

`~/.ssh/id_dsa`

`~/.ssh/id_ecdsa`

`~/.ssh/id_ecdsa_sk`

`~/.ssh/id_ed25519`

`~/.ssh/id_ed25519_sk`

`~/.ssh/id_rsa`

Contains the private key for authentication. These files contain sensitive data and should be readable by the user but not accessible by others (read/write/execute). **ssh** will simply ignore a private key file if it is accessible by others. It is possible to specify a passphrase when generating the key which will be used to encrypt the sensitive part of this file using AES-128.

`~/.ssh/id_dsa.pub`

`~/.ssh/id_ecdsa.pub`

`~/.ssh/id_ecdsa_sk.pub`

`~/.ssh/id_ed25519.pub`

`~/.ssh/id_ed25519_sk.pub`

`~/.ssh/id_rsa.pub`

Contains the public key for authentication. These files are not sensitive and can (but need not) be readable by anyone.

`~/.ssh/known_hosts`

Contains a list of host keys for all hosts the user has logged into that are not already in the systemwide list of known host keys. See `sshd(8)` for further details of the format of this file.

`~/.ssh/rc`

Commands in this file are executed by **ssh** when the user logs in, just before the user's shell (or command) is started. See the `sshd(8)` manual page for more information.

`/etc/hosts.equiv`

This file is for host-based authentication (see above). It should only be writable by root.

`/etc/ssh/shosts.equiv`

This file is used in exactly the same way as `hosts.equiv`, but allows host-based authentication without permitting login with rlogin/rsh.

`/etc/ssh/ssh_config`

Systemwide configuration file. The file format and configuration options are described in `ssh_config(5)`.

`/etc/ssh/ssh_host_key`

/etc/ssh/ssh_host_dsa_key
/etc/ssh/ssh_host_ecdsa_key
/etc/ssh/ssh_host_ed25519_key
/etc/ssh/ssh_host_rsa_key

These files contain the private parts of the host keys and are used for host-based authentication.

/etc/ssh/ssh_known_hosts

Systemwide list of known host keys. This file should be prepared by the system administrator to contain the public host keys of all machines in the organization. It should be world-readable. See sshd(8) for further details of the format of this file.

/etc/ssh/sshrc

Commands in this file are executed by **ssh** when the user logs in, just before the user's shell (or command) is started. See the sshd(8) manual page for more information.

EXIT STATUS

ssh exits with the exit status of the remote command or with 255 if an error occurred.

AUTHORS

OpenSSH is a derivative of the original and free ssh 1.2.12 release by [Tatu Ylonen](#). Aaron Campbell, Bob Beck, Markus Friedl, Niels Provos, Theo de Raadt and Dug Song removed many bugs, re-added newer features and created OpenSSH. Markus Friedl contributed the support for SSH protocol versions 1.5 and 2.0.

NAME**sshd** — OpenSSH daemon**SYNOPSIS**

```
sshd [-46DdeiqTt] [-C connection_spec] [-c host_certificate_file]
      [-E log_file] [-f config_file] [-g login_grace_time]
      [-h host_key_file] [-o option] [-p port] [-u len]
```

DESCRIPTION

sshd (OpenSSH Daemon) is the daemon program for ssh(1). It provides secure encrypted communications between two untrusted hosts over an insecure network.

sshd listens for connections from clients. It is normally started at boot from /etc/init.d/ssh. It forks a new daemon for each incoming connection. The forked daemons handle key exchange, encryption, authentication, command execution, and data exchange.

sshd can be configured using command-line options or a configuration file (by default sshd_config(5)); command-line options override values specified in the configuration file. **sshd** rereads its configuration file when it receives a hangup signal, SIGHUP, by executing itself with the name and options it was started with, e.g. /usr/sbin/sshd.

The options are as follows:

-4 Forces **sshd** to use IPv4 addresses only.

-6 Forces **sshd** to use IPv6 addresses only.

-C *connection_spec*

Specify the connection parameters to use for the **-T** e xtended test mode. If provided, any **Match** directives in the configuration file that would apply are applied before the configuration is written to standard output. The connection parameters are supplied as keyword=value pairs and may be supplied in any order, either with multiple **-C** options or as a comma-separated list. The keywords are “addr”, “user”, “host”, “laddr”, “lport”, and “rdomain” and correspond to source address, user, resolved source host name, local address, local port number and routing domain respectively.

-c *host_certificate_file*

Specifies a path to a certificate file to identify **sshd** during key exchange. The certificate file must match a host key file specified using the **-h** option or the **HostKey** configuration directive.

-D When this option is specified, **sshd** will not detach and does not become a daemon. This allows easy monitoring of **sshd**.

-d Debug mode. The server sends verbose debug output to standard error, and does not put itself in the background. The server also will not fork(2) and will only process one connection. This option is only intended for debugging for the server. Multiple **-d** options increase the debugging level. Maximum is 3.

-E *log_file*

Append debug logs to *log_file* instead of the system log.

-e Write debug logs to standard error instead of the system log.

-f *config_file*

Specifies the name of the configuration file. The default is /etc/ssh/sshd_config. **sshd** refuses to start if there is no configuration file.

-g *login_grace_time*

Gives the grace time for clients to authenticate themselves (default 120 seconds). If the client fails to authenticate the user within this many seconds, the server disconnects and exits. A value of zero indicates no limit.

-h *host_key_file*

Specifies a file from which a host key is read. This option must be given if **sshd** is not run as root (as the normal host key files are normally not readable by anyone but root). The default is `/etc/ssh/ssh_host_ecdsa_key`, `/etc/ssh/ssh_host_ed25519_key` and `/etc/ssh/ssh_host_rsa_key`. It is possible to have multiple host key files for the different host key algorithms.

-i Specifies that **sshd** is being run from **inetd(8)**.**-o** *option*

Can be used to give options in the format used in the configuration file. This is useful for specifying options for which there is no separate command-line flag. For full details of the options, and their values, see **sshd_config(5)**.

-p *port*

Specifies the port on which the server listens for connections (default 22). Multiple port options are permitted. Ports specified in the configuration file with the **Port** option are ignored when a command-line port is specified. Ports specified using the **ListenAddress** option override command-line ports.

-q Quiet mode. Nothing is sent to the system log. Normally the beginning, authentication, and termination of each connection is logged.**-T** Extended test mode. Check the validity of the configuration file, output the effective configuration to stdout and then exit. Optionally, **Match** rules may be applied by specifying the connection parameters using one or more **-C** options.**-t** Test mode. Only check the validity of the configuration file and sanity of the keys. This is useful for updating **sshd** reliably as configuration options may change.**-u** *len*

This option is used to specify the size of the field in the **utmp** structure that holds the remote host name. If the resolved host name is longer than *len*, the dotted decimal value will be used instead. This allows hosts with very long host names that overflow this field to still be uniquely identified. Specifying **-u0** indicates that only dotted decimal addresses should be put into the **utmp** file. **-u0** may also be used to prevent **sshd** from making DNS requests unless the authentication mechanism or configuration requires it. Authentication mechanisms that may require DNS include **HostbasedAuthentication** and using a **from="pattern-list"** option in a key file. Configuration options that require DNS include using a **USER@HOST** pattern in **AllowUsers** or **DenyUsers**.

AUTHENTICATION

The OpenSSH SSH daemon supports SSH protocol 2 only. Each host has a host-specific key, used to identify the host. Whenever a client connects, the daemon responds with its public host key. The client compares the host key against its own database to verify that it has not changed. Forward secrecy is provided through a Diffie-Hellman key agreement. This key agreement results in a shared session key. The rest of the session is encrypted using a symmetric cipher. The client selects the encryption algorithm to use from those offered by the server. Additionally, session integrity is provided through a cryptographic message authentication code (MAC).

Finally, the server and the client enter an authentication dialog. The client tries to authenticate itself using host-based authentication, public key authentication, challenge-response authentication, or password authentication.

Regardless of the authentication type, the account is checked to ensure that it is accessible. An account is not accessible if it is locked, listed in **DenyUsers** or its group is listed in **DenyGroups**. The definition of a locked account is system dependent. Some platforms have their own account database (eg AIX) and some modify the passwd field (*LK* on Solaris and UnixWare, '*' on HP-UX, containingNoLogin on Tru64, a leading *LOCKED* on FreeBSD and a leading '!' on most Linuxes). If there is a requirement to disable password authentication for the account while allowing still public-key, then the passwd field should be set to something other than these values (eg 'NP' or*NP*).

If the client successfully authenticates itself, a dialog for preparing the session is entered. At this time the client may request things like allocating a pseudo-tty, forwarding X11 connections, forwarding TCP connections, or forwarding the authentication agent connection over the secure channel.

After this, the client either requests an interactive shell or execution or a non-interactive command, which **sshd** will execute via the user's shell using its **-c** option. The sides then enter session mode. In this mode, either side may send data at any time, and such data is forwarded to/from the shell or command on the server side, and the user terminal in the client side.

When the user program terminates and all forwarded X11 and other connections have been closed, the server sends command exit status to the client, and both sides exit.

LOGIN PROCESS

When a user successfully logs in, **sshd** does the following:

1. If the login is on a tty, and no command has been specified, prints last login time and /etc/motd (unless prevented in the configuration file or by ~/.hushlogin; see the **FILES** section).
2. If the login is on a tty, records login time.
3. Checks /etc/nologin; if it exists, prints contents and quits (unless root).
4. Changes to run with normal user privileges.
5. Sets up basic environment.
6. Reads the file ~/.ssh/environment, if it exists, and users are allowed to change their environment. See the **PermitUserEnvironment** option in **sshd_config(5)**.
7. Changes to user's home directory.
8. If ~/.ssh/rc exists and the **sshd_config(5)** **PermitUserRC** option is set, runs it; else if /etc/ssh/sshrc exists, runs it; otherwise runs xauth(1). The "rc" files are given the X11 authentication protocol and cookie in standard input. See **SSHRC**, below.
9. Runs user's shell or command. All commands are run under the user's login shell as specified in the system password database.

SSHRC

If the file ~/.ssh/rc exists, sh(1) runs it after reading the environment files but before starting the user's shell or command. It must not produce any output on stdout; stderr must be used instead. If X11 forwarding is in use, it will receive the "proto cookie" pair in its standard input (and DISPLAY in its environment). The script must call xauth(1) because **sshd** will not run xauth automatically to add X11 cookies.

The primary purpose of this file is to run any initialization routines which may be needed before the user's home directory becomes accessible; AFS is a particular example of such an environment.

This file will probably contain some initialization code followed by something similar to:

```
if read proto cookie && [ -n "$DISPLAY" ]; then
    if [ `echo $DISPLAY | cut -c1-10` = 'localhost:' ]; then
        # X11UseLocalhost=yes
        echo add unix:'echo $DISPLAY |
            cut -c11-' $proto $cookie
    else
        # X11UseLocalhost=no
        echo add $DISPLAY $proto $cookie
    fi | xauth -q -
fi
```

If this file does not exist, `/etc/ssh/sshrc` is run, and if that does not exist either, `xauth` is used to add the cookie.

AUTHORIZED_KEYS FILE FORMAT

AuthorizedKeysFile specifies the files containing public keys for public key authentication; if this option is not specified, the default is `~/.ssh/authorized_keys` and `~/.ssh/authorized_keys2`. Each line of the file contains one key (empty lines and lines starting with a '#' are ignored as comments). Public keys consist of the following space-separated fields: options, keytype, base64-encoded key, comment. The options field is optional. The supported key types are:

```
sk-ecdsa-sha2-nistp256@openssh.com
ecdsa-sha2-nistp256
ecdsa-sha2-nistp384
ecdsa-sha2-nistp521
sk-ssh-ed25519@openssh.com
ssh-ed25519
ssh-dss
ssh-rsa
```

The comment field is not used for anything (but may be convenient for the user to identify the key).

Note that lines in this file can be several hundred bytes long (because of the size of the public key encoding) up to a limit of 8 kilobytes, which permits RSA keys up to 16 kilobits. You don't want to type them in; instead, copy the `id_dsa.pub`, `id_ecdsa.pub`, `id_ecdsa_sk.pub`, `id_ed25519.pub`, `id_ed25519_sk.pub`, or the `id_rsa.pub` file and edit it.

sshd enforces a minimum RSA key modulus size of 1024 bits.

The options (if present) consist of comma-separated option specifications. No spaces are permitted, except within double quotes. The following option specifications are supported (note that option keywords are case-insensitive):

agent-forwarding

Enable authentication agent forwarding previously disabled by the **restrict** option.

cert-authority

Specifies that the listed key is a certification authority (CA) that is trusted to validate signed certificates for user authentication.

Certificates may encode access restrictions similar to these key options. If both certificate restrictions and key options are present, the most restrictive union of the two is applied.

command="command"

Specifies that the command is executed whenever this key is used for authentication. The command supplied by the user (if any) is ignored. The command is run on a pty if the client requests a pty; otherwise it is run without a tty. If an 8-bit clean channel is required, one must not request a pty or should specify **no-pty**. A quote may be included in the command by quoting it with a backslash.

This option might be useful to restrict certain public keys to perform just a specific operation. An example might be a key that permits remote backups but nothing else. Note that the client may specify TCP and/or X11 forwarding unless they are explicitly prohibited, e.g. using the **restrict** key option.

The command originally supplied by the client is available in the `SSH_ORIGINAL_COMMAND` environment variable. Note that this option applies to shell, command or subsystem execution. Also note that this command may be superseded by a `sshd_config(5)` **ForceCommand** directive.

If a command is specified and a forced-command is embedded in a certificate used for authentication, then the certificate will be accepted only if the two commands are identical.

environment="NAME=value"

Specifies that the string is to be added to the environment when logging in using this key. Environment variables set this way override other default environment values. Multiple options of this type are permitted. Environment processing is disabled by default and is controlled via the **PermitUserEnvironment** option.

expiry-time="timespec"

Specifies a time after which the key will not be accepted. The time may be specified as a YYYYMMDDHHMM[SS] date or a YYYYMMDDHHMM[SS] time in the system time-zone.

from="pattern-list"

Specifies that in addition to public key authentication, either the canonical name of the remote host or its IP address must be present in the comma-separated list of patterns. See PATTERNS in `ssh_config(5)` for more information on patterns.

In addition to the wildcard matching that may be applied to hostnames or addresses, a **from** stanza may match IP addresses using CIDR address/masklen notation.

The purpose of this option is to optionally increase security: public key authentication by itself does not trust the network or name servers or anything (but the key); however, if somebody somehow steals the key, the key permits an intruder to log in from anywhere in the world. This additional option makes using a stolen key more difficult (name servers and/or routers would have to be compromised in addition to just the key).

no-agent-forwarding

Forbids authentication agent forwarding when this key is used for authentication.

no-port-forwarding

Forbids TCP forwarding when this key is used for authentication. Any port forward requests by the client will return an error. This might be used, e.g. in connection with the **command** option.

no-pty

Prevents tty allocation (a request to allocate a pty will fail).

no-user-rc

Disables execution of `~/.ssh/rc`.

no-X11-forwarding

Forbids X11 forwarding when this key is used for authentication. Any X11 forward requests by the client will return an error.

permitlisten="[:host:]port"

Limit remote port forwarding with the ssh(1) **-R** option such that it may only listen on the specified host (optional) and port. IPv6 addresses can be specified by enclosing the address in square brackets. Multiple **permitlisten** options may be applied separated by commas. Hostnames may include wildcards as described in the PATTERNS section in ssh_config(5). A port specification of * matches any port. Note that the setting of **GatewayPorts** may further restrict listen addresses. Note that ssh(1) will send a hostname of “localhost” if a listen host was not specified when the forwarding was requested, and that this name is treated differently to the explicit localhost addresses “127.0.0.1” and “::1”.

permitopen="host:port"

Limit local port forwarding with the ssh(1) **-L** option such that it may only connect to the specified host and port. IPv6 addresses can be specified by enclosing the address in square brackets. Multiple **permitopen** options may be applied separated by commas. No pattern matching or name lookup is performed on the specified hostnames, they must be literal host names and/or addresses. A port specification of * matches any port.

port-forwarding

Enable port forwarding previously disabled by the **restrict** option.

principals="principals"

On a **cert-authority** line, specifies allowed principals for certificate authentication as a comma-separated list. At least one name from the list must appear in the certificate’s list of principals for the certificate to be accepted. This option is ignored for keys that are not marked as trusted certificate signers using the **cert-authority** option.

pty

Permits tty allocation previously disabled by the **restrict** option.

no-touch-required

Do not require demonstration of user presence for signatures made using this key. This option only makes sense for the FIDO authenticator algorithms **ecdsa-sk** and **ed25519-sk**.

verify-required

Require that signatures made using this key attest that they verified the user, e.g. via a PIN. This option only makes sense for the FIDO authenticator algorithms **ecdsa-sk** and **ed25519-sk**.

restrict

Enable all restrictions, i.e. disable port, agent and X11 forwarding, as well as disabling PTY allocation and execution of ~/.ssh/rc. If any future restriction capabilities are added to authorized_keys files they will be included in this set.

tunnel="n"

Force a tun(4) device on the server. Without this option, the next available device will be used if the client requests a tunnel.

user-rc

Enables execution of ~/.ssh/rc previously disabled by the **restrict** option.

x11-forwarding

Permits X11 forwarding previously disabled by the **restrict** option.

An example authorized_keys file:

```
# Comments are allowed at start of line. Blank lines are allowed.
# Plain key, no restrictions
ssh-rsa ...
# Forced command, disable PTY and all forwarding
restrict,command="dump /home" ssh-rsa ...
```

```

# Restriction of ssh -L forwarding destinations
permitopen="192.0.2.1:80",permitopen="192.0.2.2:25" ssh-rsa ...
# Restriction of ssh -R forwarding listeners
permitlisten="localhost:8080",permitlisten="[:1]:22000" ssh-rsa ...
# Configuration for tunnel forwarding
tunnel="0",command="sh /etc/netstart tun0" ssh-rsa ...
# Override of restriction to allow PTY allocation
restrict,pty,command="nethack" ssh-rsa ...
# Allow FIDO key without requiring touch
no-touch-required sk-ecdsa-sha2-nistp256@openssh.com ...
# Require user-verification (e.g. PIN or biometric) for FIDO key
verify-required sk-ecdsa-sha2-nistp256@openssh.com ...
# Trust CA key, allow touch-less FIDO if requested in certificate
cert-authority,no-touch-required,principals="user_a" ssh-rsa ...

```

SSH_KNOWN_HOSTS FILE FORMAT

The `/etc/ssh/ssh_known_hosts` and `~/.ssh/known_hosts` files contain host public keys for all known hosts. The global file should be prepared by the administrator (optional), and the per-user file is maintained automatically: whenever the user connects to an unknown host, its key is added to the per-user file.

Each line in these files contains the following fields: marker (optional), hostnames, keytype, base64-encoded key, comment. The fields are separated by spaces.

The marker is optional, but if it is present then it must be one of “`@cert-authority`”, to indicate that the line contains a certification authority (CA) key, or “`@revoked`”, to indicate that the key contained on the line is revoked and must not ever be accepted. Only one marker should be used on a key line.

Hostnames is a comma-separated list of patterns (“`*`” and “`?`” act as wildcards); each pattern in turn is matched against the host name. When `sshd` is authenticating a client, such as when using **HostbasedAuthentication**, this will be the canonical client host name. When `ssh(1)` is authenticating a server, this will be the host name given by the user, the value of the `ssh(1)` **HostkeyAlias** if it was specified, or the canonical server hostname if the `ssh(1)` **CanonicalizeHostname** option was used.

A pattern may also be preceded by ‘`!`’ to indicate negation: if the host name matches a negated pattern, it is not accepted (by that line) even if it matched another pattern on the line. A hostname or address may optionally be enclosed within ‘`[`’ and ‘`]`’ brackets then followed by ‘`:`’ and a non-standard port number.

Alternately, hostnames may be stored in a hashed form which hides host names and addresses should the file’s contents be disclosed. Hashed hostnames start with a ‘`]`’ character. Only one hashed hostname may appear on a single line and none of the above negation or wildcard operators may be applied.

The keytype and base64-encoded key are taken directly from the host key; they can be obtained, for example, from `/etc/ssh/ssh_host_rsa_key.pub`. The optional comment field continues to the end of the line, and is not used.

Lines starting with ‘`#`’ and empty lines are ignored as comments.

When performing host authentication, authentication is accepted if any matching line has the proper key; either one that matches exactly or, if the server has presented a certificate for authentication, the key of the certification authority that signed the certificate. For a key to be trusted as a certification authority, it must use the “`@cert-authority`” marker described above.

The known hosts file also provides a facility to mark keys as revoked, for example when it is known that the associated private key has been stolen. Revoked keys are specified by including the “`@revoked`” marker at the beginning of the key line, and are never accepted for authentication or as certification authorities, but in-

stead will produce a warning from `ssh(1)` when they are encountered.

It is permissible (but not recommended) to have several lines or different host keys for the same names. This will inevitably happen when short forms of host names from different domains are put in the file. It is possible that the files contain conflicting information; authentication is accepted if valid information can be found from either file.

Note that the lines in these files are typically hundreds of characters long, and you definitely don't want to type in the host keys by hand. Rather, generate them by a script, `ssh-keyscan(1)` or by taking, for example, `/etc/ssh/ssh_host_rsa_key.pub` and adding the host names at the front. `ssh-keygen(1)` also offers some basic automated editing for `~/.ssh/known_hosts` including removing hosts matching a host name and converting all host names to their hashed representations.

An example `ssh_known_hosts` file:

```
# Comments allowed at start of line
closenet,...,192.0.2.53 1024 37 159...93 closenet.example.net
cvs.example.net,192.0.2.10 ssh-rsa AAAA1234....=
# A hashed hostname
|1|JfKTdBh7rNbXkVAQCRp4OQoPfmI=|USECr3SWf1JUPsms5Aqfd5QfxkM= ssh-rsa
AAAAA1234....=
# A revoked key
@revoked * ssh-rsa AAAAB5W...
# A CA key, accepted for any host in *.mydomain.com or *.mydomain.org
@cert-authority *.mydomain.org,*.mydomain.com ssh-rsa AAAAB5W...
```

FILES

`~/.hushlogin`

This file is used to suppress printing the last login time and `/etc/motd`, if **PrintLastLog** and **PrintMotd**, respectively, are enabled. It does not suppress printing of the banner specified by **Banner**.

`~/.rhosts`

This file is used for host-based authentication (see `ssh(1)` for more information). On some machines this file may need to be world-readable if the user's home directory is on an NFS partition, because `sshd` reads it as root. Additionally, this file must be owned by the user, and must not have write permissions for anyone else. The recommended permission for most machines is read/write for the user, and not accessible by others.

`~/.shosts`

This file is used in exactly the same way as `.rhosts`, but allows host-based authentication without permitting login with `rlogin/rsh`.

`~/.ssh`

This directory is the default location for all user-specific configuration and authentication information. There is no general requirement to keep the entire contents of this directory secret, but the recommended permissions are read/write/execute for the user, and not accessible by others.

`~/.ssh/authorized_keys`

Lists the public keys (DSA, ECDSA, Ed25519, RSA) that can be used for logging in as this user. The format of this file is described above. The content of the file is not highly sensitive, but the recommended permissions are read/write for the user, and not accessible by others.

If this file, the `~/.ssh` directory, or the user's home directory are writable by other users, then the file could be modified or replaced by unauthorized users. In this case, `sshd` will not allow it to be used unless the **StrictModes** option has been set to "no".

`~/.ssh/environment`

This file is read into the environment at login (if it exists). It can only contain empty lines, comment lines (that start with '#'), and assignment lines of the form name=value. The file should be writable only by the user; it need not be readable by anyone else. Environment processing is disabled by default and is controlled via the **PermitUserEnvironment** option.

`~/.ssh/known_hosts`

Contains a list of host keys for all hosts the user has logged into that are not already in the systemwide list of known host keys. The format of this file is described above. This file should be writable only by root/the owner and can, but need not be, world-readable.

`~/.ssh/rc`

Contains initialization routines to be run before the user's home directory becomes accessible. This file should be writable only by the user, and need not be readable by anyone else.

`/etc/hosts.allow`

`/etc/hosts.deny`

Access controls that should be enforced by tcp-wrappers are defined here. Further details are described in `hosts_access(5)`.

`/etc/hosts.equiv`

This file is for host-based authentication (see `ssh(1)`). It should only be writable by root.

`/etc/ssh/moduli`

Contains Diffie-Hellman groups used for the "Diffie-Hellman Group Exchange" key exchange method. The file format is described in `moduli(5)`. If no usable groups are found in this file then fixed internal groups will be used.

`/etc/motd`

See `motd(5)`.

`/etc/nologin`

If this file exists, **sshd** refuses to let anyone except root log in. The contents of the file are displayed to anyone trying to log in, and non-root connections are refused. The file should be world-readable.

`/etc/ssh/shosts.equiv`

This file is used in exactly the same way as `hosts.equiv`, but allows host-based authentication without permitting login with rlogin/rsh.

`/etc/ssh/ssh_host_ecdsa_key`

`/etc/ssh/ssh_host_ed25519_key`

`/etc/ssh/ssh_host_rsa_key`

These files contain the private parts of the host keys. These files should only be owned by root, readable only by root, and not accessible to others. Note that **sshd** does not start if these files are group/world-accessible.

`/etc/ssh/ssh_host_ecdsa_key.pub`

`/etc/ssh/ssh_host_ed25519_key.pub`

`/etc/ssh/ssh_host_rsa_key.pub`

These files contain the public parts of the host keys. These files should be world-readable but writable only by root. Their contents should match the respective private parts. These files are not really used for anything; they are provided for the convenience of the user so their contents can be copied to known hosts files. These files are created using `ssh-keygen(1)`.

/etc/ssh/ssh_known_hosts

Systemwide list of known host keys. This file should be prepared by the system administrator to contain the public host keys of all machines in the organization. The format of this file is described above. This file should be writable only by root/the owner and should be world-readable.

/etc/ssh/sshd_config

Contains configuration data for **sshd**. The file format and configuration options are described in **sshd_config(5)**.

/etc/ssh/sshrc

Similar to `~/.ssh/rc`, it can be used to specify machine-specific login-time initializations globally. This file should be writable only by root, and should be world-readable.

/run/sshd

`chroot(2)` directory used by **sshd** during privilege separation in the pre-authentication phase. The directory should not contain any files and must be owned by root and not group or world-writable.

/run/sshd.pid

Contains the process ID of the **sshd** listening for connections (if there are several daemons running concurrently for different ports, this contains the process ID of the one started last). The content of this file is not sensitive; it can be world-readable.

AUTHORS

OpenSSH is a derivative of the original and free ssh 1.2.12 release by Tatu Ylonen. Aaron Campbell, Bob Beck, Markus Friedl, Niels Provos, Theo de Raadt and Dug Song removed many bugs, re-added newer features and created OpenSSH. Markus Friedl contributed the support for SSH protocol versions 1.5 and 2.0. Niels Provos and Markus Friedl contributed support for privilege separation.

NAME

sudo, sudoedit — execute a command as another user

SYNOPSIS

```
sudo -h | -K | -k | -v
sudo -v[ -ABknS] [-g group] [-h host] [-p prompt] [-u user]
sudo -l[ -ABknS] [-g group] [-h host] [-p prompt] [-U user] [-u user] [command]
sudo [ -ABbEHnPS] [-C num] [-D directory] [-g group] [-h host] [-p prompt]
      [-R directory] [-r role] [-t type] [-T timeout] [-u user] [VAR=value]
      [-i | -s] [command]
sudoedit [ -ABknS] [-C num] [-D directory] [-g group] [-h host] [-p prompt]
      [-R directory] [-r role] [-t type] [-T timeout] [-u user] file ...
```

DESCRIPTION

sudo allows a permitted user to execute a *command* as the superuser or another user, as specified by the security policy. The invoking user's real (*not effective*) user-ID is used to determine the user name with which to query the security policy.

sudo supports a plugin architecture for security policies, auditing, and input/output logging. Third parties can develop and distribute their own plugins to work seamlessly with the **sudo** front-end. The default security policy is *sudoers*, which is configured via the file /etc/sudoers, or via LDAP. See the **Plugins** section for more information.

The security policy determines what privileges, if any, a user has to run **sudo**. The policy may require that users authenticate themselves with a password or another authentication mechanism. If authentication is required, **sudo** will exit if the user's password is not entered within a configurable time limit. This limit is policy-specific; the default password prompt timeout for the *sudoers* security policy is 0 minutes.

Security policies may support credential caching to allow the user to run **sudo** again for a period of time without requiring authentication. By default, the *sudoers* policy caches credentials on a per-terminal basis for 15 minutes. See the *timestamp_type* and *timestamp_timeout* options in *sudoers*(5) for more information. By running **sudo** with the **-v** option, a user can update the cached credentials without running a *command*.

On systems where **sudo** is the primary method of gaining superuser privileges, it is imperative to avoid syntax errors in the security policy configuration files. For the default security policy, *sudoers*(5), changes to the configuration files should be made using the *visudo*(8) utility which will ensure that no syntax errors are introduced.

When invoked as **sudoedit**, the **-e** option (described below), is implied.

Security policies and audit plugins may log successful and failed attempts to run **sudo**. If an I/O plugin is configured, the running command's input and output may be logged as well.

The options are as follows:

-A, --askpass

Normally, if **sudo** requires a password, it will read it from the user's terminal. If the **-A** (*askpass*) option is specified, a (possibly graphical) helper program is executed to read the user's password and output the password to the standard output. If the **SUDO_ASKPASS** environment variable is set, it specifies the path to the helper program. Otherwise, if *sudo.conf*(5) contains a line specifying the *askpass* program, that value will be used. For example:

```
# Path to askpass helper program
Path askpass /usr/X11R6/bin/ssh-askpass
```

If no askpass program is available, **sudo** will exit with an error.

-B, --bell

Ring the bell as part of the password prompt when a terminal is present. This option has no effect if an askpass program is used.

-b, --background

Run the given command in the background. Note that it is not possible to use shell job control to manipulate background processes started by **sudo**. Most interactive commands will fail to work properly in background mode.

-C num, --close-from=num

Close all file descriptors greater than or equal to *num* before executing a command. Values less than three are not permitted. By default, **sudo** will close all open file descriptors other than standard input, standard output, and standard error when executing a command. The security policy may restrict the user's ability to use this option. The *sudoers* policy only permits use of the **-C** option when the administrator has enabled the *closefrom_override* option.

-D directory, --chdir=directory

Run the command in the specified *directory* instead of the current working directory. The security policy may return an error if the user does not have permission to specify the working directory.

-E, --preserve-env

Indicates to the security policy that the user wishes to preserve their existing environment variables. The security policy may return an error if the user does not have permission to preserve the environment.

--preserve-env=list

Indicates to the security policy that the user wishes to add the comma-separated list of environment variables to those preserved from the user's environment. The security policy may return an error if the user does not have permission to preserve the environment. This option may be specified multiple times.

-e, --edit

Edit one or more files instead of running a command. In lieu of a path name, the string "sudoeedit" is used when consulting the security policy. If the user is authorized by the policy, the following steps are taken:

1. Temporary copies are made of the files to be edited with the owner set to the invoking user.
2. The editor specified by the policy is run to edit the temporary files. The *sudoers* policy uses the *SUDO_EDITOR*, *VISUAL* and *EDITOR* environment variables (in that order). If none of *SUDO_EDITOR*, *VISUAL* or *EDITOR* are set, the first program listed in the *editor sudoers(5)* option is used.
3. If they have been modified, the temporary files are copied back to their original location and the temporary versions are removed.

To help prevent the editing of unauthorized files, the following restrictions are enforced unless explicitly allowed by the security policy:

- Symbolic links may not be edited (version 1.8.15 and higher).
- Symbolic links along the path to be edited are not followed when the parent directory is writable by the invoking user unless that user is root (version 1.8.16 and higher).

- Files located in a directory that is writable by the invoking user may not be edited unless that user is root (version 1.8.16 and higher).

Users are never allowed to edit device special files.

If the specified file does not exist, it will be created. Note that unlike most commands run by **sudo**, the editor is run with the invoking user's environment unmodified. If the temporary file becomes empty after editing, the user will be prompted before it is installed. If, for some reason, **sudo** is unable to update a file with its edited version, the user will receive a warning and the edited copy will remain in a temporary file.

-g group, --group=group

Run the command with the primary group set to *group* instead of the primary group specified by the target user's password database entry. The *group* may be either a group name or a numeric group-ID (GID) prefixed with the '#' character (e.g., #0 for GID 0). When running a command as a GID, many shells require that the '#' be escaped with a backslash ('\'). If no **-u** option is specified, the command will be run as the invoking user. In either case, the primary group will be set to *group*. The *sudoer*'s policy permits any of the target user's groups to be specified via the **-g** option as long as the **-P** option is not in use.

-H, --set-home

Request that the security policy set the HOME environment variable to the home directory specified by the target user's password database entry. Depending on the policy, this may be the default behavior.

-h, --help

Display a short help message to the standard output and exit.

-h host, --host=host

Run the command on the specified *host* if the security policy plugin supports remote commands. Note that the *sudoer*'s plugin does not currently support running remote commands. This may also be used in conjunction with the **-l** option to list a user's privileges for the remote host.

-i, --login

Run the shell specified by the target user's password database entry as a login shell. This means that login-specific resource files such as *.profile*, *.bash_profile*, or *.login* will be read by the shell. If a command is specified, it is passed to the shell as a simple command using the **-c** option. The command and any arguments are concatenated, separated by spaces, after escaping each character (including white space) with a backslash ('\') except for alphanumerics, underscores, hyphens, and dollar signs. If no command is specified, an interactive shell is executed. **sudo** attempts to change to that user's home directory before running the shell. The command is run with an environment similar to the one a user would receive at log in. Note that most shells behave differently when a command is specified as compared to an interactive session; consult the shell's manual for details. The *Command environment* section in the *sudoers(5)* manual documents how the **-i** option affects the environment in which a command is run when the *sudoers* policy is in use.

-K, --remove-timestamp

Similar to the **-k** option, except that it removes the user's cached credentials entirely and may not be used in conjunction with a command or other option. This option does not require a password. Not all security policies support credential caching.

-k, --reset-timestamp

When used without a command, invalidates the user's cached credentials. In other words, the next time **sudo** is run a password will be required. This option does not require a password,

and was added to allow a user to revoke **sudo** permissions from a .logout file.

When used in conjunction with a command or an option that may require a password, this option will cause **sudo** to ignore the user's cached credentials. As a result, **sudo** will prompt for a password (if one is required by the security policy) and will not update the user's cached credentials.

Not all security policies support credential caching.

-l, --list

If no *command* is specified, list the allowed (and forbidden) commands for the invoking user (or the user specified by the **-U** option) on the current host. A longer list format is used if this option is specified multiple times and the security policy supports a verbose output format.

If a *command* is specified and is permitted by the security policy, the fully-qualified path to the command is displayed along with any command line arguments. If a *command* is specified but not allowed by the policy, **sudo** will exit with a status value of 1.

-n, --non-interactive

Avoid prompting the user for input of any kind. If a password is required for the command to run, **sudo** will display an error message and exit.

-P, --preserve-groups

Preserve the invoking user's group vector unaltered. By default, the *sudoers* policy will initialize the group vector to the list of groups the target user is a member of. The real and effective group-IDs, however, are still set to match the target user.

-p *prompt*, --prompt=*prompt*

Use a custom password prompt with optional escape sequences. The following percent ('%') escape sequences are supported by the *sudoers* policy:

%H

expanded to the host name including the domain name (only if the machine's host name is fully qualified or the *fqdn* option is set in *sudoers*(5))

%h

expanded to the local host name without the domain name

%p

expanded to the name of the user whose password is being requested (respects the *rootpw*, *targetpw*, and *runaspw* flags in *sudoers*(5))

%U

expanded to the login name of the user the command will be run as (defaults to root unless the **-u** option is also specified)

%u

expanded to the invoking user's login name

%%

two consecutive '%' characters are collapsed into a single '%' character

The custom prompt will override the default prompt specified by either the security policy or the *SUDO_PROMPT* environment variable. On systems that use PAM, the custom prompt will also override the prompt specified by a PAM module unless the *passprompt_override* flag is disabled in *sudoers*.

-R directory, --chroot=directory

Change to the specified root *directory* (see *chroot(8)*) before running the command. The security policy may return an error if the user does not have permission to specify the root directory.

-r role, --role=role

Run the command with an SELinux security context that includes the specified *role*.

-s, --stdin

Write the prompt to the standard error and read the password from the standard input instead of using the terminal device.

-s, --shell

Run the shell specified by the SHELL environment variable if it is set or the shell specified by the invoking user's password database entry. If a command is specified, it is passed to the shell as a simple command using the **-c** option. The command and any arguments are concatenated, separated by spaces, after escaping each character (including white space) with a backslash ('\\') except for alphanumerics, underscores, hyphens, and dollar signs. If no command is specified, an interactive shell is executed. Note that most shells behave differently when a command is specified as compared to an interactive session; consult the shell's manual for details.

-t type, --type=type

Run the command with an SELinux security context that includes the specified *type*. If no *type* is specified, the default type is derived from the role.

-U user, --other-user=user

Used in conjunction with the **-l** option to list the privileges for *user* instead of for the invoking user. The security policy may restrict listing other users' privileges. The *sudoer*'s policy only allows root or a user with the ALL privilege on the current host to use this option.

-T timeout, --command-timeout=timeout

Used to set a timeout for the command. If the timeout expires before the command has exited, the command will be terminated. The security policy may restrict the ability to set command timeouts. The *sudoer*'s policy requires that user-specified timeouts be explicitly enabled.

-u user, --user=user

Run the command as a user other than the default target user (usually *root*). The *user* may be either a user name or a numeric user-ID (UID) prefixed with the '#' character (e.g.,#0 for UID 0). When running commands as a UID, many shells require that the '#' be escaped with a backslash ('\\'). Some security policies may restrict UIDs to those listed in the password database. The *sudoer*'s policy allows UIDs that are not in the password database as long as the *targetpw* option is not set. Other security policies may not support this.

-v, --version

Print the **sudo** version string as well as the version string of any configured plugins. If the invoking user is already root, the **-V** option will display the arguments passed to configure when **sudo** was built; plugins may display additional information such as default options.

-v, --validate

Update the user's cached credentials, authenticating the user if necessary. For the *sudoers* plugin, this extends the **sudo** timeout for another 15 minutes by default, but does not run a command. Not all security policies support cached credentials.

-- The **--** option indicates that **sudo** should stop processing command line arguments.

Options that take a value may only be specified once unless otherwise indicated in the description. This is to help guard against problems caused by poorly written scripts that invoke **sudo** with user-controlled input.

Environment variables to be set for the command may also be passed on the command line in the form of `VAR=value`, e.g., `LD_LIBRARY_PATH=/usr/local/pkg/lib`. Variables passed on the command line are subject to restrictions imposed by the security policy plugin. The *sudoers* policy subjects variables passed on the command line to the same restrictions as normal environment variables with one important exception. If the `setenv v` option is set in *sudoers*, the command to be run has the `SETENV` tag set or the command matched is `ALL`, the user may set variables that would otherwise be forbidden. See *sudoers*(5) for more information.

COMMAND EXECUTION

When **sudo** executes a command, the security policy specifies the execution environment for the command. Typically, the real and effective user and group and IDs are set to match those of the target user, as specified in the password database, and the group vector is initialized based on the group database (unless the `-P` option was specified).

The following parameters may be specified by security policy:

- real and effective user-ID
- real and effective group-ID
- supplementary group-IDs
- the environment list
- current working directory
- file creation mode mask (umask)
- SELinux role and type
- scheduling priority (aka nice value)

Process model

There are two distinct ways **sudo** can run a command.

If an I/O logging plugin is configured or if the security policy explicitly requests it, a new pseudo-terminal (“pty”) is allocated and `fork(2)` is used to create a second **sudo** process, referred to as the *monitor*. The *monitor* creates a new terminal session with itself as the leader and the pty as its controlling terminal, calls `fork(2)`, sets up the execution environment as described above, and then uses the `execve(2)` system call to run the command in the child process. The *monitor* exists to relay job control signals between the user’s existing terminal and the pty the command is being run in. This makes it possible to suspend and resume the command. Without the monitor, the command would be in what POSIX terms an “orphaned process group” and it would not receive any job control signals from the kernel. When the command exits or is terminated by a signal, the *monitor* passes the command’s exit status to the main **sudo** process and exits. After receiving the command’s exit status, the main **sudo** passes the command’s exit status to the security policy’s close function and exits.

If no pty is used, **sudo** calls `fork(2)`, sets up the execution environment as described above, and uses the `execve(2)` system call to run the command in the child process. The main **sudo** process waits until the command has completed, then passes the command’s exit status to the security policy’s close function and exits. As a special case, if the policy plugin does not define a close function, **sudo** will execute the command directly instead of calling `fork(2)` first. The *sudoers* policy plugin will only define a close function when I/O logging is enabled, a pty is required, an SELinux role is specified, the command has an associated timeout, or the *pam_session* or *pam_setcred* options are enabled. Note that *pam_session* and *pam_setcred* are enabled by default on systems using PAM.

On systems that use PAM, the security policy's close function is responsible for closing the PAM session. It may also log the command's exit status.

Signal handling

When the command is run as a child of the **sudo** process, **sudo** will relay signals it receives to the command. The SIGINT and SIGQUIT signals are only relayed when the command is being run in a new pty or when the signal was sent by a user process, not the kernel. This prevents the command from receiving SIGINT twice each time the user enters control-C. Some signals, such as SIGSTOP and SIGKILL, cannot be caught and thus will not be relayed to the command. As a general rule, SIGTSTP should be used instead of SIGSTOP when you wish to suspend a command being run by **sudo**.

As a special case, **sudo** will not relay signals that were sent by the command it is running. This prevents the command from accidentally killing itself. On some systems, the **reboot(8)** command sends SIGTERM to all non-system processes other than itself before rebooting the system. This prevents **sudo** from relaying the SIGTERM signal it received back to **reboot(8)**, which might then exit before the system was actually rebooted, leaving it in a half-dead state similar to single user mode. Note, however, that this check only applies to the command run by **sudo** and not any other processes that the command may create. As a result, running a script that calls **reboot(8)** or **shutdown(8)** via **sudo** may cause the system to end up in this undefined state unless the **reboot(8)** or **shutdown(8)** are run using the **exec()** family of functions instead of **system()** (which interposes a shell between the command and the calling process).

If no I/O logging plugins are loaded and the policy plugin has not defined a **close()** function, set a command timeout, or required that the command be run in a new pty, **sudo** may execute the command directly instead of running it as a child process.

Plugins

Plugins may be specified via Plugin directives in the **sudo.conf(5)** file. They may be loaded as dynamic shared objects (on systems that support them), or compiled directly into the **sudo** binary. If no **sudo.conf(5)** file is present, or if it doesn't contain any Plugin lines, **sudo** will use **sudoers(5)** for the policy, auditing, and I/O logging plugins. See the **sudo.conf(5)** manual for details of the **/etc/sudo.conf** file and the **sudo_plugin(5)** manual for more information about the **sudo** plugin architecture.

EXIT VALUE

Upon successful execution of a command, the exit status from **sudo** will be the exit status of the program that was executed. If the command terminated due to receipt of a signal, **sudo** will send itself the same signal that terminated the command.

If the **-l** option was specified without a command, **sudo** will exit with a value of 0 if the user is allowed to run **sudo** and they authenticated successfully (as required by the security policy). If a command is specified with the **-l** option, the exit value will only be 0 if the command is permitted by the security policy, otherwise it will be 1.

If there is an authentication failure, a configuration/permission problem, or if the given command cannot be executed, **sudo** exits with a value of 1. In the latter case, the error string is printed to the standard error. If **sudo** cannot stat(2) one or more entries in the user's PATH, an error is printed to the standard error. (If the directory does not exist or if it is not really a directory, the entry is ignored and no error is printed.) This should not happen under normal circumstances. The most common reason for stat(2) to return "permission denied" is if you are running an automounter and one of the directories in your PATH is on a machine that is currently unreachable.

SECURITY NOTES

sudo tries to be safe when executing external commands.

To prevent command spoofing, **sudo** checks "." and "" (both denoting current directory) last when searching for a command in the user's PATH (if one or both are in the PATH). Depending on the security policy, the user's PATH environment variable may be modified, replaced, or passed unchanged to the program that **sudo** executes.

Users should *never* be granted **sudo** privileges to execute files that are writable by the user or that reside in a directory that is writable by the user. If the user can modify or replace the command there is no way to limit what additional commands they can run.

Please note that **sudo** will normally only log the command it explicitly runs. If a user runs a command such as **sudo su** or **sudo sh**, subsequent commands run from that shell are not subject to **sudo**'s security policy. The same is true for commands that offer shell escapes (including most editors). If I/O logging is enabled, subsequent commands will have their input and/or output logged, but there will not be traditional logs for those commands. Because of this, care must be taken when giving users access to commands via **sudo** to verify that the command does not inadvertently give the user an effective root shell. For information on ways to address this, please see the *Preventing shell escapes* section in **sudoers(5)**.

To prevent the disclosure of potentially sensitive information, **sudo** disables core dumps by default while it is executing (they are re-enabled for the command that is run). This historical practice dates from a time when most operating systems allowed set-user-ID processes to dump core by default. To aid in debugging **sudo** crashes, you may wish to re-enable core dumps by setting "disable_coredump" to false in the **sudo.conf(5)** file as follows:

```
Set disable_coredump false
```

See the **sudo.conf(5)** manual for more information.

ENVIRONMENT

sudo utilizes the following environment variables. The security policy has control over the actual content of the command's environment.

EDITOR	Default editor to use in -e (sudoedit) mode if neither SUDO_EDITOR nor VISUAL is set.
MAIL	Set to the mail spool of the target user when the -i option is specified, or when env_reset is enabled in sudoers (unless MAIL is present in the env_keep list).
HOME	Set to the home directory of the target user when the -i or -H options are specified, when the -s option is specified and set_home is set in sudoers , when always_set_home is enabled in sudoers , or when env_reset is enabled in sudoers and HOME is not present in the env_keep list.
LOGNAME	Set to the login name of the target user when the -i option is specified, when the set_logname option is enabled in sudoers , or when the env_reset option is enabled in sudoers (unless LOGNAME is present in the env_keep list).
PATH	May be overridden by the security policy.
SHELL	Used to determine shell to run with -s option.
SUDO_ASKPASS	Specifies the path to a helper program used to read the password if no terminal is available or if the -A option is specified.
SUDO_COMMAND	Set to the command run by sudo, including command line arguments. The command line arguments are truncated at 4096 characters to prevent a potential execution error.

SUDO_EDITOR	Default editor to use in -e (sudoedit) mode.
SUDO_GID	Set to the group-ID of the user who invoked sudo.
SUDO_PROMPT	Used as the default password prompt unless the -p option was specified.
SUDO_PS1	If set, PS1 will be set to its value for the program being run.
SUDO_UID	Set to the user-ID of the user who invoked sudo.
SUDO_USER	Set to the login name of the user who invoked sudo.
USER	Set to the same value as LOGNAME, described above.
VISUAL	Default editor to use in -e (sudoedit) mode if SUDO_EDITOR is not set.

FILES

/etc/sudo.conf	sudo front-end configuration
----------------	-------------------------------------

EXAMPLES

Note: the following examples assume a properly configured security policy.

To get a file listing of an unreadable directory:

```
$ sudo ls /usr/local/protected
```

To list the home directory of user yaz on a machine where the file system holding ~yaz is not exported as root:

```
$ sudo -u yaz ls ~yaz
```

To edit the index.html file as user www:

```
$ sudoedit -u www ~www/htdocs/index.html
```

To view system logs only accessible to root and users in the adm group:

```
$ sudo -g adm more /var/log/syslog
```

To run an editor as jim with a different primary group:

```
$ sudoedit -u jim -g audio ~jim/sound.txt
```

To shut down a machine:

```
$ sudo shutdown -r +15 "quick reboot"
```

To make a usage listing of the directories in the /home partition. Note that this runs the commands in a sub-shell to make the cd and file redirection work.

```
$ sudo sh -c "cd /home ; du -s * | sort -rn > USAGE"
```

DIAGNOSTICS

Error messages produced by **sudo** include:

editing files in a writable directory is not permitted

By default, **sudoedit** does not permit editing a file when any of the parent directories are writable by the invoking user. This avoids a race condition that could allow the user to overwrite an arbitrary file. See the *sudoedit_c heckdir* option in sudoers(5) for more information.

editing symbolic links is not permitted

By default, **sudoedit** does not follow symbolic links when opening files. See the *sudoedit_follow* option in sudoers(5) for more information.

effective uid is not 0, is sudo installed setuid root?

sudo was not run with root privileges. The **sudo** binary must be owned by the root user and have the set-user-ID bit set. Also, it must not be located on a file system mounted with the ‘nosuid’ option or on an NFS file system that maps uid 0 to an unprivileged uid.

effective uid is not 0, is sudo on a file system with the ‘nosuid’ option set or an NFS file system without root privileges?

sudo was not run with root privileges. The **sudo** binary has the proper owner and permissions but it still did not run with root privileges. The most common reason for this is that the file system the **sudo** binary is located on is mounted with the ‘nosuid’ option or it is an NFS file system that maps uid 0 to an unprivileged uid.

fatal error, unable to load plugins

An error occurred while loading or initializing the plugins specified in **sudo.conf(5)**.

invalid environment variable name

One or more environment variable names specified via the **-E** option contained an equal sign (‘=’). The arguments to the **-E** option should be environment variable names without an associated value.

no password was provided

When **sudo** tried to read the password, it did not receive any characters. This may happen if no terminal is available (or the **-s** option is specified) and the standard input has been redirected from **/dev/null**.

a terminal is required to read the password

sudo needs to read the password but there is no mechanism available for it to do so. A terminal is not present to read the password from, **sudo** has not been configured to read from the standard input, the **-s** option was not used, and no askpass helper has been specified either via the **sudo.conf(5)** file or the **SUDO_ASKPASS** environment variable.

no writable temporary directory found

sudoedit was unable to find a usable temporary directory in which to store its intermediate files.

The “no new privileges” flag is set, which prevents sudo from running as root.

sudo was run by a process that has the Linux “no new privileges” flag is set. This causes the set-user-ID bit to be ignored when running an executable, which will prevent **sudo** from functioning. The most likely cause for this is running **sudo** within a container that sets this flag. Check the documentation to see if it is possible to configure the container such that the flag is not set.

sudo must be owned by uid 0 and have the setuid bit set

sudo was not run with root privileges. The **sudo** binary does not have the correct owner or permissions. It must be owned by the root user and have the set-user-ID bit set.

sudoedit is not supported on this platform

It is only possible to run **sudoedit** on systems that support setting the effective user-ID.

timed out reading password

The user did not enter a password before the password timeout (5 minutes by default) expired.

you do not exist in the passwd database

Your user-ID does not appear in the system passwd database.

you may not specify environment variables in edit mode

It is only possible to specify environment variables when running a command. When editing a file, the editor is run with the user’s environment unmodified.

HISTORY

See the HISTORY file in the `sudo` distribution (<https://www.sudo.ws/history.html>) for a brief history of `sudo`.

AUTHORS

Many people have worked on `sudo` over the years; this version consists of code written primarily by:

Todd C. Miller

See the CONTRIBUTORS file in the `sudo` distribution (<https://www.sudo.ws/contributors.html>) for an exhaustive list of people who have contributed to `sudo`.

CAVEATS

There is no easy way to prevent a user from gaining a root shell if that user is allowed to run arbitrary commands via `sudo`. Also, many programs (such as editors) allow the user to run commands via shell escapes, thus avoiding `sudo`'s checks. However, on most systems it is possible to prevent shell escapes with the `sudoers(5)` plugin's `noexec` functionality.

It is not meaningful to run the `cd` command directly via `sudo`, e.g.,

```
$ sudo cd /usr/local/protected
```

since when the command exits the parent process (your shell) will still be the same. Please see the **EXAMPLES** section for more information.

Running shell scripts via `sudo` can expose the same kernel bugs that make set-user-ID shell scripts unsafe on some operating systems (if your OS has a `/dev/fd/` directory, set-user-ID shell scripts are generally safe).

BUGS

If you feel you have found a bug in `sudo`, please submit a bug report at <https://bugzilla.sudo.ws/>

SUPPORT

Limited free support is available via the `sudo-users` mailing list, see <https://www.sudo.ws/mailman/listinfo/sudo-users> to subscribe or search the archives.

DISCLAIMER

`sudo` is provided "AS IS" and any express or implied warranties, including, but not limited to, the implied warranties of merchantability and fitness for a particular purpose are disclaimed. See the LICENSE file distributed with `sudo` or <https://www.sudo.ws/license.html> for complete details.

NAME

sudo.conf — configuration for sudo front-end

DESCRIPTION

The **sudo.conf** file is used to configure the **sudo** front-end. It is used to configure sudo plugins, plugin-agnostic path names, debug flags, and other settings.

The **sudo.conf** file supports the following directives, described in detail below.

Plugin an approval, audit, I/O logging, or security policy plugin

Path a plugin-agnostic path

Set a front-end setting, such as *disable_coredump* or *group_source*

Debug debug flags to aid in debugging **sudo**, **sudoreplay**, **visudo**, and the **sudoers** plugin.

The pound sign ('#') is used to indicate a comment. Both the comment character and any text after it, up to the end of the line, are ignored.

Long lines can be continued with a backslash ('\') as the last character on the line. Note that leading white space is removed from the beginning of lines even when the continuation character is used.

Non-comment lines that don't begin with Plugin, Path, Debug, or Set are silently ignored.

The **sudo.conf** file is always parsed in the "C" locale.

Plugin configuration

sudo supports a plugin architecture for security policies and input/output logging. Third parties can develop and distribute their own policy and I/O logging plugins to work seamlessly with the **sudo** front-end. Plugins are dynamically loaded based on the contents of **sudo.conf**.

A Plugin line consists of the Plugin keyword, followed by the *symbol_name* and the *path* to the dynamic shared object that contains the plugin. The *symbol_name* is the name of the *approval_plugin*, *audit_plugin*, *io_plugin*, or *policy_plugin* struct contained in the plugin. If a plugin implements multiple plugin types, there must be a Plugin line for each unique symbol name. The *path* may be fully qualified or relative. If not fully qualified, it is relative to the directory specified by the *plugin_dir* Path setting, which defaults to /usr/libexec/sudo. In other words:

```
Plugin sudoers_policy sudoers.so
```

is equivalent to:

```
Plugin sudoers_policy /usr/libexec/sudo/sudoers.so
```

If the plugin was compiled statically into the **sudo** binary instead of being installed as a dynamic shared object, the *path* should be specified without a leading directory, as it does not actually exist in the file system. For example:

```
Plugin sudoers_policy sudoers.so
```

Starting with **sudo** 1.8.5, any additional parameters after the *path* are passed as arguments to the plugin's *open* function. For example, to override the compile-time default sudoers file mode:

```
Plugin sudoers_policy sudoers.so sudoers_mode=0440
```

See the **sudoers(5)** manual for a list of supported arguments.

The same dynamic shared object may contain multiple plugins, each with a different symbol name. The file must be owned by user-ID 0 and only writable by its owner. Because of ambiguities that arise from composite policies, only a single policy plugin may be specified. This limitation does not apply to I/O plugins.

If no **sudo.conf** file is present, or if it contains no **Plugin** lines, the **sudoers** plugin will be used as the default security policy, for I/O logging (if enabled by the policy), and for auditing. This is equivalent to the following:

```
Plugin sudoers_policy sudoers.so
Plugin sudoers_io sudoers.so
Plugin sudoers_audit sudoers.so
```

Starting with **sudo** version 1.9.1, some of the logging functionality of the **sudoers** plugin has been moved from the policy plugin to an audit plugin. To maintain compatibility with **sudo.conf** files from older **sudo** versions, if **sudoers** is configured as the security policy, it will be used as an audit plugin as well. This guarantees that the logging behavior will be consistent with that of **sudo** versions 1.9.0 and below.

For more information on the **sudo** plugin architecture, see the **sudo_plugin(5)** manual.

Path settings

A Path line consists of the Path keyword, followed by the name of the path to set and its value. For example:

```
Path intercept /usr/libexec/sudo/sudo_intercept.so
Path noexec /usr/libexec/sudo/sudo_noexec.so
Path askpass /usr/X11R6/bin/ssh-askpass
```

If no path name is specified, features relying on the specified setting will be disabled. Disabling Path settings is only supported in **sudo** version 1.8.16 and higher.

The following plugin-agnostic paths may be set in the **/etc/sudo.conf** file:

askpass	The fully qualified path to a helper program used to read the user's password when no terminal is available. This may be the case when sudo is executed from a graphical (as opposed to text-based) application. The program specified by <i>askpass</i> should display the argument passed to it as the prompt and write the user's password to the standard output. The value of <i>askpass</i> may be overridden by the SUDO_ASKPASS environment variable.
devsearch	An ordered, colon-separated search path of directories to look in for device nodes. This is used when mapping the process's tty device number to a device name on systems that do not provide such a mechanism. Sudo will <i>not</i> recurse into sub-directories. If terminal devices may be located in a sub-directory of /dev , that path must be explicitly listed in <i>devsearch</i> . The default value is /dev/pts:/dev/vt:/dev/term:/dev/zcons:/dev/pty:/dev . This option is ignored on systems that support either the devname() or _ttyname_dev() functions, for example BSD, macOS and Solaris.
intercept	The fully-qualified path to a shared library containing wrappers for the exec1() , execle() , execlp() , execv() , execve() , execvp() , and execvpe() library functions that intercepts attempts to run further commands and performs a policy check before allowing them to be executed. This is used to implement the <i>intercept</i> functionality on systems that support LD_PRELOAD or its equivalent. The default value is /usr/libexec/sudo/sudo_intercept.so .
noexec	The fully-qualified path to a shared library containing wrappers for the exec1() , execle() , execlp() , exec() , execv() , execve() , execveat() , execvp() , execvpe() , fexecve() , popen() , posix_spawn() , posix_spawnnp() , system() , and wordexp() library functions that prevent the execution of further commands. This is used to implement the <i>noexec</i> functionality on systems that support LD_PRELOAD or its equivalent. The default value is /usr/libexec/sudo/sudo_noexec.so .

plugin_dir

The default directory to use when searching for plugins that are specified without a fully qualified path name. The default value is `/usr/libexec/sudo`.

sesh

The fully-qualified path to the **sesh** binary. This setting is only used when **sudo** is built with SELinux support. The default value is `/usr/libexec/sudo/sesh`.

Other settings

The **sudo.conf** file also supports the following front-end settings:

disable_coredump

Core dumps of **sudo** itself are disabled by default to prevent the disclosure of potentially sensitive information. To aid in debugging **sudo** crashes, you may wish to re-enable core dumps by setting “`disable_coredump`” to false in **sudo.conf** as follows:

```
Set disable_coredump false
```

All modern operating systems place restrictions on core dumps from set-user-ID processes like **sudo** so this option can be enabled without compromising security. To actually get a **sudo** core file you will likely need to enable core dumps for set-user-ID processes. On BSD and Linux systems this is accomplished in the `sysctl(8)` command. On Solaris, the `coreadm(1m)` command is used to configure core dump behavior.

This setting is only available in **sudo** version 1.8.4 and higher.

developer_mode

By default **sudo** refuses to load plugins which can be modified by other than the root user. The plugin should be owned by root and write access permissions should be disabled for “group” and “other”. To make development of a plugin easier, you can disable that by setting “`developer_mode`” option to true in **sudo.conf** as follows:

```
Set developer_mode true
```

Please note that this creates a security risk, so it is not recommended on critical systems such as a desktop machine for daily use, but is intended to be used in development environments (VM, container, etc). Before enabling developer mode, ensure you understand the implications.

This setting is only available in **sudo** version 1.9.0 and higher.

group_source

sudo passes the invoking user’s group list to the policy and I/O plugins. On most systems, there is an upper limit to the number of groups that a user may belong to simultaneously (typically 16 for compatibility with NFS). On systems with the `getconf(1)` utility, running:

```
getconf NGROUPS_MAX
```

will return the maximum number of groups.

However, it is still possible to be a member of a larger number of groups--they simply won’t be included in the group list returned by the kernel for the user. Starting with **sudo** version 1.8.7, if the user’s kernel group list has the maximum number of entries, **sudo** will consult the group database directly to determine the group list. This makes it possible for the security policy to perform matching by group name even when the user is a member of more than the maximum number of groups.

The `group_source` setting allows the administrator to change this default behavior. Supported values for `group_source` are:

static	Use the static group list that the kernel returns. Retrieving the group list this way is very fast but it is subject to an upper limit as described above. It is “static” in that it does not reflect changes to the group database made after the user logs in. This was the default behavior prior to sudo 1.8.7.
dynamic	Always query the group database directly. It is “dynamic” in that changes made to the group database after the user logs in will be reflected in the group list. On some systems, querying the group database for all of a user’s groups can be time consuming when querying a network-based group database. Most operating systems provide an efficient method of performing such queries. Currently, sudo supports efficient group queries on AIX, BSD, HP-UX, Linux, macOS, and Solaris. This is the default behavior on macOS in sudo 1.9.6 and higher.
adaptive	Only query the group database if the static group list returned by the kernel has the maximum number of entries. This is the default behavior on systems other than macOS in sudo 1.8.7 and higher.

For example, to cause **sudo** to only use the kernel’s static list of groups for the user:

```
Set group_source static
```

This setting is only available in **sudo** version 1.8.7 and higher.

max_groups

The maximum number of user groups to retrieve from the group database. Values less than one or larger than 1024 will be ignored. This setting is only used when querying the group database directly. It is intended to be used on systems where it is not possible to detect when the array to be populated with group entries is not sufficiently large. By default, **sudo** will allocate four times the system’s maximum number of groups (see above) and retry with double that number if the group database query fails.

This setting is only available in **sudo** version 1.8.7 and higher. It should not be required in **sudo** versions 1.8.24 and higher and may be removed in a later release.

probe_interfaces

By default, **sudo** will probe the system’s network interfaces and pass the IP address of each enabled interface to the policy plugin. This makes it possible for the plugin to match rules based on the IP address without having to query DNS. On Linux systems with a large number of virtual interfaces, this may take a non-negligible amount of time. If IP-based matching is not required, network interface probing can be disabled as follows:

```
Set probe_interfaces false
```

This setting is only available in **sudo** version 1.8.10 and higher.

Debug settings

sudo versions 1.8.4 and higher support a flexible debugging framework that can log what **sudo** is doing internally if there is a problem.

A Debug line consists of the Debug keyword, followed by the name of the program, plugin, or shared object to debug, the debug file name, and a comma-separated list of debug flags. The debug flag syntax used by **sudo**, the **sudoers** plugin along with its associated programs and shared objects is *subsystem@priority* but a third-party plugin is free to use a different format so long as it does not include a comma (‘,’).

Examples:

```
Debug sudo /var/log/sudo_debug all@warn,plugin@info
```

would log all debugging statements at the *warn* level and higher in addition to those at the *info* level for the plugin subsystem.

```
Debug sudo_intercept.so /var/log/intercept_debug all@debug
```

would log all debugging statements, regardless of level, for the `sudo_intercept.so` shared object that implements **sudo**'s intercept functionality.

As of **sudo** 1.8.12, multiple Debug entries may be specified per program. Older versions of **sudo** only support a single Debug entry per program. Plugin-specific Debug entries are also supported starting with **sudo** 1.8.12 and are matched by either the base name of the plugin that was loaded (for example `sudoers.so`) or by the plugin's fully-qualified path name. Previously, the `sudoers` plugin shared the same Debug entry as the **sudo** front-end and could not be configured separately.

The following priorities are supported, in order of decreasing severity: *crit*, *err*, *warn*, *notice*, *diag*, *info*, *trace*, and *debug*. Each priority, when specified, also includes all priorities higher than it. For example, a priority of *notice* would include debug messages logged at *notice* and higher.

The priorities *trace* and *debug* also include function call tracing which logs when a function is entered and when it returns. For example, the following trace is for the `get_user_groups()` function located in `src/sudo.c`:

```
sudo[123] -> get_user_groups @ src/sudo.c:385
sudo[123] <- get_user_groups @ src/sudo.c:429 := groups=10,0,5
```

When the function is entered, indicated by a right arrow ‘->’, the program, process ID, function, source file, and line number are logged. When the function returns, indicated by a left arrow ‘<-’, the same information is logged along with the return value. In this case, the return value is a string.

The following subsystems are used by the **sudo** front-end:

<i>all</i>	matches every subsystem
<i>args</i>	command line argument processing
<i>conv</i>	user conversation
<i>edit</i>	<code>sudoedit</code>
<i>event</i>	event subsystem
<i>exec</i>	command execution
<i>main</i>	sudo main function
<i>netif</i>	network interface handling
<i>pcomm</i>	communication with the plugin
<i>plugin</i>	plugin configuration
<i>pty</i>	pseudo-terminal related code
<i>selinux</i>	SELinux-specific handling
<i>util</i>	utility functions
<i>utmp</i>	utmp handling

The `sudoers`(5) plugin includes support for additional subsystems.

FILES

/etc/sudo.conf	sudo front-end configuration
----------------	-------------------------------------

EXAMPLES

```

#
# Default /etc/sudo.conf file
#
# Sudo plugins:
#   Plugin plugin_name plugin_path plugin_options ...
#
# The plugin_path is relative to /usr/libexec/sudo unless
#   fully qualified.
# The plugin_name corresponds to a global symbol in the plugin
#   that contains the plugin interface structure.
# The plugin_options are optional.
#
# The sudoers plugin is used by default if no Plugin lines are present.
#Plugin sudoers_policy sudoers.so
#Plugin sudoers_io sudoers.so
#Plugin sudoers_audit sudoers.so

#
# Sudo askpass:
#   Path askpass /path/to/askpass
#
# An askpass helper program may be specified to provide a graphical
# password prompt for "sudo -A" support. Sudo does not ship with its
# own askpass program but can use the OpenSSH askpass.
#
# Use the OpenSSH askpass
#Path askpass /usr/X11R6/bin/ssh-askpass
#
# Use the Gnome OpenSSH askpass
#Path askpass /usr/libexec/openssh/gnome-ssh-askpass

#
# Sudo device search path:
#   Path devsearch /dev/path1:/dev/path2:/dev
#
# A colon-separated list of paths to check when searching for a user's
# terminal device.
#
#Path devsearch /dev/pts:/dev/vt:/dev/term:/dev/zcons:/dev/pty:/dev

#
# Sudo command interception:
#   Path intercept /path/to/sudo_intercept.so
#
# Path to a shared library containing replacements for the execv()
# and execve() library functions that perform a policy check to verify
# the command is allowed and simply return an error if not. This is
# used to implement the "intercept" functionality on systems that

```

```
# support LD_PRELOAD or its equivalent.  
#  
# The compiled-in value is usually sufficient and should only be changed  
# if you rename or move the sudo_intercept.so file.  
#  
#Path intercept /usr/libexec/sudo/sudo_intercept.so  
  
#  
# Sudo noexec:  
#   Path noexec /path/to/sudo_noexec.so  
#  
# Path to a shared library containing replacements for the execv()  
# family of library functions that just return an error. This is  
# used to implement the "noexec" functionality on systems that support  
# LD_PRELOAD or its equivalent.  
#  
# The compiled-in value is usually sufficient and should only be changed  
# if you rename or move the sudo_noexec.so file.  
#  
#Path noexec /usr/libexec/sudo/sudo_noexec.so  
  
#  
# Sudo plugin directory:  
#   Path plugin_dir /path/to/plugins  
#  
# The default directory to use when searching for plugins that are  
# specified without a fully qualified path name.  
#  
#Path plugin_dir /usr/libexec/sudo  
  
#  
# Sudo developer mode:  
#   Set developer_mode true|false  
#  
# Allow loading of plugins that are owned by non-root or are writable  
# by "group" or "other". Should only be used during plugin development.  
#Set developer_mode true  
  
#  
# Core dumps:  
#   Set disable_coredump true|false  
#  
# By default, sudo disables core dumps while it is executing (they  
# are re-enabled for the command that is run).  
# To aid in debugging sudo problems, you may wish to enable core  
# dumps by setting "disable_coredump" to false.  
#  
#Set disable_coredump false  
  
#  
# User groups:  
#   Set group_source static|dynamic|adaptive
```

```

#
# Sudo passes the user's group list to the policy plugin.
# If the user is a member of the maximum number of groups (usually 16),
# sudo will query the group database directly to be sure to include
# the full list of groups.
#
# On some systems, this can be expensive so the behavior is configurable.
# The "group_source" setting has three possible values:
#   static - use the user's list of groups returned by the kernel.
#   dynamic - query the group database to find the list of groups.
#   adaptive - if user is in less than the maximum number of groups.
#               use the kernel list, else query the group database.
#
#Set group_source static

#
# Sudo interface probing:
#   Set probe_interfaces true|false
#
# By default, sudo will probe the system's network interfaces and
# pass the IP address of each enabled interface to the policy plugin.
# On systems with a large number of virtual interfaces this may take
# a noticeable amount of time.
#
#Set probe_interfaces false

#
# Sudo debug files:
#   Debug program /path/to/debug_log subsystem@priority[,subsystem@priority]
#
# Sudo and related programs support logging debug information to a file.
# The program is typically sudo, sudoers.so, sudoreplay, or visudo.
#
# Subsystems vary based on the program; "all" matches all subsystems.
# Priority may be crit, err, warn, notice, diag, info, trace, or debug.
# Multiple subsystem@priority may be specified, separated by a comma.
#
#Debug sudo /var/log/sudo_debug all@debug
#Debug sudoers.so /var/log/sudoers_debug all@debug

```

NAME

sudo_logsrv.proto — Sudo log server protocol

DESCRIPTION

Starting with version 1.9.0, **sudo** supports sending event and I/O logs to a log server. The protocol used is written in Google’s Protocol Buffers domain specific language. The **EXAMPLES** section includes a complete description of the protocol in Protocol Buffers format.

Because there is no way to determine message boundaries when using Protocol Buffers, the wire size of each message is sent immediately preceding the message itself as a 32-bit unsigned integer in network byte order. This is referred to as “length-prefix framing” and is how Google suggests handling the lack of message delimiters.

The protocol is made up of two basic messages, *ClientMessage* and *ServerMessage*, described below. The server must accept messages up to two megabytes in size. The server may return an error if the client tries to send a message larger than two megabytes.

Client Messages

A *ClientMessage* is a container used to encapsulate all the possible message types a client may send to the server.

```
message ClientMessage {
    oneof type {
        AcceptMessage accept_msg = 1;
        RejectMessage reject_msg = 2;
        ExitMessage exit_msg = 3;
        RestartMessage restart_msg = 4;
        AlertMessage alert_msg = 5;
        IoBuffer ttyin_buf = 6;
        IoBuffer ttyout_buf = 7;
        IoBuffer stdin_buf = 8;
        IoBuffer stdout_buf = 9;
        IoBuffer stderr_buf = 10;
        ChangeWindowSize winsize_event = 11;
        CommandSuspend suspend_event = 12;
        ClientHello hello_msg = 13;
    }
}
```

The different *ClientMessage* sub-messages the client may sent to the server are described below.

TimeSpec

```
message TimeSpec {
    int64 tv_sec = 1;
    int32 tv_nsec = 2;
}
```

A *TimeSpec* is the equivalent of a POSIX struct `timespec`, containing seconds and nanoseconds members. The `tv_sec` member is a 64-bit integer to support dates after the year 2038.

InfoMessage

```
message InfoMessage {
    message StringList {
        repeated string strings = 1;
```

```

    }
  message NumberList {
    repeated int64 numbers = 1;
  }
  string key = 1;
  oneof value {
    int64 numval = 2;
    string strval = 3;
    StringList strlistval = 4;
    NumberList numlistval = 5;
  }
}

```

An *InfoMessage* is used to represent information about the invoking user as well as the execution environment the command runs in the form of key-value pairs. The key is always a string but the value may be a 64-bit integer, a string, an array of strings, or an array of 64-bit integers. The event log data is composed of *InfoMessage* entries. See the **EVENT LOG VARIABLES** section for more information.

ClientHello hello_msg

```

message ClientHello {
  string client_id = 1;
}

```

A *ClientHello* message consists of client information that may be sent to the server when the client first connects.

client_id

A free-form client description. This usually includes the name and version of the client implementation.

AcceptMessage accept_msg

```

message AcceptMessage {
  TimeSpec submit_time = 1;
  repeated InfoMessage info_msgs = 2;
  bool expect_iobufs = 3;
}

```

An *AcceptMessage* is sent by the client when a command is allowed by the security policy. It contains the following members:

submit_time

The wall clock time when the command was submitted to the security policy.

info_msgs

An array of *InfoMessage* describing the user who submitted the command as well as the execution environment of the command. This information is used to generate an event log entry and may also be used by server to determine where and how the I/O log is stored.

expect_iobufs

Set to true if the server should expect *IoBuffer* messages to follow (for I/O logging) or false if the server should only store the event log.

If an *AcceptMessage* is sent, the client must not send a *RejectMessage* or *RestartMessage*.

RejectMessage reject_msg

```
message RejectMessage {
    TimeSpec submit_time = 1;
    string reason = 2;
    repeated InfoMessage info_msgs = 3;
}
```

A *RejectMessage* is sent by the client when a command is denied by the security policy. It contains the following members:

submit_time

The wall clock time when the command was submitted to the security policy.

reason

The reason the security policy gave for denying the command.

info_msgs

An array of *InfoMessage* describing the user who submitted the command as well as the execution environment of the command. This information is used to generate an event log entry.

If a *RejectMessage* is sent, the client must not send an *AcceptMessage* or *RestartMessage*.

ExitMessage exit_msg

```
message ExitMessage {
    TimeSpec run_time = 1;
    int32 exit_value = 2;
    bool dumped_core = 3;
    string signal = 4;
    string error = 5;
}
```

An *ExitMessage* is sent by the client after the command has exited or has been terminated by a signal. It contains the following members:

run_time

The total amount of elapsed time since the command started, calculated using a monotonic clock where possible. This is not the wall clock time.

exit_value

The command's exit value in the range 0-255.

dumped_core

True if the command was terminated by a signal and dumped core.

signal

If the command was terminated by a signal, this is set to the name of the signal without the leading

“SIG”. For example, INT, TERM, KILL, SEGV.

error

A message from the client indicating that the command was terminated unexpectedly due to an error.

When performing I/O logging, the client should wait for a *commit_point* corresponding to the final *IoBuffer* before closing the connection unless the final *commit_point* has already been received.

RestartMessage restart_msg

```
message RestartMessage {
    string log_id = 1;
    TimeSpec resume_point = 2;
}
```

A *RestartMessage* is sent by the client to resume sending an existing I/O log that was previously interrupted. It contains the following members:

log_id The the server-side name for an I/O log that was previously sent to the client by the server. This may be a path name on the server or some other kind of server-side identifier.

resume_point

The point in time after which to resume the I/O log. This is in the form of a *TimeSpec* representing the amount of time since the command started, not the wall clock time. The *resume_point* should correspond to a *commit_point* previously sent to the client by the server. If the server receives a *RestartMessage* containing a *resume_point* it has not previously seen, an error will be returned to the client and the connection will be dropped.

If a *RestartMessage* is sent, the client must not send an *AcceptMessage* or *RejectMessage*.

AlertMessage alert_msg

```
message AlertMessage {
    TimeSpec alert_time = 1;
    string reason = 2;
    repeated InfoMessage info_msgs = 3;
}
```

An *AlertMessage* is sent by the client to indicate a problem detected by the security policy while the command is running that should be stored in the event log. It contains the following members:

alert_time

The wall clock time when the alert occurred.

reason The reason for the alert.

info_msgs

An optional array of *InfoMessage* describing the user who submitted the command as well as the execution environment of the command. This information is used to generate an event log entry.

IoBuffer ttyin_buf | ttyout_buf | stdin_buf | stdout_buf | stderr_buf

```
message IoBuffer {
    TimeSpec delay = 1;
    bytes data = 2;
}
```

An *IoBuffer* is used to represent data from terminal input, terminal output, standard input, standard output, or standard error. It contains the following members:

delay The elapsed time since the last record in the form of a *TimeSpec*. The *delay* should be calculated using a monotonic clock where possible.

data The binary I/O log data from terminal input, terminal output, standard input, standard output, or standard error.

ChangeWindowSize winsize_event

```
message ChangeWindowSize {
    TimeSpec delay = 1;
    int32 rows = 2;
    int32 cols = 3;
}
```

A *ChangeWindowSize* message is sent by the client when the terminal running the command changes size. It contains the following members:

- delay The elapsed time since the last record in the form of a *TimeSpec*. The *delay* should be calculated using a monotonic clock where possible.
- rows The new number of terminal rows.
- cols The new number of terminal columns.

CommandSuspend suspend_event

```
message CommandSuspend {
    TimeSpec delay = 1;
    string signal = 2;
}
```

A *CommandSuspend* message is sent by the client when the command is either suspended or resumed. It contains the following members:

- delay The elapsed time since the last record in the form of a *TimeSpec*. The *delay* should be calculated using a monotonic clock where possible.
- signal The signal name without the leading “SIG”. For example, STOP, TSTP, CONT.

Server Messages

A *ServerMessage* is a container used to encapsulate all the possible message types the server may send to a client.

```
message ServerMessage {
    oneof type {
        ServerHello hello = 1;
        TimeSpec commit_point = 2;
        string log_id = 3;
        string error = 4;
        string abort = 5;
    }
}
```

The different *ServerMessage* sub-messages the server may sent to the client are described below.

ServerHello hello

```
message ServerHello {
    string server_id = 1;
    string redirect = 2;
    repeated string servers = 3;
    bool subcommands = 4;
}
```

The *ServerHello* message consists of server information sent when the client first connects. It contains the following members:

server_id

A free-form server description. Usually this includes the name and version of the implementation running on the log server. This member is always present.

redirect

A host and port separated by a colon (:) that the client should connect to instead. The host may be a host name, an IPv4 address, or an IPv6 address in square brackets. This may be used for server load balancing. The server will disconnect after sending the *ServerHello* when it includes a **redirect**.

servers A list of other known log servers. This can be used to implement log server redundancy and allows the client to discover all other log servers simply by connecting to one known server. This member may be omitted when there is only a single log server.

subcommands

If set, the server supports logging additional commands during a session. The client may send an *AcceptMessage* or *RejectMessage* when **sudo** is running in *intercept* mode. In this mode, commands spawned from the initial command authorized by **sudo** are subject to policy restrictions and/or are logged. If *subcommands* is false, the client must not attempt to log additional commands.

TimeSpec commit_point

A periodic time stamp sent by the server to indicate when I/O log buffers have been committed to storage. This message is not sent after every *IoBuffer* but rather at a server-configurable interval. When the server receives an *ExitMessage*, it will respond with a *commit_point* corresponding to the last received *IoBuffer* before closing the connection.

string log_id

The server-side ID of the I/O log being stored, sent in response to an *AcceptMessage* where *expect_iobufs* is true.

string error

A fatal server-side error. The server will close the connection after sending the *error* message.

string abort

An *abort* message from the server indicates that the client should kill the command and terminate the session. It may be used to implement simple server-side policy. The server will close the connection after sending the *abort* message.

Protocol flow of control

The expected protocol flow is as follows:

1. Client connects to the first available server. If the client is configured to use TLS, a TLS handshake will be attempted.
2. Client sends *ClientHello*. This is currently optional but allows the server to detect a non-TLS connection on the TLS port.
3. Server sends *ServerHello*.
4. Client responds with either *AcceptMessage*, *RejectMessage*, or *RestartMessage*.
5. If client sent a *AcceptMessage* with *expect_iobufs* set, server creates a new I/O log and responds with a *log_id*.
6. Client sends zero or more *IoBuffer* messages.
7. Server periodically responds to *IoBuffer* messages with a *commit_point*.
8. Client sends an *ExitMessage* when the command exits or is killed.

9. Server sends the final *commit_point* if one is pending.
10. Server closes the connection. After receiving the final *commit_point*, the client shuts down its side of the TLS connection if TLS is in use, and closes the connection.
11. Server shuts down its side of the TLS connection if TLS is in use, and closes the connection.

At any point, the server may send an *error* or *abort* message to the client at which point the server will close the connection. If an *abort* message is received, the client should terminate the running command.

EVENT LOG VARIABLES

AcceptMessage, *AlertMessage* and *RejectMessage* classes contain an array of *InfoMessage* that should contain information about the user who submitted the command as well as information about the execution environment of the command if it was accepted.

Some variables have a *client*, *run*, or *submit* prefix. These prefixes are used to eliminate ambiguity for variables that could apply to the client program, the user submitting the command, or the command being run. Variables with a *client* prefix pertain to the program performing the connection to the log server, for example **sudo**. Variables with a *run* prefix pertain to the command that the user requested be run. Variables with a *submit* prefix pertain to the user submitting the request (the user running **sudo**).

The following *InfoMessage* entries are required:

Key	Type	Description
command	string	command that was submitted
runuser	string	name of user the command was run as
submithost	string	name of host the command was submitted on
submituser	string	name of user submitting the command

The following *InfoMessage* entries are recognized, but not required:

Key	Type	Description	
clientargv	StringList	client's original argument vector	
clientpid	int64	client's process ID	
clientppid	int64	client's parent process ID	
clientsid	int64	client's terminal session ID	
columns	int64	number of columns in the terminal	
lines	int64	number of lines in the terminal	
runargv	StringList	argument vector of command to run	
runchroot	string	root directory of command to run	
runcwd	string	running command's working directory	
runenv	StringList	the running command's environment	
rungid	int64	primary group-ID of the command	
rungids	NumberList		supplementary group-IDs for the command
rungroup	string	primary group name of the command	
rungroups	StringList	supplementary group names for the command	
runuid	int64	run user's user-ID	
submitcwd	string	submit user's current working directory	
submitenv	StringList	the submit user's environment	
submitgid	int64	submit user's primary group-ID	
submitgids	NumberList		submit user's supplementary group-IDs

```

submitgroup  string      submitting user's primary group name
submitgroups StringList submit user's supplementary group names
submituid    int64       submit user's user-ID
ttyname     string      the terminal the command was submitted from

```

The server must accept other variables not listed above but may ignore them.

EXAMPLES

The Protocol Buffers description of the log server protocol is included in full below. Note that this uses the newer “proto3” syntax.

```

syntax = "proto3";

/*
 * Client message to the server.  Messages on the wire are
 * prefixed with a 32-bit size in network byte order.
 */
message ClientMessage {
    oneof type {
        AcceptMessage accept_msg = 1;
        RejectMessage reject_msg = 2;
        ExitMessage exit_msg = 3;
        RestartMessage restart_msg = 4;
        AlertMessage alert_msg = 5;
        IoBuffer ttyin_buf = 6;
        IoBuffer ttyout_buf = 7;
        IoBuffer stdin_buf = 8;
        IoBuffer stdout_buf = 9;
        IoBuffer stderr_buf = 10;
        ChangeWindowSize winsize_event = 11;
        CommandSuspend suspend_event = 12;
    }
}

/* Equivalent of POSIX struct timespec */
message TimeSpec {
    int64 tv_sec = 1;           /* seconds */
    int32 tv_nsec = 2;          /* nanoseconds */
}

/* I/O buffer with keystroke data */
message IoBuffer {
    TimeSpec delay = 1;         /* elapsed time since last record */
    bytes data = 2;             /* keystroke data */
}

/*
 * Key/value pairs, like Privilege Manager struct info.
 * The value may be a number, a string, or a list of strings.
 */
message InfoMessage {
    message StringList {
        repeated string strings = 1;
    }
}

```

```

    }
  message NumberList {
    repeated int64 numbers = 1;
  }
  string key = 1;
  oneof value {
    int64 numval = 2;
    string strval = 3;
    StringList strlistval = 4;
    NumberList numlistval = 5;
  }
}

/*
 * Event log data for command accepted by the policy.
 */
message AcceptMessage {
  TimeSpec submit_time = 1;           /* when command was submitted */
  repeated InfoMessage info_msgs = 2; /* key,value event log data */
  bool expect_iobufs = 3;            /* true if I/O logging enabled */
}

/*
 * Event log data for command rejected by the policy.
 */
message RejectMessage {
  TimeSpec submit_time = 1;           /* when command was submitted */
  string reason = 2;                 /* reason command was rejected */
  repeated InfoMessage info_msgs = 3; /* key,value event log data */
}

/* Message sent by client when command exits. */
/* Might revisit runtime and use end_time instead */
message ExitMessage {
  TimeSpec run_time = 1;             /* total elapsed run time */
  int32 exit_value = 2;              /* 0-255 */
  bool dumped_core = 3;             /* true if command dumped core */
  string signal = 4;                /* signal name if killed by signal */
  string error = 5;                 /* if killed due to other error */
}

/* Alert message, policy module-specific. */
message AlertMessage {
  TimeSpec alert_time = 1;           /* time alert message occurred */
  string reason = 2;                 /* policy alert error string */
  repeated InfoMessage info_msgs = 3; /* key,value event log data */
}

/* Used to restart an existing I/O log on the server. */
message RestartMessage {
  string log_id = 1;                 /* ID of log being restarted */
  TimeSpec resume_point = 2;         /* resume point (elapsed time) */
}

```

```

}

/* Window size change event. */
message ChangeWindowSize {
    TimeSpec delay = 1;           /* elapsed time since last record */
    int32 rows = 2;              /* new number of rows */
    int32 cols = 3;              /* new number of columns */
}

/* Command suspend/resume event. */
message CommandSuspend {
    TimeSpec delay = 1;           /* elapsed time since last record */
    string signal = 2;            /* signal that caused suspend/resume */
}

/*
 * Server messages to the client.  Messages on the wire are
 * prefixed with a 32-bit size in network byte order.
 */
message ServerMessage {
    oneof type {
        ServerHello hello = 1;      /* server hello message */
        TimeSpec commit_point = 2;   /* cumulative time of records stored */
        string log_id = 3;          /* ID of server-side I/O log */
        string error = 4;           /* error message from server */
        string abort = 5;           /* abort message, kill command */
    }
}

/* Hello message from server when client connects. */
message ServerHello {
    string server_id = 1;          /* free-form server description */
    string redirect = 2;            /* optional redirect if busy */
    repeated string servers = 3;   /* optional list of known servers */
}

```

NAME

sudo_logsrvd — sudo event and I/O log server

SYNOPSIS

```
sudo_logsrvd [-hnv] [-f file] [-R percentage]
```

DESCRIPTION

sudo_logsrvd is a high-performance log server that accepts event and I/O logs from **sudo**. It can be used to implement centralized logging of **sudo** logs. The server has two modes of operation: local and relay. By default, **sudo_logsrvd** stores the logs locally but it can also be configured to relay them to another server that supports the `sudo_logsrv.proto(5)` protocol.

When not relaying, event log entries may be logged either via `syslog(3)` or to a local file. I/O Logs stored locally by **sudo_logsrvd** can be replayed via the `sudoreplay(8)` utility in the same way as logs generated directly by the `sudoers` plugin.

The server also supports restarting interrupted log transfers. To distinguish completed I/O logs from incomplete ones, the I/O log timing file is set to be read-only when the log is complete.

Configuration parameters for **sudo_logsrvd** may be specified in the `sudo_logsrvd.conf(5)` file or the file specified via the **-f** option.

sudo_logsrvd rereads its configuration file when it receives SIGHUP and writes server state to the debug file (if one is configured) when it receives SIGUSR1.

The options are as follows:

-f file, --file=file

Read configuration from *file* instead of the default, `/etc/sudo_logsrvd.conf`.

-h, --help

Display a short help message to the standard output and exit.

-n, --no-fork

Run **sudo_logsrvd** in the foreground instead of detaching from the terminal and becoming a daemon.

-R percentage, --random-drop=percentage

For each message, there is a *percentage* chance that the server will drop the connection. This is only intended for debugging the ability of a client to restart a connection.

-v, --version

Print the **sudo_logsrvd** version and exit.

Securing server connections

The I/O log data sent to **sudo_logsrvd** may contain sensitive information such as passwords and should be secured using Transport Layer Security (TLS). Doing so requires having a signed certificate on the server and, if `tls_checkpeer` is enabled in `sudo_logsrvd.conf(5)`, a signed certificate on the client as well.

The certificates can either be signed by a well-known Certificate Authority (CA), or a private CA can be used. Instructions for creating a private CA are included below in the **EXAMPLES** section.

Debugging sudo_logsrvd

sudo_logsrvd supports a flexible debugging framework that is configured via `Debug` lines in the `sudo.conf(5)` file.

For more information on configuring `sudo.conf(5)`, please refer to its manual.

FILES

<code>/etc/sudo.conf</code>	Sudo front-end configuration
<code>/etc/sudo_logsrvd.conf</code>	Sudo log server configuration file
<code>/var/log/sudo_logsrvd/incoming</code>	Directory where new journals are stored when the <code>store_first_relay</code> setting is enabled.
<code>/var/log/sudo_logsrvd/outgoing</code>	Directory where completed journals are stored when the <code>store_first_relay</code> setting is enabled.
<code>/var/log/sudo-io</code>	Default I/O log file location
<code>/run/sudo/sudo_logsrvd.pid</code>	Process ID file for <code>sudo_logsrvd</code>

EXAMPLES

Creating self-signed certificates

Unless you are using certificates signed by a well-known Certificate Authority (or a local enterprise CA), you will need to create your own CA that can sign the certificates used by `sudo_logsrvd`, `sudo_sendlog`, and the `sudoers` plugin. The following steps use the `openssl(1)` command to create keys and certificates.

Initial setup

First, we need to create a directory structure to store the files for the CA. We'll create a new directory hierarchy in `/etc/ssl/sudo` for this purpose.

```
# mkdir /etc/ssl/sudo
# cd /etc/ssl/sudo
# mkdir certs csr newcerts private
# chmod 700 private
# touch index.txt
# echo 1000 > serial
```

The `serial` and `index.txt` files are used to keep track of signed certificates.

Next, we need to make a copy of the `openssl.conf` file and customize it for our new CA. The path to `openssl.cnf` is system-dependent but `/etc/ssl/openssl.cnf` is the most common location. You will need to adjust the example below if it has a different location on your system.

```
# cp /etc/ssl/openssl.cnf .
```

Now edit the `openssl.cnf` file in the current directory and make sure it contains “ca” and “CA_default” sections. Those sections should include the following settings:

```
[ ca ]
default_ca      = CA_default

[ CA_default ]
dir            = /etc/ssl/sudo
certs          = $dir/certs
database       = $dir/index.txt
```

```
certificate      = $dir/cacert.pem
serial          = $dir/serial
```

If your `openssl.conf` file already has a “CA_default” section, you may only need to modify the “dir” setting.

Creating the CA key and certificate

In order to create and sign our own certificates, we need to create a private key and a certificate for the root of the CA. First, create the private key and protect it with a pass phrase:

```
# openssl genrsa -aes256 -out private/cakey.pem 4096
# chmod 400 private/cakey.pem
```

Next, generate the root certificate, using appropriate values for the site-specific fields:

```
# openssl req -config openssl.cnf -key private/cakey.pem \
  -new -x509 -days 7300 -sha256 -extensions v3_ca \
  -out cacert.pem
```

Enter pass phrase for `private/cakey.pem`:

You are about to be asked to enter information that will be incorporated into your certificate request.

What you are about to enter is what is called a Distinguished Name or a DN.

There are quite a few fields but you can leave some blank.

For some fields there will be a default value,

If you enter ‘.’, the field will be left blank.

Country Name (2 letter code) [AU]:US

State or Province Name (full name) [Some-State]:Colorado

Locality Name (eg, city) []:

Organization Name (eg, company) [Internet Widgits Pty Ltd]:sudo

Organizational Unit Name (eg, section) []:sudo Certificate Authority

Common Name (e.g., server FQDN or YOUR name) []:sudo Root CA

Email Address []:

```
# chmod 444 cacert.pem
```

Finally, verify the root certificate:

```
# openssl x509 -noout -text -in cacert.pem
```

Creating and signing certificates

The server and client certificates will be signed by the previously created root CA. Usually, the root CA is not used to sign server/client certificates directly. Instead, intermediate certificates are created and signed with the root CA and the intermediate certs are used to sign CSRs (Certificate Signing Request). In this example we'll skip this part for simplicity's sake and sign the CSRs with the root CA.

First, generate the private key without a pass phrase.

```
# openssl genrsa -out private/logsrvd_key.pem 2048
# chmod 400 private/logsrvd_key.pem
```

Next, create a certificate signing request (CSR) for the server's certificate. The organization name must match the name given in the root certificate. The common name should be either the server's IP address or a fully qualified domain name.

```
# openssl req -config openssl.cnf -key private/logsrvd_key.pem -new \
             -sha256 -out csr/logsrvd_csr.pem

Enter pass phrase for private/logsrvd_key.pem:
You are about to be asked to enter information that will be
incorporated into your certificate request.
What you are about to enter is what is called a Distinguished Name
or a DN.
There are quite a few fields but you can leave some blank.
For some fields there will be a default value,
If you enter '.', the field will be left blank.
-----
Country Name (2 letter code) [AU]:US
State or Province Name (full name) [Some-State]:Colorado
Locality Name (eg, city) []:
Organization Name (eg, company) [Internet Widgits Pty Ltd]:sudo
Organizational Unit Name (eg, section) []:sudo log server
Common Name (e.g., server FQDN or YOUR name) []:logserver.example.com
Email Address []:

Please enter the following 'extra' attributes
to be sent with your certificate request
A challenge password []:
An optional company name []:
```

Now sign the CSR that was just created:

```
# openssl ca -config openssl.cnf -days 375 -notext -md sha256 \
             -in csr/logsrvd_csr.pem -out certs/logsrvd_cert.pem

Using configuration from openssl.cnf
Enter pass phrase for ./private/cakey.pem:
Check that the request matches the signature
Signature ok
Certificate Details:
    Serial Number: 4096 (0x1000)
    Validity
        Not Before: Nov 11 14:05:05 2019 GMT
        Not After : Nov 20 14:05:05 2020 GMT
    Subject:
        countryName          = US
        stateOrProvinceName   = Colorado
        organizationName      = sudo
        organizationalUnitName = sudo log server
        commonName            = logserve.example.com
    X509v3 extensions:
        X509v3 Basic Constraints:
            CA:FALSE
        Netscape Comment:
            OpenSSL Generated Certificate
        X509v3 Subject Key Identifier:
            4C:50:F9:D0:BE:1A:4C:B2:AC:90:76:56:C7:9E:16:AE:E6:9E:E5:B5
        X509v3 Authority Key Identifier:
```

```
keyid:D7:91:24:16:B1:03:06:65:1A:7A:6E:CF:51:E9:5C:CB:7A:95:3
```

```
Certificate is to be certified until Nov 20 14:05:05 2020 GMT (375 days)
Sign the certificate? [y/n]:y
```

```
1 out of 1 certificate requests certified, commit? [y/n]y
Write out database with 1 new entries
Data Base Updated
```

Finally, verify the new certificate:

```
# openssl verify -CAfile cacert.pem certs/ologsrvd_cert.pem
certs/ologsrvd_cert.pem: OK
```

The /etc/ssl/sudo/certs directory now contains a signed and verified certificate for use with **sudo_ologsrvd**.

To generate a client certificate, repeat the process above using a different file name.

Configuring sudo_ologsrvd to use TLS

To use TLS for client/server communication, both **sudo_ologsrvd** and the **sudoers** plugin need to be configured to use TLS. Configuring **sudo_ologsrvd** for TLS requires the following settings, assuming the same path names used earlier:

```
# Listen on port 30344 for TLS connections to any address.
listen_address = *:30344(tls)

# Path to the certificate authority bundle file in PEM format.
tls_cacert = /etc/ssl/sudo/cacert.pem

# Path to the server's certificate file in PEM format.
tls_cert = /etc/ssl/sudo/certs/ologsrvd_cert.pem

# Path to the server's private key file in PEM format.
tls_key = /etc/ssl/sudo/private/ologsrvd_key.pem
```

The root CA cert (`cacert.pem`) must be installed on the system running **sudo_ologsrvd**. If peer authentication is enabled on the client, a copy of `cacert.pem` must be present on the client system too.

BUGS

If you feel you have found a bug in **sudo_ologsrvd**, please submit a bug report at <https://bugzilla.sudo.ws/>

SUPPORT

Limited free support is available via the sudo-users mailing list, see <https://www.sudo.ws/mailman/listinfo/sudo-users> to subscribe or search the archives.

DISCLAIMER

sudo_logsrvd is provided “AS IS” and any express or implied warranties, including, but not limited to, the implied warranties of merchantability and fitness for a particular purpose are disclaimed. See the LICENSE file distributed with **sudo** or <https://www.sudo.ws/license.html> for complete details.

NAME

sudo_logsrvd.conf — configuration for sudo_logsrvd

DESCRIPTION

The **sudo_logsrvd.conf** file is used to configure the **sudo_logsrvd** log server. It uses an INI-style format made up of sections in square brackets and “key = value” pairs specific to each section below the section name. Depending on the key, values may be integers, booleans, or strings. Section and key names are not case sensitive, but values are.

The pound sign (‘#’) is used to indicate a comment. Both the comment character and any text after it, up to the end of the line, are ignored. Lines beginning with a semi-colon (‘;’) are also ignored.

Long lines can be continued with a backslash (‘\’) as the last character on the line. Note that leading white space is removed from the beginning of lines even when the continuation character is used.

The **EXAMPLES** section contains a copy of the default **sudo_logsrvd.conf** file.

The following configuration sections are recognized:

- server
- relay
- iolog
- eventlog
- syslog
- logfile

Each section is described in detail below.

server

The *server* section configures the address and port the server will listen on. The following keys are recognized:

listen_address = host[:port][(tls)]

The host name or IP address, optional port to listen on and an optional Transport Layer Security (TLS) flag in parentheses.

The host may be a host name, an IPv4 address, an IPv6 address in square brackets or the wild card entry ‘*’. A host setting of ‘*’ will cause **sudo_logsrvd** to listen on all configured network interfaces.

If the optional *tls* flag is present, **sudo_logsrvd** will secure the connection with TLS version 1.2 or 1.3. Versions of TLS prior to 1.2 are not supported. See **sudo_logsrvd(8)** for details on generating TLS keys and certificates.

If a port is specified, it may either be a port number or a known service name as defined by the system service name database. If no port is specified, port 30343 will be used for plaintext connections and port 30344 will be used for TLS connections.

The default value is:

```
listen_address = *:30343
listen_address = *:30344(tls)
```

which will listen on all configured network interfaces for both plaintext and TLS connections.

Multiple *listen_address* lines may be specified to listen on more than one port or interface.

server_log = string

Where to log server warning and error messages. Supported values are *none*, *stderr*, *syslog*, or a path name beginning with the ‘/’ character. Note that a value of *stderr* is only effective when used in conjunction with the **-n** option. The default value is *syslog*.

`pid_file = path`

The path to the file containing the process ID of the running **sudo_logsrvd**. If set to an empty value, or if **sudo_logsrvd** is run with the **-n** option, no `pid_file` will be created. If `pid_file` refers to a symbolic link, it will be ignored. The default value is `/run/sudo/sudo_logsrvd.pid`.

`tcp_keepalive = boolean`

If true, **sudo_logsrvd** will enable the TCP keepalive socket option on the client connection. This enables the periodic transmission of keepalive messages to the client. If the client does not respond to a message in time, the connection will be closed. Defaults to true.

`timeout = number`

The amount of time, in seconds, **sudo_logsrvd** will wait for the client to respond. A value of 0 will disable the timeout. The default value is 30.

`tls_cacert = path`

The path to a certificate authority bundle file, in PEM format, to use instead of the system's default certificate authority database when authenticating clients. The default is to use `/etc/ssl/sudo/cacert.pem` if it exists, otherwise the system's default certificate authority database is used.

`tls_cert = path`

The path to the server's certificate file, in PEM format. The default value is `/etc/ssl/sudo/certs/logsrvd_cert.pem`.

`tls_checkpeer = bool`

If true, client certificates will be validated by **sudo_logsrvd**; clients without a valid certificate will be unable to connect. If false, no validation of client certificates will be performed. If true and client certificates are created using a private certificate authority, the `tls_cacert` setting must be set to a CA bundle that contains the CA certificate used to generate the client certificate. The default value is `false`.

`tls_ciphers_v12 = string`

A list of ciphers to use for connections secured by TLS version 1.2 only, separated by a colon ':'. See the **CIPHER LIST FORMAT** section in `openssl-ciphers(1)` for full details. The default value is `HIGH:!aNULL` which consists of encryption cipher suites with key lengths larger than 128 bits, and some cipher suites with 128-bit keys. Cipher suites that offer no authentication are excluded.

`tls_ciphers_v13 = string`

A list of ciphers to use for connections secured by TLS version 1.3 only, separated by a colon ':'. Supported cipher suites depend on the version of OpenSSL used, but should include the following:

```
TLS_AES_128_GCM_SHA256
TLS_AES_256_GCM_SHA384
TLS_CHACHA20_POLY1305_SHA256
TLS_AES_128_CCM_SHA256
TLS_AES_128_CCM_8_SHA256
```

The default cipher suite is `TLS_AES_256_GCM_SHA384`.

`tls_dhparams = path`

The path to a file containing custom Diffie-Hellman parameters in PEM format. This file can be created with the following command:

```
openssl dhparam -out /etc/sudo_logsrvd_dhparams.pem 2048
```

By default, **sudo_logsrvd** will use the OpenSSL defaults for Diffie-Hellman key generation.

tls_key = path

The path to the server's private key file, in PEM format. The default value is `/etc/ssl/sudo/private/logsrvd_key.pem`.

tls_verify = bool

If true, **sudo_logsrvd.conf** will validate its own certificate at startup time or when the configuration is changed. If false, no verification is performed of the server certificate. When using self-signed certificates without a certificate authority, this setting should be set to false. The default value is true.

relay

The *relay* section configures the optional logsrv relay host and port the server will connect to. The TLS configuration keys are optional, by default the corresponding keys in the **server** section will be used. They are only present in this section to make it possible for the relay connection to use a different set of TLS parameters from the client-facing server. The following keys are recognized:

connect_timeout = number

The amount of time, in seconds, **sudo_logsrvd** will wait for the connection to a *relay_host* (see below) to complete. Once the connection is complete, the *timeout* setting controls the amount of time **sudo_logsrvd** will wait for the relay to respond. A value of 0 will disable the timeout. The default value is 30.

relay_dir = path

The directory in which log messages are temporarily stored before they are sent to the relay host. Messages are stored in the wire format specified by **sudo_logsrv.proto(5)**. The default value is `/var/log/sudo_logsrvd`.

relay_host = host[:port][(tls)]

The relay host name or IP address, optional port to connect to and an optional Transport Layer Security (TLS) flag in parentheses. The syntax is identical to *listen_address* in the **server** section with one exception: the wild card '*' syntax is not supported.

When this setting is enabled, messages from the client will be forwarded to one of the specified relay hosts instead of being stored locally. The *host* could be running an instance of **sudo_logsrvd** or another server that supports the **sudo_logsrv.proto(5)** protocol.

If multiple *relay_host* lines are specified, the first available relay host will be used.

retry_interval = number

The number of seconds to wait after a connection error before making a new attempt to forward a message to a relay host. The default value is 30 seconds.

store_first = boolean

If true, **sudo_logsrvd** will store logs locally before relaying them. Once the log is complete, a connection to the relay host is opened and the log is relayed. If the network connection is interrupted before the log can be fully transferred, it will be retransmitted later. The default is to relay logs in real-time.

tcp_keepalive = boolean

If true, **sudo_logsrvd** will enable the TCP keepalive socket option on the relay connection. This enables the periodic transmission of keepalive messages to the relay server. If the relay does not respond to a message in time, the connection will be closed.

timeout = number

The amount of time, in seconds, **sudo_logsrvd** will wait for the relay server to respond after a connection has succeeded. A value of 0 will disable the timeout. The default value is 30.

tls_cacert = path

The path to a certificate authority bundle file, in PEM format, to use instead of the system's default certificate authority database when authenticating clients. The default is to use the value specified in the **server** section, or the system's default certificate authority database if no value is set.

tls_cert = path

The path to the server's certificate file, in PEM format. The default is to use the value specified in the **server** section.

tls_checkpeer = bool

If true, the relay host's certificate will be validated by **sudo_logsrvd**; connections to a relay without a valid certificate will fail. If false, no validation of relay certificates will be performed. If true and relay certificates are created using a private certificate authority, the **tls_cacert** setting must be set to a CA bundle that contains the CA certificate used to generate the relay certificate. The default is to use the value specified in the **server** section.

tls_ciphers_v12 = string

A list of ciphers to use for connections secured by TLS version 1.2 only, separated by a colon ':'. See the **CIPHER LIST FORMAT** section in **openssl-ciphers(1)** for full details. The default is to use the value specified in the **server** section.

tls_ciphers_v13 = string

A list of ciphers to use for connections secured by TLS version 1.3 only, separated by a colon ':'. Supported cipher suites depend on the version of OpenSSL used, see the **server** section for more information. The default is to use the value specified in the **server** section.

tls_dhparams = path

The path to a file containing custom Diffie-Hellman parameters in PEM format. The default is to use the value specified in the **server** section.

tls_key = path

The path to the server's private key file, in PEM format. The default is to use the value specified in the **server** section.

tls_verify = bool

If true, the server's certificate used for relaying will be verified at startup. If false, no verification is performed of the server certificate. When using self-signed certificates without a certificate authority, this setting should be set to false. The default is to use the value specified in the **server** section.

ilog

The **ilog** section configures I/O log parameters. These settings are identical to the I/O configuration in **sudoers(5)**. The following keys are recognized:

ilog_compress = boolean

If set, I/O logs will be compressed using **zlib**. Enabling compression can make it harder to view the logs in real-time as the program is executing due to buffering. The default value is **false**.

ilog_dir = path

The top-level directory to use when constructing the path name for the I/O log directory. The session sequence number, if any, is stored in the directory. The default value is **/var/log/sudo-io**.

The following percent ('%') escape sequences are supported:

- %{seq}
expanded to a monotonically increasing base-36 sequence number, such as 0100A5, where every two digits are used to form a new directory, e.g., 01/00/A5
- %{user}
expanded to the invoking user's login name
- %{group}
expanded to the name of the invoking user's real group-ID
- %{runas_user}
expanded to the login name of the user the command will be run as (e.g., root)
- %{runas_group}
expanded to the group name of the user the command will be run as (e.g., wheel)
- %{hostname}
expanded to the local host name without the domain name
- %{command}
expanded to the base name of the command being run

In addition, any escape sequences supported by the system's `strftime(3)` function will be expanded.

To include a literal '%' character, the string '%%' should be used.

iolog_file = path

The path name, relative to *iolog_dir*, in which to store I/O logs. Note that *iolog_file* may contain directory components. The default value is %{seq}.

See the *iolog_dir* setting above for a list of supported percent ('%') escape sequences.

In addition to the escape sequences, path names that end in six or more Xs will have the Xs replaced with a unique combination of digits and letters, similar to the `mkttemp(3)` function.

If the path created by concatenating *iolog_dir* and *iolog_file* already exists, the existing I/O log file will be truncated and overwritten unless *iolog_file* ends in six or more Xs.

iolog_flush = boolean

If set, I/O log data is flushed to disk after each write instead of buffering it. This makes it possible to view the logs in real-time as the program is executing but may significantly reduce the effectiveness of I/O log compression. I/O logs are always flushed before sending a commit point to the client regardless of this setting. The default value is true.

iolog_group = name

The group name to look up when setting the group-ID on new I/O log files and directories. If *iolog_group* is not set, the primary group-ID of the user specified by *iolog_user* is used. If neither *iolog_group* nor *iolog_user* are set, I/O log files and directories are created with group-ID 0.

iolog_mode = mode

The file mode to use when creating I/O log files. Mode bits for read and write permissions for owner, group, or other are honored, everything else is ignored. The file permissions will always include the owner read and write bits, even if they are not present in the specified mode. When creating I/O log directories, search (execute) bits are added to match the read and write bits specified by *iolog_mode*. The default value is 0600.

iolog_user = name

The user name to look up when setting the owner of new I/O log files and directories. If *iolog_group* is set, it will be used instead of the user's primary group-ID. By default, I/O log files and directories are created with user and group-ID 0.

maxseq = number

The maximum sequence number that will be substituted for the "%{seq}" escape in the I/O log file (see the *iolog_dir* description above for more information). While the value substituted for "%{seq}" is in base 36, *maxseq* itself should be expressed in decimal. Values larger than 2176782336 (which corresponds to the base 36 sequence number "ZZZZZZ") will be silently truncated to 2176782336. The default value is 2176782336.

eventlog

The *eventlog* section configures how (and if) security policy events are logged.

log_type = string

Where to log accept, reject, and alert events reported by the policy. Supported values are *syslog*, *logfile*, and *none*. The default value is *syslog*.

log_exit = boolean

If true, **sudo_logsrvd** will log an event when a command exits or is terminated by a signal. Defaults to false.

log_format = string

The event log format. Supported log formats are "sudo" for traditional sudo-style logs and "json" for JSON-format logs. The JSON log entries contain the full contents of the accept, reject, exit and alert messages. The default value is *sudo*.

syslog

The *syslog* section configures how events are logged via *syslog(3)*.

facility = string

Syslog facility if syslog is being used for logging. Defaults to authpriv.

The following syslog facilities are supported: **authpriv** (if your OS supports it), **auth**, **daemon**, **user**, **local0**, **local1**, **local2**, **local3**, **local4**, **local5**, **local6**, and **local7**.

accept_priority = string

Syslog priority to use when the user is allowed to run a command and authentication is successful. Defaults to notice.

The following syslog priorities are supported: **alert**, **crit**, **debug**, **emerg**, **err**, **info**, **notice**, **warning**, and **none**. Setting it to a value of **none** will disable logging of successful commands.

reject_priority = string

Syslog priority to use when the user is not allowed to run a command or when authentication is unsuccessful. Defaults to alert.

See *accept_priority* for the list of supported syslog priorities.

alert_priority = string

Syslog priority to use for event log alert messages received from the client. Defaults to alert.

See *accept_priority* for the list of supported syslog priorities.

maxlen = number

On many systems, *syslog(3)* has a relatively small log buffer. IETF RFC 5424 states that syslog servers must support messages of at least 480 bytes and should support messages up to 2048 bytes. By

default, **sudo_logsrvd** creates log messages up to 960 bytes which corresponds to the historic BSD syslog implementation which used a 1024 byte buffer to store the message, date, hostname, and program name.

To prevent syslog messages from being truncated, **sudo_logsrvd** will split up sudo-style log messages that are larger than *maxlen* bytes. When a message is split, additional parts will include the string “(command continued)” after the user name and before the continued command line arguments. JSON-format log entries are never split and are not affected by *maxlen*.

server_facility = string

Syslog facility if syslog is being used for server warning messages. See above for a list of supported facilities. Defaults to daemon

logfile

The *logfile* section consists of settings related to logging to a plain file (not syslog).

path = string

The path to the file-based event log. This path must be fully-qualified and start with a ‘/’ character. The default value is /var/log/sudo.log.

time_format = string

The string used when formatting the date and time for file-based event logs. Formatting is performed via the system’s strftime(3) function so any escape sequences supported by that function will be expanded. The default value is “%h %e %T” which produces dates like “Oct 3 07:15:24” in the C locale.

FILES

/etc/sudo_logsrvd.conf
Sudo log server configuration file

EXAMPLES

```
#  
# sudo logsrv daemon configuration  
  
[server]  
# The host name or IP address and port to listen on with an optional TLS  
# flag. If no port is specified, port 30343 will be used for plaintext  
# connections and port 30344 will be used to TLS connections.  
# The following forms are accepted:  
#   listen_address = hostname(tls)  
#   listen_address = hostname:port(tls)  
#   listen_address = IPv4_address(tls)  
#   listen_address = IPv4_address:port(tls)  
#   listen_address = [IPv6_address](tls)  
#   listen_address = [IPv6_address]:port(tls)  
#  
# The (tls) suffix should be omitted for plaintext connections.  
#  
# Multiple listen_address settings may be specified.  
# The default is to listen on all addresses.  
#listen_address = *:30343  
#listen_address = *:30344(tls)
```

```
# The file containing the ID of the running sudo_logsrvd process.  
#pid_file = /run/sudo/sudo_logsrvd.pid  
  
# Where to log server warnings: none, stderr, syslog, or a path name.  
#server_log = syslog  
  
# If true, enable the SO_KEEPALIVE socket option on client connections.  
# Defaults to true.  
#tcp_keepalive = true  
  
# The amount of time, in seconds, the server will wait for the client to  
# respond. A value of 0 will disable the timeout. The default value is 30.  
#timeout = 30  
  
# If true, the server will validate its own certificate at startup.  
# Defaults to true.  
#tls_verify = true  
  
# If true, client certificates will be validated by the server;  
# clients without a valid certificate will be unable to connect.  
# By default, client certs are not checked.  
#tls_checkpeer = false  
  
# Path to a certificate authority bundle file in PEM format to use  
# instead of the system's default certificate authority database.

# respond. A value of 0 will disable the timeout. The default value is 30.
#timeout = 30

# If true, the server's relay certificate will be verified at startup.
# The default is to use the value in the [server] section.
#tls_verify = true

# Whether to verify the relay's certificate for TLS connections.
# The default is to use the value in the [server] section.
#tls_checkpeer = false

# Path to a certificate authority bundle file in PEM format to use
# instead of the system's default certificate authority database.
# The default is to use the value in the [server] section.
#tls_cacert = /etc/ssl/sudo/cacert.pem

# Path to the server's certificate file in PEM format.
# The default is to use the certificate in the [server] section.
#tls_cert = /etc/ssl/sudo/certs/logsrvd_cert.pem

# Path to the server's private key file in PEM format.
```

```

# The default is to use the key in the [server] section.
#tls_key = /etc/ssl/sudo/private/logsrvd_key.pem

# TLS cipher list (see "CIPHER LIST FORMAT" in the openssl-ciphers manual).
# NOTE that this setting is only effective if the negotiated protocol
# is TLS version 1.2.
# The default is to use the value in the [server] section.
#tls_ciphers_v12 = HIGH:!aNULL

# TLS cipher list if the negotiated protocol is TLS version 1.3.
# The default is to use the value in the [server] section.
#tls_ciphers_v13 = TLS_AES_256_GCM_SHA384

# Path to the Diffie-Hellman parameter file in PEM format.
# The default is to use the value in the [server] section.
#tls_dhparams = /etc/ssl/sudo/logsrvd_dhparams.pem

[iolog]
# The top-level directory to use when constructing the path name for the
# I/O log directory. The session sequence number, if any, is stored here.
#iolog_dir = /var/log/sudo-io

# The path name, relative to iolog_dir, in which to store I/O logs.
# Note that iolog_file may contain directory components.
#iolog_file = %{seq}

# If set, I/O logs will be compressed using zlib. Enabling compression can
# make it harder to view the logs in real-time as the program is executing.
#iolog_compress = false

# If set, I/O log data is flushed to disk after each write instead of
# buffering it. This makes it possible to view the logs in real-time
# as the program is executing but reduces the effectiveness of compression.
#iolog_flush = true

# The group to use when creating new I/O log files and directories.
# If iolog_group is not set, the primary group-ID of the user specified
# by iolog_user is used. If neither iolog_group nor iolog_user
# are set, I/O log files and directories are created with group-ID 0.
#iolog_group = wheel

# The user to use when setting the user-ID and group-ID of new I/O
# log files and directories. If iolog_group is set, it will be used
# instead of the user's primary group-ID. By default, I/O log files
# and directories are created with user and group-ID 0.
#iolog_user = root

# The file mode to use when creating I/O log files. The file permissions
# will always include the owner read and write bits, even if they are
# not present in the specified mode. When creating I/O log directories,
# search (execute) bits are added to match the read and write bits
# specified by iolog_mode.

```

```

#ilog_mode = 0600

# The maximum sequence number that will be substituted for the "%{seq}"
# escape in the I/O log file. While the value substituted for "%{seq}"
# is in base 36, maxseq itself should be expressed in decimal. Values
# larger than 2176782336 (which corresponds to the base 36 sequence
# number "ZZZZZZ") will be silently truncated to 2176782336.
#maxseq = 2176782336

[eventlog]
# Where to log accept, reject, exit, and alert events.
# Accepted values are syslog, logfile, or none.
# Defaults to syslog
#log_type = syslog

# Whether to log an event when a command exits or is terminated by a signal.
# Defaults to false
#log_exit = true

# Event log format.
# Currently only sudo-style event logs are supported.
#log_format = sudo

[syslog]
# The maximum length of a syslog payload.
# On many systems, syslog(3) has a relatively small log buffer.
# IETF RFC 5424 states that syslog servers must support messages
# of at least 480 bytes and should support messages up to 2048 bytes.
# Messages larger than this value will be split into multiple messages.
# maxlen = 960

# The syslog facility to use for event log messages.
# The following syslog facilities are supported: authpriv (if your OS
# supports it), auth, daemon, user, local0, local1, local2, local3,
# local4, local5, local6, and local7.
#facility = authpriv

# Syslog priority to use for event log accept messages, when the command
# is allowed by the security policy. The following syslog priorities are
# supported: alert, crit, debug, emerg, err, info, notice, warning, none.
#accept_priority = notice

# Syslog priority to use for event log reject messages, when the command
# is not allowed by the security policy.
#reject_priority = alert

# Syslog priority to use for event log alert messages reported by the
# client.
#alert_priority = alert

# The syslog facility to use for server warning messages.
# Defaults to daemon.

```

```
#server_facility = daemon

[logfile]
# The path to the file-based event log.
# This path must be fully-qualified and start with a '/' character.
#path = /var/log/sudo

# The format string used when formatting the date and time for
# file-based event logs. Formatting is performed via strftime(3) so
# any format string supported by that function is allowed.
#time_format = %h %e %T
```

BUGS

If you feel you have found a bug in `sudo`, please submit a bug report at <https://bugzilla.sudo.ws/>

SUPPORT

Limited free support is available via the sudo-users mailing list, see <https://www.sudo.ws/mailman/listinfo/sudo-users> to subscribe or search the archives.

DISCLAIMER

`sudo` is provided “AS IS” and any express or implied warranties, including, but not limited to, the implied warranties of merchantability and fitness for a particular purpose are disclaimed. See the LICENSE file distributed with `sudo` or <https://www.sudo.ws/license.html> for complete details.

NAME

sudo_plugin — Sudo Plugin API

DESCRIPTION

Starting with version 1.8, **sudo** supports a plugin API for policy and session logging. Plugins may be compiled as dynamic shared objects (the default on systems that support them) or compiled statically into the **sudo** binary itself. By default, the **sudoers** plugin provides audit, security policy and I/O logging capabilities. Via the plugin API, **sudo** can be configured to use alternate plugins provided by third parties. The plugins to be used are specified in the **sudo.conf(5)** file.

The API is versioned with a major and minor number. The minor version number is incremented when additions are made. The major number is incremented when incompatible changes are made. A plugin should be check the version passed to it and make sure that the major version matches.

The plugin API is defined by the **sudo_plugin.h** header file.

Policy plugin API

A policy plugin must declare and populate a **policy_plugin** struct in the global scope. This structure contains pointers to the functions that implement the **sudo** policy checks. The name of the symbol should be specified in **sudo.conf(5)** along with a path to the plugin so that **sudo** can load it.

```
struct policy_plugin {
#define SUDO_POLICY_PLUGIN 1
    unsigned int type; /* always SUDO_POLICY_PLUGIN */
    unsigned int version; /* always SUDO_API_VERSION */
    int (*open)(unsigned int version, sudo_conv_t conversation,
                sudo_printf_t plugin_printf, char * const settings[],
                char * const user_info[], char * const user_env[],
                char * const plugin_options[], const char **errstr);
    void (*close)(int exit_status, int error);
    int (*show_version)(int verbose);
    int (*check_policy)(int argc, char * const argv[],
                        char *env_add[], char **command_info[],
                        char **argv_out[], char **user_env_out[], const char **errstr);
    int (*list)(int argc, char * const argv[], int verbose,
                const char *list_user, const char **errstr);
    int (*validate)(const char **errstr);
    void (*invalidate)(int remove);
    int (*init_session)(struct passwd *pwd, char **user_env[],
                        const char **errstr);
    void (*register_hooks)(int version,
                          int (*register_hook)(struct sudo_hook *hook));
    void (*deregister_hooks)(int version,
                            int (*deregister_hook)(struct sudo_hook *hook));
    struct sudo_plugin_event * (*event_alloc)(void);
};
```

The **policy_plugin** struct has the following fields:

type The **type** field should always be set to **SUDO_POLICY_PLUGIN**.

version

The **version** field should be set to **SUDO_API_VERSION**.

This allows **sudo** to determine the API version the plugin was built against.

open

```
int (*open)(unsigned int version, sudo_conv_t conversation,
            sudo_printf_t plugin_printf, char * const settings[],
            char * const user_info[], char * const user_env[],
            char * const plugin_options[], const char **errstr);
```

Returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error. In the latter case, **sudo** will print a usage message before it exits. If an error occurs, the plugin may optionally call the **conversation()** or **plugin_printf()** function with **SUDO_CONF_ERROR_MSG** to present additional error information to the user.

The function arguments are as follows:

version

The version passed in by **sudo** allows the plugin to determine the major and minor version number of the plugin API supported by **sudo**.

conversation

A pointer to the **conversation()** function that can be used by the plugin to interact with the user (see **Conversation API** for details). Returns 0 on success and -1 on failure.

plugin_printf

A pointer to a **printf()**-style function that may be used to display informational or error messages (see **Conversation API** for details). Returns the number of characters printed on success and -1 on failure.

settings

A vector of user-supplied **sudo** settings in the form of “name=value” strings. The vector is terminated by a NULL pointer. These settings correspond to options the user specified when running **sudo**. As such, they will only be present when the corresponding option has been specified on the command line.

When parsing *settings*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

The following values may be set by **sudo**:

bsdauth_type=string

Authentication type, if specified by the **-a** option, to use on systems where BSD authentication is supported.

closefrom=number

If specified, the user has requested via the **-C** option that **sudo** close all files descriptors with a value of *number* or higher. The plugin may optionally pass this, or another value, back in the *command_info* list.

cmnd_chroot=string

The root directory (see **chroot(2)**) to run the command in, as specified by the user via the **-R** option. The plugin may ignore or restrict the user’s ability to specify a new root directory. Only available starting with API version 1.16.

cmnd_cwd=string

The working directory to run the command in, as specified by the user via the **-D** option. The plugin may ignore or restrict the user’s ability to specify a new working directory. Only available starting with API version 1.16.

debug_flags=string

A debug file path name followed by a space and a comma-separated list of debug flags that correspond to the plugin's Debug entry in sudo.conf(5), if there is one. The flags are passed to the plugin exactly as they appear in sudo.conf(5). The syntax used by **sudo** and the **sudoers** plugin is *subsystem@priority* but a plugin is free to use a different format so long as it does not include a comma (‘,’). Prior to **sudo** 1.8.12, there was no way to specify plugin-specific *debug_flags* so the value was always the same as that used by the **sudo** front-end and did not include a path name, only the flags themselves. As of version 1.7 of the plugin interface, **sudo** will only pass *debug_flags* if sudo.conf(5) contains a plugin-specific Debug entry.

ignore_ticket=bool

Set to true if the user specified the **-k** option along with a command, indicating that the user wishes to ignore any cached authentication credentials. *implied_shell* to true. This allows **sudo** with no arguments to be used similarly to su(1). If the plugin does not support this usage, it may return a value of -2 from the **check_policy()** function, which will cause **sudo** to print a usage message and exit.

implied_shell=bool

If the user does not specify a program on the command line, **sudo** will pass the plugin the path to the user's shell and set

login_class=string

BSD login class to use when setting resource limits and nice value, if specified by the **-c** option.

login_shell=bool

Set to true if the user specified the **-i** option, indicating that the user wishes to run a login shell.

max_groups=int

The maximum number of groups a user may belong to. This will only be present if there is a corresponding setting in sudo.conf(5).

network_addrs=list

A space-separated list of IP network addresses and netmasks in the form “addr/netmask”, e.g., “192.168.1.2/255.255.255.0”. The address and netmask pairs may be either IPv4 or IPv6, depending on what the operating system supports. If the address contains a colon (‘:’), it is an IPv6 address, else it is IPv4.

noninteractive=bool

Set to true if the user specified the **-n** option, indicating that **sudo** should operate in non-interactive mode. The plugin may reject a command run in non-interactive mode if user interaction is required.

plugin_dir=string

The default plugin directory used by the **sudo** front-end. This is the default directory set at compile time and may not correspond to the directory the running plugin was loaded from. It may be used by a plugin to locate support files.

plugin_path=string

The path name of plugin loaded by the **sudo** front-end. The path name will be a fully-qualified unless the plugin was statically compiled into **sudo**.

preserve_environment=bool

Set to true if the user specified the **-E** option, indicating that the user wishes to preserve the environment.

preserve_groups=bool
Set to true if the user specified the **-P** option, indicating that the user wishes to preserve the group vector instead of setting it based on the runas user.

progname=string
The command name that sudo was run as, typically “sudo” or “sudoedit”.

prompt=string
The prompt to use when requesting a password, if specified via the **-p** option.

remote_host=string
The name of the remote host to run the command on, if specified via the **-h** option. Support for running the command on a remote host is meant to be implemented via a helper program that is executed in place of the user-specified command. The **sudo** front-end is only capable of executing commands on the local host. Only available starting with API version 1.4.

run_shell=bool
Set to true if the user specified the **-s** option, indicating that the user wishes to run a shell.

runas_group=string
The group name or group-ID to run the command as, if specified via the **-g** option.

runas_user=string
The user name or user-ID to run the command as, if specified via the **-u** option.

selinux_role=string
SELinux role to use when executing the command, if specified by the **-r** option.

selinux_type=string
SELinux type to use when executing the command, if specified by the **-t** option.

set_home=bool
Set to true if the user specified the **-H** option. If true, set the HOME environment variable to the target user’s home directory.

sudoedit=bool
Set to true when the **-e** option is specified or if invoked as **sudoedit**. The plugin shall substitute an editor into *argv* in the **check_policy()** function or return -2 with a usage error if the plugin does not support *sudoedit*. For more information, see the *check_policy* section.

timeout=string
Command timeout specified by the user via the **-T** option. Not all plugins support command timeouts and the ability of the user to set a timeout may be restricted by policy. The format of the timeout string is plugin-specific.

Additional settings may be added in the future so the plugin should silently ignore settings that it does not recognize.

user_info
A vector of information about the user running the command in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing *user_info*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

The following values may be set by **sudo**:

cols=int

The number of columns the user's terminal supports. If there is no terminal device available, a default value of 80 is used.

cwd=string

The user's current working directory.

egid=gid_t

The effective group-ID of the user invoking **sudo**.

euid=uid_t

The effective user-ID of the user invoking **sudo**.

gid=gid_t

The real group-ID of the user invoking **sudo**.

groups=list

The user's supplementary group list formatted as a string of comma-separated group-IDs.

host=string

The local machine's hostname as returned by the `gethostname(2)` system call.

lines=int

The number of lines the user's terminal supports. If there is no terminal device available, a default value of 24 is used.

pgid=int

The ID of the process group that the running **sudo** process is a member of. Only available starting with API version 1.2.

pid=int

The process ID of the running **sudo** process. Only available starting with API version 1.2.

ppid=int

The parent process ID of the running **sudo** process. Only available starting with API version 1.2.

rlimit_as=soft,hard

The maximum size to which the process's address space may grow (in bytes), if supported by the operating system. The soft and hard limits are separated by a comma. A value of "infinity" indicates that there is no limit. Only available starting with API version 1.16.

rlimit_core=soft,hard

The largest size core dump file that may be created (in bytes). The soft and hard limits are separated by a comma. A value of "infinity" indicates that there is no limit. Only available starting with API version 1.16.

rlimit_cpu=soft,hard

The maximum amount of CPU time that the process may use (in seconds). The soft and hard limits are separated by a comma. A value of "infinity" indicates that there is no limit. Only available starting with API version 1.16.

rlimit_data=soft,hard

The maximum size of the data segment for the process (in bytes). The soft and hard limits are separated by a comma. A value of "infinity" indicates that there is no limit. Only available starting with API version 1.16.

rlimit_fsize=soft,hard

The largest size file that the process may create (in bytes). The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

rlimit_locks=soft,hard

The maximum number of locks that the process may establish, if supported by the operating system. The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

rlimit_memlock=soft,hard

The maximum size that the process may lock in memory (in bytes), if supported by the operating system. The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

rlimit_nofile=soft,hard

The maximum number of files that the process may have open. The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

rlimit_nproc=soft,hard

The maximum number of processes that the user may run simultaneously. The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

rlimit_rss=soft,hard

The maximum size to which the process’s resident set size may grow (in bytes). The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

rlimit_stack=soft,hard

The maximum size to which the process’s stack may grow (in bytes). The soft and hard limits are separated by a comma. A value of “infinity” indicates that there is no limit. Only available starting with API version 1.16.

sid=int

The session ID of the running **sudo** process or 0 if **sudo** is not part of a POSIX job control session. Only available starting with API version 1.2.

tcpgid=int

The ID of the foreground process group associated with the terminal device associated with the **sudo** process or 0 if there is no terminal present. Only available starting with API version 1.2.

tty=string

The path to the user’s terminal device. If the user has no terminal device associated with the session, the value will be empty, as in “`tty=`”.

uid=uid_t

The real user-ID of the user invoking **sudo**.

umask=octal

The invoking user’s file creation mask. Only available starting with API version 1.10.

user=string

The name of the user invoking **sudo**.

user_env

The user's environment in the form of a NULL-terminated vector of "name=value" strings.

When parsing *user_env*, the plugin should split on the **first** equal sign ('=') since the *name* field will never include one itself but the *value* might.

plugin_options

Any (non-comment) strings immediately after the plugin path are passed as arguments to the plugin. These arguments are split on a white space boundary and are passed to the plugin in the form of a NULL-terminated array of strings. If no arguments were specified, *plugin_options* will be the NULL pointer.

NOTE: the *plugin_options* parameter is only available starting with API version 1.2. A plugin **must** check the API version specified by the **sudo** front-end before using *plugin_options*. Failure to do so may result in a crash.

errstr

If the **open()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

close

```
void (*close)(int exit_status, int error);
```

The **close()** function is called when **sudo** is finished, shortly before it exits. Starting with API version 1.15, **close()** is called regardless of whether or not a command was actually executed. This makes it possible for plugins to perform cleanup even when a command was not run. It is not possible to tell whether a command was run based solely on the arguments passed to the **close()** function. To determine if a command was actually run, the plugin must keep track of whether or not the **check_policy()** function returned successfully.

The function arguments are as follows:

exit_status

The command's exit status, as returned by the **wait(2)** system call, or zero if no command was run. The value of *exit_status* is undefined if *error* is non-zero.

error If the command could not be executed, this is set to the value of **errno** set by the **execve(2)** system call. The plugin is responsible for displaying error information via the **conversation()** or **plugin_printf()** function. If the command was successfully executed, the value of *error* is zero.

If no **close()** function is defined, no I/O logging plugins are loaded, and neither the **timeout** nor **use_pty** options are set in the **command_info** list, the **sudo** front-end may execute the command directly instead of running it as a child process.

show_version

```
int (*show_version)(int verbose);
```

The **show_version()** function is called by **sudo** when the user specifies the **-v** option. The plugin may display its version information to the user via the **conversation()** or **plugin_printf()** function using **SUDO_CONV_INFO_MSG**. If the user requests detailed version information, the *verbose* flag will be set.

Returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error, although the return value is currently ignored.

check_policy

```
int (*check_policy)(int argc, char * const argv[], char *env_add[],
    char **command_info[], char **argv_out[], char **user_env_out[],
    const char **errstr);
```

The **check_policy()** function is called by **sudo** to determine whether the user is allowed to run the specified commands.

If the *sudoedit* option was enabled in the *settings* array passed to the **open()** function, the user has requested *sudoedit* mode. *sudoedit* is a mechanism for editing one or more files where an editor is run with the user's credentials instead of with elevated privileges. **sudo** achieves this by creating user-writable temporary copies of the files to be edited and then overwriting the originals with the temporary copies after editing is complete. If the plugin supports *sudoedit*, it should choose the editor to be used, potentially from a variable in the user's environment, such as `EDITOR`, and include it in *argv_out* (note that environment variables may include command line options). The files to be edited should be copied from *argv* into *argv_out*, separated from the editor and its arguments by a “--” element. The “--” will be removed by **sudo** before the editor is executed. The plugin should also set *sudoedit=true* in the *command_info* list.

The **check_policy()** function returns 1 if the command is allowed, 0 if not allowed, -1 for a general error, or -2 for a usage error or if *sudoedit* was specified but is unsupported by the plugin. In the latter case, **sudo** will print a usage message before it exits. If an error occurs, the plugin may optionally call the **conversation()** or **plugin_printf()** function with `SUDO_CONF_ERROR_MSG` to present additional error information to the user.

The function arguments are as follows:

argc The number of elements in *argv*, not counting the final NULL pointer.

argv The argument vector describing the command the user wishes to run, in the same form as what would be passed to the `execve(2)` system call. The vector is terminated by a NULL pointer.

env_add

Additional environment variables specified by the user on the command line in the form of a NULL-terminated vector of “name=value” strings. The plugin may reject the command if one or more variables are not allowed to be set, or it may silently ignore such variables.

When parsing *env_add*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

command_info

Information about the command being run in the form of “name=value” strings. These values are used by **sudo** to set the execution environment when running a command. The plugin is responsible for creating and populating the vector, which must be terminated with a NULL pointer. The following values are recognized by **sudo**:

chroot=string

The root directory to use when running the command.

closefrom=number

If specified, **sudo** will close all files descriptors with a value of *number* or higher.

command=string

Fully qualified path to the command to be executed.

cwd=string

The current working directory to change to when executing the command. If **sudo** is unable to change to the new working directory, the command will not be run unless *cwd_optional* is also set (see below).

cwd_optional=bool

If enabled, **sudo** will treat an inability to change to the new working directory as a non-fatal error. This setting has no effect unless *cwd* is also set.

exec_background=bool

By default, **sudo** runs a command as the foreground process as long as **sudo** itself is running in the foreground. When *exec_background* is enabled and the command is being run in a pseudo-terminal (due to I/O logging or the *use_pty* setting), the command will be run as a background process. Attempts to read from the controlling terminal (or to change terminal settings) will result in the command being suspended with the SIGTTIN signal (or SIGTTOU in the case of terminal settings). If this happens when **sudo** is a foreground process, the command will be granted the controlling terminal and resumed in the foreground with no user intervention required. The advantage of initially running the command in the background is that **sudo** need not read from the terminal unless the command explicitly requests it. Otherwise, any terminal input must be passed to the command, whether it has required it or not (the kernel buffers terminals so it is not possible to tell whether the command really wants the input). This is different from historic *sudo* behavior or when the command is not being run in a pseudo-terminal.

For this to work seamlessly, the operating system must support the automatic restarting of system calls. Unfortunately, not all operating systems do this by default, and even those that do may have bugs. For example, macOS fails to restart the **tcgetattr()** and **tcsetattr()** system calls (this is a bug in macOS). Furthermore, because this behavior depends on the command stopping with the SIGTTIN or SIGTTOU signals, programs that catch these signals and suspend themselves with a different signal (usually SIGTOP) will not be automatically foregrounded. Some versions of the linux **su(1)** command behave this way. Because of this, a plugin should not set *exec_background* unless it is explicitly enabled by the administrator and there should be a way to enable or disable it on a per-command basis.

This setting has no effect unless I/O logging is enabled or *use_pty* is enabled.

execfd=number

If specified, **sudo** will use the **fexecve(2)** system call to execute the command instead of **execve(2)**. The specified *number* must refer to an open file descriptor.

iolog_compress=bool

Set to true if the I/O logging plugins, if any, should compress the log data. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_group=string

The group that will own newly created I/O log files and directories. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_mode=octal

The file permission mode to use when creating I/O log files and directories. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_user=string

The user that will own newly created I/O log files and directories. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_path=string

Fully qualified path to the file or directory in which I/O log is to be stored. This is a hint to the I/O logging plugin which may choose to ignore it. If no I/O logging plugin is loaded, this setting has no effect.

iolog_stdin=bool

Set to true if the I/O logging plugins, if any, should log the standard input if it is not connected to a terminal device. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_stdout=bool

Set to true if the I/O logging plugins, if any, should log the standard output if it is not connected to a terminal device. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_stderr=bool

Set to true if the I/O logging plugins, if any, should log the standard error if it is not connected to a terminal device. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_ttyin=bool

Set to true if the I/O logging plugins, if any, should log all terminal input. This only includes input typed by the user and not from a pipe or redirected from a file. This is a hint to the I/O logging plugin which may choose to ignore it.

iolog_ttyout=bool

Set to true if the I/O logging plugins, if any, should log all terminal output. This only includes output to the screen, not output to a pipe or file. This is a hint to the I/O logging plugin which may choose to ignore it.

login_class=string

BSD login class to use when setting resource limits and nice value (optional). This option is only set on systems that support login classes.

nice=int

Nice value (priority) to use when executing the command. The nice value, if specified, overrides the priority associated with the *login_class* on BSD systems.

noexec=bool

If set, prevent the command from executing other programs.

preserve_fds=list

A comma-separated list of file descriptors that should be preserved, regardless of the value of the *closefrom* setting. Only available starting with API version 1.5.

preserve_groups=bool

If set, **sudo** will preserve the user's group vector instead of initializing the group vector based on *runas_user*.

rlimit_as=soft,hard

The maximum size to which the process's address space may grow (in bytes), if supported by the operating system. The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of "infinity" indicates that there is no limit. A value of "user" will cause the invoking user's resource limit to be preserved. A value of "default" will cause the target user's default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_core=soft,hard

The largest size core dump file that may be created (in bytes). The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_cpu=soft,hard

The maximum amount of CPU time that the process may use (in seconds). The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_data=soft,hard

The maximum size of the data segment for the process (in bytes). The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_fsize=soft,hard

The largest size file that the process may create (in bytes). The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_locks=soft,hard

The maximum number of locks that the process may establish, if supported by the operating system. The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_memlock=soft,hard

The maximum size that the process may lock in memory (in bytes), if supported by the operating system. The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_nofile=soft,hard

The maximum number of files that the process may have open. The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the tar-

get user's default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_nproc=soft,hard

The maximum number of processes that the user may run simultaneously. The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_rss=soft,hard

The maximum size to which the process’s resident set size may grow (in bytes). The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

rlimit_stack=soft,hard

The maximum size to which the process’s stack may grow (in bytes). The soft and hard limits are separated by a comma. If only a single value is specified, both the hard and soft limits are set. A value of “infinity” indicates that there is no limit. A value of “user” will cause the invoking user’s resource limit to be preserved. A value of “default” will cause the target user’s default resource limit to be used on systems that allow per-user resource limits to be configured. Only available starting with API version 1.17.

runas_egid=gid

Effective group-ID to run the command as. If not specified, the value of *runas_gid* is used.

runas_euid=uid

Effective user-ID to run the command as. If not specified, the value of *runas_uid* is used.

runas_gid=gid

Group-ID to run the command as.

runas_group=string

The name of the group the command will run as, if it is different from the *runas_user*’s default group. This value is provided for auditing purposes only, the **sudo** front-end uses *runas_egid* and *runas_gid* when executing the command.

runas_groups=list

The supplementary group vector to use for the command in the form of a comma-separated list of group-IDs. If *preserve_groups* is set, this option is ignored.

runas_uid=uid

User-ID to run the command as.

runas_user=string

The name of the user the command will run as, which should correspond to *runas_euid* (or *runas_uid* if *runas_euid* is not set). This value is provided for auditing purposes only, the **sudo** front-end uses *runas_euid* and *runas_uid* when executing the command.

selinux_role=string
SELinux role to use when executing the command.

selinux_type=string
SELinux type to use when executing the command.

set_utmp=bool
Create a utmp (or utmpx) entry when a pseudo-terminal is allocated. By default, the new entry will be a copy of the user's existing utmp entry (if any), with the tty, time, type, and pid fields updated.

sudoedit=bool
Set to true when in *sudoedit* mode. The plugin may enable *sudoedit* mode even if **sudo** was not invoked as **sudoedit**. This allows the plugin to perform command substitution and transparently enable *sudoedit* when the user attempts to run an editor.

sudoedit_checkdir=bool
Set to false to disable directory writability checks in **sudoedit**. By default, **sudoedit** 1.8.16 and higher will check all directory components of the path to be edited for writability by the invoking user. Symbolic links will not be followed in writable directories and **sudoedit** will refuse to edit a file located in a writable directory. These restrictions are not enforced when **sudoedit** is run by root. The *sudoedit_follow* option can be set to false to disable this check. Only available starting with API version 1.8.

sudoedit_follow=bool
Set to true to allow **sudoedit** to edit files that are symbolic links. By default, **sudoedit** 1.8.15 and higher will refuse to open a symbolic link. The *sudoedit_follow* option can be used to restore the older behavior and allow **sudoedit** to open symbolic links. Only available starting with API version 1.8.

timeout=int
Command timeout. If non-zero then when the timeout expires the command will be killed.

umask=octal
The file creation mask to use when executing the command. This value may be overridden by PAM or login.conf on some systems unless the *umask_override* option is also set.

umask_override=bool
Force the value specified by the *umask* option to override any umask set by PAM or login.conf.

use_pty=bool
Allocate a pseudo-terminal to run the command in, regardless of whether or not I/O logging is in use. By default, **sudo** will only run the command in a pseudo-terminal when an I/O log plugin is loaded.

utmp_user=string
User name to use when constructing a new utmp (or utmpx) entry when *set_utmp* is enabled. This option can be used to set the user field in the utmp entry to the user the command runs as rather than the invoking user. If not set, **sudo** will base the new entry on the invoking user's existing entry.

Unsupported values will be ignored.

argv_out
The NULL-terminated argument vector to pass to the `execve(2)` system call when executing the command. The plugin is responsible for allocating and populating the vector.

user_env_out

The NULL-terminated environment vector to use when executing the command. The plugin is responsible for allocating and populating the vector.

errstr

If the **check_policy()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

list

```
int (*list)(int argc, char * const argv[], int verbose,
           const char *list_user, const char **errstr);
```

List available privileges for the invoking user. Returns 1 on success, 0 on failure, and -1 on error. On error, the plugin may optionally call the **conversation()** or **plugin_printf()** function with **SUDO_CONF_ERROR_MSG** to present additional error information to the user.

Privileges should be output via the **conversation()** or **plugin_printf()** function using **SUDO_CONV_INFO_MSG**.

The function arguments are as follows:

argc The number of elements in *argv*, not counting the final NULL pointer.

argv If non-NUL, an argument vector describing a command the user wishes to check against the policy in the same form as what would be passed to the **execve(2)** system call. If the command is permitted by the policy, the fully-qualified path to the command should be displayed along with any command line arguments.

verbose

Flag indicating whether to list in verbose mode or not.

list_user

The name of a different user to list privileges for if the policy allows it. If NULL, the plugin should list the privileges of the invoking user.

errstr

If the **list()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

validate

```
int (*validate)(const char **errstr);
```

The **validate()** function is called when **sudo** is run with the **-v** option. For policy plugins such as **sudoers** that cache authentication credentials, this function will validate and cache the credentials.

The **validate()** function should be NULL if the plugin does not support credential caching.

Returns 1 on success, 0 on failure, and -1 on error. On error, the plugin may optionally call the **conversation()** or **plugin_printf()** function with SUDO_CONF_ERROR_MSG to present additional error information to the user.

The function arguments are as follows:

errstr

If the **validate()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

invalidate

```
void (*invalidate)(int remove);
```

The **invalidate()** function is called when **sudo** is run with the **-k** or **-K** option. For policy plugins such as **sudoers** that cache authentication credentials, this function will invalidate the credentials. If the *remove* flag is set, the plugin may remove the credentials instead of simply invalidating them.

The **invalidate()** function should be NULL if the plugin does not support credential caching.

init_session

```
int (*init_session)(struct passwd *pwd, char **user_env_out[]);
```

The **init_session()** function is called before **sudo** sets up the execution environment for the command. It is run in the parent **sudo** process and before any user-ID or group-ID changes. This can be used to perform session setup that is not supported by *command_info*, such as opening the PAM session. The **close()** function can be used to tear down the session that was opened by **init_session**.

The *pwd* argument points to a **passwd** struct for the user the command will be run as if the user-ID the command will run as was found in the password database, otherwise it will be NULL.

The *user_env_out* argument points to the environment the command will run in, in the form of a NULL-terminated vector of "name=value" strings. This is the same string passed back to the front-end via the Policy Plugin's *user_env_out* parameter. If the **init_session()** function needs to modify the user environment, it should update the pointer stored in *user_env_out*. The expected use case is to merge the contents of the PAM environment (if any) with the contents of *user_env_out*. NOTE: the *user_env_out* parameter is only available starting with API version 1.2. A plugin **must** check the API version specified by the **sudo** front-end before using *user_env_out*. Failure to do so may result in a crash.

Returns 1 on success, 0 on failure, and -1 on error. On error, the plugin may optionally call the **conversation()** or **plugin_printf()** function with SUDO_CONF_ERROR_MSG to present additional error information to the user.

register_hooks

```
void (*register_hooks)(int version,
                      int (*register_hook)(struct sudo_hook *hook));
```

The **register_hooks()** function is called by the sudo front-end to register any hooks the plugin needs. If the plugin does not support hooks, **register_hooks** should be set to the NULL pointer.

The *version* argument describes the version of the hooks API supported by the **sudo** front-end.

The **register_hook()** function should be used to register any supported hooks the plugin needs. It returns 0 on success, 1 if the hook type is not supported, and -1 if the major version in **struct hook** does not match the front-end's major hook API version.

See the **Hook function API** section below for more information about hooks.

NOTE: the **register_hooks()** function is only available starting with API version 1.2. If the **sudo** front-end doesn't support API version 1.2 or higher, **register_hooks** will not be called.

deregister_hooks

```
void (*deregister_hooks)(int version,
    int (*deregister_hook)(struct sudo_hook *hook));
```

The **deregister_hooks()** function is called by the sudo front-end to deregister any hooks the plugin has registered. If the plugin does not support hooks, **deregister_hooks** should be set to the NULL pointer.

The *version* argument describes the version of the hooks API supported by the **sudo** front-end.

The **deregister_hook()** function should be used to deregister any hooks that were put in place by the **register_hook()** function. If the plugin tries to deregister a hook that the front-end does not support, **deregister_hook** will return an error.

See the **Hook function API** section below for more information about hooks.

NOTE: the **deregister_hooks()** function is only available starting with API version 1.2. If the **sudo** front-end doesn't support API version 1.2 or higher, **deregister_hooks** will not be called.

event_alloc

```
struct sudo_plugin_event * (*event_alloc)(void);
```

The **event_alloc()** function is used to allocate a **struct sudo_plugin_event** which provides access to the main **sudo** event loop. Unlike the other fields, the **event_alloc()** pointer is filled in by the **sudo** front-end, not by the plugin.

See the **Event API** section below for more information about events.

NOTE: the **event_alloc()** function is only available starting with API version 1.15. If the **sudo** front-end doesn't support API version 1.15 or higher, **event_alloc()** will not be set.

errstr

If the **init_session()** function returns a value other than 1, the plugin may store a message describing the failure or error in **errstr**. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in **errstr** must remain valid until the plugin's **close()** function is called.

NOTE: the **errstr** parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using **errstr**. Failure to do so may result in a crash.

Policy Plugin Version Macros

```
/* Plugin API version major/minor. */
#define SUDO_API_VERSION_MAJOR 1
#define SUDO_API_VERSION_MINOR 13
#define SUDO_API_MKVERSION(x, y) ((x << 16) | y)
#define SUDO_API_VERSION SUDO_API_MKVERSION(SUDO_API_VERSION_MAJOR, \
                                         SUDO_API_VERSION_MINOR)
```

```
/* Getters and setters for API version */
#define SUDO_API_VERSION_GET_MAJOR(v) ((v) >> 16)
#define SUDO_API_VERSION_GET_MINOR(v) ((v) & 0xffff)
#define SUDO_API_VERSION_SET_MAJOR(vp, n) do { \
    *(vp) = (*(vp) & 0x0000ffff) | ((n) << 16); \
} while(0)
#define SUDO_API_VERSION_SET_MINOR(vp, n) do { \
    *(vp) = (*(vp) & 0xffff0000) | (n); \
} while(0)
```

I/O plugin API

```
struct io_plugin {
#define SUDO_IO_PLUGIN 2
    unsigned int type; /* always SUDO_IO_PLUGIN */
    unsigned int version; /* always SUDO_API_VERSION */
    int (*open)(unsigned int version, sudo_conv_t conversation,
        sudo_printf_t plugin_printf, char * const settings[],
        char * const user_info[], char * const command_info[],
        int argc, char * const argv[], char * const user_env[],
        char * const plugin_options[], const char **errstr);
    void (*close)(int exit_status, int error); /* wait status or error */
    int (*show_version)(int verbose);
    int (*log_ttyin)(const char *buf, unsigned int len,
        const char **errstr);
    int (*log_ttyout)(const char *buf, unsigned int len,
        const char **errstr);
    int (*log_stdin)(const char *buf, unsigned int len,
        const char **errstr);
    int (*log_stdout)(const char *buf, unsigned int len,
        const char **errstr);
    int (*log_stderr)(const char *buf, unsigned int len,
        const char **errstr);
    void (*register_hooks)(int version,
        int (*register_hook)(struct sudo_hook *hook));
    void (*deregister_hooks)(int version,
        int (*deregister_hook)(struct sudo_hook *hook));
    int (*change_winsize)(unsigned int lines, unsigned int cols,
        const char **errstr);
    int (*log_suspend)(int signo, const char **errstr);
    struct sudo_plugin_event * (*event_alloc)(void);
};
```

When an I/O plugin is loaded, **sudo** runs the command in a pseudo-terminal. This makes it possible to log the input and output from the user's session. If any of the standard input, standard output, or standard error do not correspond to a tty, **sudo** will open a pipe to capture the I/O for logging before passing it on.

The **log_ttyin** function receives the raw user input from the terminal device (note that this will include input even when echo is disabled, such as when a password is read). The **log_ttyout** function receives output from the pseudo-terminal that is suitable for replaying the user's session at a later time. The **log_stdin()**, **log_stdout()**, and **log_stderr()** functions are only called if the standard input, standard output, or standard error respectively correspond to something other than a tty.

Any of the logging functions may be set to the NULL pointer if no logging is to be performed. If the open function returns 0, no I/O will be sent to the plugin.

If a logging function returns an error (-1), the running command will be terminated and all of the plugin's logging functions will be disabled. Other I/O logging plugins will still receive any remaining input or output that has not yet been processed.

If an input logging function rejects the data by returning 0, the command will be terminated and the data will not be passed to the command, though it will still be sent to any other I/O logging plugins. If an output logging function rejects the data by returning 0, the command will be terminated and the data will not be written to the terminal, though it will still be sent to any other I/O logging plugins.

The audit_plugin struct has the following fields:

type The type field should always be set to SUDO_IO_PLUGIN.

version

The version field should be set to SUDO_API_VERSION.

This allows sudo to determine the API version the plugin was built against.

open

```
int (*open)(unsigned int version, sudo_conv_t conversation,
            sudo_printf_t plugin_printf, char * const settings[],
            char * const user_info[], char * const command_info[],
            int argc, char * const argv[], char * const user_env[],
            char * const plugin_options[]);
```

The open() function is run before the log_ttyin(), log_ttyout(), log_stdin(), log_stdout(), log_stderr(), log_suspend(), change_winsize(), or show_version() functions are called. It is only called if the version is being requested or if the policy plugin's check_policy() function has returned successfully. It returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error. In the latter case, sudo will print a usage message before it exits. If an error occurs, the plugin may optionally call the conversation() or plugin_printf() function with SUDO_CONF_ERROR_MSG to present additional error information to the user.

The function arguments are as follows:

version

The version passed in by sudo allows the plugin to determine the major and minor version number of the plugin API supported by sudo.

conversation

A pointer to the conversation() function that may be used by the show_version() function to display version information (see show_version() below). The conversation() function may also be used to display additional error message to the user. The conversation() function returns 0 on success and -1 on failure.

plugin_printf

A pointer to a printf()-style function that may be used by the show_version() function to display version information (see show_version below). The plugin_printf() function may also be used to display additional error message to the user. The plugin_printf() function returns number of characters printed on success and -1 on failure.

settings

A vector of user-supplied sudo settings in the form of "name=value" strings. The vector is terminated by a NULL pointer. These settings correspond to options the user specified when run-

ning **sudo**. As such, they will only be present when the corresponding option has been specified on the command line.

When parsing *settings*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible settings.

user_info

A vector of information about the user running the command in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing *user_info*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

command_info

A vector of information describing the command being run in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing *command_info*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

argc The number of elements in *argv*, not counting the final NULL pointer. It can be zero, when **sudo** is called with **-V**.

argv If non-NUL, an argument vector describing a command the user wishes to run in the same form as what would be passed to the `execve(2)` system call.

user_env

The user’s environment in the form of a NULL-terminated vector of “name=value” strings.

When parsing *user_env*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

plugin_options

Any (non-comment) strings immediately after the plugin path are treated as arguments to the plugin. These arguments are split on a white space boundary and are passed to the plugin in the form of a NULL-terminated array of strings. If no arguments were specified, *plugin_options* will be the NULL pointer.

NOTE: the *plugin_options* parameter is only available starting with API version 1.2. A plugin **must** check the API version specified by the **sudo** front-end before using *plugin_options*. Failure to do so may result in a crash.

errstr

If the `open()` function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin’s `close()` function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

close

```
void (*close)(int exit_status, int error);
```

The **close()** function is called when **sudo** is finished, shortly before it exits.

The function arguments are as follows:

exit_status

The command's exit status, as returned by the `wait(2)` system call, or zero if no command was run. The value of `exit_status` is undefined if `error` is non-zero.

error If the command could not be executed, this is set to the value of `errno` set by the `execve(2)` system call. If the command was successfully executed, the value of `error` is zero.

show_version

```
int (*show_version)(int verbose);
```

The **show_version()** function is called by **sudo** when the user specifies the `-v` option. The plugin may display its version information to the user via the **conversation()** or **plugin_printf()** function using `SUDO_CONV_INFO_MSG`.

Returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error, although the return value is currently ignored.

log_ttyin

```
int (*log_ttyin)(const char *buf, unsigned int len,
                  const char **errstr);
```

The **log_ttyin()** function is called whenever data can be read from the user but before it is passed to the running command. This allows the plugin to reject data if it chooses to (for instance if the input contains banned content). Returns 1 if the data should be passed to the command, 0 if the data is rejected (which will terminate the running command), or -1 if an error occurred.

The function arguments are as follows:

buf The buffer containing user input.

len The length of `buf` in bytes.

errstr

If the **log_ttyin()** function returns a value other than 1, the plugin may store a message describing the failure or error in `errstr`. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in `errstr` must remain valid until the plugin's **close()** function is called.

NOTE: the `errstr` parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using `errstr`. Failure to do so may result in a crash.

log_ttyout

```
int (*log_ttyout)(const char *buf, unsigned int len,
                  const char **errstr);
```

The **log_ttyout()** function is called whenever data can be read from the command but before it is written to the user's terminal. This allows the plugin to reject data if it chooses to (for instance if the output contains banned content). Returns 1 if the data should be passed to the user, 0 if the data is rejected (which will terminate the running command), or -1 if an error occurred.

The function arguments are as follows:

buf The buffer containing command output.

len The length of *buf* in bytes.

errstr

If the **log_ttyout()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

log_stdin

```
int (*log_stdin)(const char *buf, unsigned int len,
                  const char **errstr);
```

The **log_stdin()** function is only used if the standard input does not correspond to a tty device. It is called whenever data can be read from the standard input but before it is passed to the running command. This allows the plugin to reject data if it chooses to (for instance if the input contains banned content). Returns 1 if the data should be passed to the command, 0 if the data is rejected (which will terminate the running command), or -1 if an error occurred.

The function arguments are as follows:

buf The buffer containing user input.

len The length of *buf* in bytes.

errstr

If the **log_stdin()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

log_stdout

```
int (*log_stdout)(const char *buf, unsigned int len,
                  const char **errstr);
```

The **log_stdout()** function is only used if the standard output does not correspond to a tty device. It is called whenever data can be read from the command but before it is written to the standard output. This allows the plugin to reject data if it chooses to (for instance if the output contains banned content). Returns 1 if the data should be passed to the user, 0 if the data is rejected (which will terminate the running command), or -1 if an error occurred.

The function arguments are as follows:

buf The buffer containing command output.

len The length of *buf* in bytes.

errstr

If the **log_stdout()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's

close() function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

```
log_stderr
int (*log_stderr)(const char *buf, unsigned int len,
                  const char **errstr);
```

The **log_stderr()** function is only used if the standard error does not correspond to a tty device. It is called whenever data can be read from the command but before it is written to the standard error. This allows the plugin to reject data if it chooses to (for instance if the output contains banned content). Returns 1 if the data should be passed to the user, 0 if the data is rejected (which will terminate the running command), or -1 if an error occurred.

The function arguments are as follows:

buf The buffer containing command output.

len The length of *buf* in bytes.

errstr

If the **log_stderr()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so may result in a crash.

register_hooks

See the **Policy plugin API** section for a description of **register_hooks**.

deregister_hooks

See the **Policy plugin API** section for a description of **deregister_hooks**.

change_winsize

```
int (*change_winsize)(unsigned int lines, unsigned int cols,
                      const char **errstr);
```

The **change_winsize()** function is called whenever the window size of the terminal changes from the initial values specified in the **user_info** list. Returns -1 if an error occurred, in which case no further calls to **change_winsize()** will be made.

The function arguments are as follows:

lines The number of lines (rows) in the re-sized terminal.

cols The number of columns in the re-sized terminal.

errstr

If the **change_winsize()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

NOTE: the *errstr* parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using *errstr*. Failure to do so

may result in a crash.

```
log_suspend
    int (*log_suspend)(int signo, const char **errstr);
```

The **log_suspend()** function is called whenever a command is suspended or resumed. Logging this information makes it possible to skip the period of time when the command was suspended during playback of a session. Returns -1 if an error occurred, in which case no further calls to **log_suspend()** will be made,

The function arguments are as follows:

signo

The signal that caused the command to be suspended, or SIGCONT if the command was resumed.

errstr

If the **log_suspend()** function returns a value other than 1, the plugin may store a message describing the failure or error in **errstr**. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in **errstr** must remain valid until the plugin's **close()** function is called.

NOTE: the **errstr** parameter is only available starting with API version 1.15. A plugin **must** check the API version specified by the **sudo** front-end before using **errstr**. Failure to do so may result in a crash.

event_alloc

```
    struct sudo_plugin_event * (*event_alloc)(void);
```

The **event_alloc()** function is used to allocate a **struct sudo_plugin_event** which provides access to the main **sudo** event loop. Unlike the other fields, the **event_alloc()** pointer is filled in by the **sudo** front-end, not by the plugin.

See the **Event API** section below for more information about events.

NOTE: the **event_alloc()** function is only available starting with API version 1.15. If the **sudo** front-end doesn't support API version 1.15 or higher, **event_alloc()** will not be set.

I/O Plugin Version Macros

Same as for the **Policy plugin API**.

Audit plugin API

```
/* Audit plugin close function status types. */
#define SUDO_PLUGIN_NO_STATUS          0
#define SUDO_PLUGIN_WAIT_STATUS        1
#define SUDO_PLUGIN_EXEC_ERROR         2
#define SUDO_PLUGIN_SUDO_ERROR         3

#define SUDO_AUDIT_PLUGIN 3
struct audit_plugin {
    unsigned int type; /* always SUDO_AUDIT_PLUGIN */
    unsigned int version; /* always SUDO_API_VERSION */
    int (*open)(unsigned int version, sudo_conv_t conversation,
               sudo_printf_t sudo_printf, char * const settings[],
               char * const user_info[], int submit_optind,
               char * const submit_argv[], char * const submit_envp[],
               char * const plugin_options[], const char **errstr);
```

```

void (*close)(int status_type, int status);
int (*accept)(const char *plugin_name,
              unsigned int plugin_type, char * const command_info[],
              char * const run_argv[], char * const run_envp[],
              const char **errstr);
int (*reject)(const char *plugin_name, unsigned int plugin_type,
              const char *audit_msg, char * const command_info[],
              const char **errstr);
int (*error)(const char *plugin_name, unsigned int plugin_type,
              const char *audit_msg, char * const command_info[],
              const char **errstr);
int (*show_version)(int verbose);
void (*register_hooks)(int version,
                      int (*register_hook)(struct sudo_hook *hook));
void (*deregister_hooks)(int version,
                        int (*deregister_hook)(struct sudo_hook *hook));
struct sudo_plugin_event * (*event_alloc)(void);
}

```

An audit plugin can be used to log successful and unsuccessful attempts to run **sudo** independent of the policy or any I/O plugins. Multiple audit plugins may be specified in **sudo.conf(5)**.

The **audit_plugin** struct has the following fields:

type The **type** field should always be set to **SUDO_AUDIT_PLUGIN**.

version

The **version** field should be set to **SUDO_API_VERSION**.

This allows **sudo** to determine the API version the plugin was built against.

open

```

int (*open)(unsigned int version, sudo_conv_t conversation,
            sudo_printf_t sudo_printf, char * const settings[],
            char * const user_info[], int submit_optind,
            char * const submit_argv[], char * const submit_envp[],
            char * const plugin_options[], const char **errstr);

```

The audit **open()** function is run before any other **sudo** plugin API functions. This makes it possible to audit failures in the other plugins. It returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error. In the latter case, **sudo** will print a usage message before it exits. If an error occurs, the plugin may optionally call the **conversation()** or **plugin_printf()** function with **SUDO_CONF_ERROR_MSG** to present additional error information to the user.

The function arguments are as follows:

version

The version passed in by **sudo** allows the plugin to determine the major and minor version number of the plugin API supported by **sudo**.

conversation

A pointer to the **conversation()** function that may be used by the **show_version()** function to display version information (see **show_version()** below). The **conversation()** function may also be used to display additional error message to the user. The **conversation()** function returns 0 on success, and -1 on failure.

plugin_printf

A pointer to a **printf()**-style function that may be used by the **show_version()** function to display version information (see **show_version** below). The **plugin_printf()** function may also be used to display additional error message to the user. The **plugin_printf()** function returns number of characters printed on success and -1 on failure.

settings

A vector of user-supplied **sudo** settings in the form of “name=value” strings. The vector is terminated by a NULL pointer. These settings correspond to options the user specified when running **sudo**. As such, they will only be present when the corresponding option has been specified on the command line.

When parsing *settings*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible settings.

user_info

A vector of information about the user running the command in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing *user_info*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

submit_optind

The index into *submit_argv* that corresponds to the first entry that is not a command line option. If *submit_argv* only consists of options, which may be the case with the **-l** or **-v** options, *submit_argv[submit_optind]* will evaluate to the NULL pointer.

submit_argv

The argument vector **sudo** was invoked with, including all command line options. The *submit_optind* argument can be used to determine the end of the command line options.

submit_envp

The invoking user’s environment in the form of a NULL-terminated vector of “name=value” strings.

When parsing *submit_envp*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

plugin_options

Any (non-comment) strings immediately after the plugin path are treated as arguments to the plugin. These arguments are split on a white space boundary and are passed to the plugin in the form of a NULL-terminated array of strings. If no arguments were specified, *plugin_options* will be the NULL pointer.

errstr

If the **open()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin’s **close()** function is called.

close

```
void (*close)(int status_type, int status);
```

The **close()** function is called when **sudo** is finished, shortly before it exits.

The function arguments are as follows:

status_type

The type of status being passed. One of SUDO_PLUGIN_NO_STATUS, SUDO_PLUGIN_WAIT_STATUS, SUDO_PLUGIN_EXEC_ERROR or SUDO_PLUGIN_SUDO_ERROR.

status

Depending on the value of *status_type*, this value is either ignored, the command's exit status as returned by the `wait(2)` system call, the value of `errno` set by the `execve(2)` system call, or the value of `errno` resulting from an error in the **sudo** front-end.

accept

```
int (*accept)(const char *plugin_name, unsigned int plugin_type,
char * const command_info[], char * const run_argv[],
char * const run_envp[], const char **errstr);
```

The **accept()** function is called when a command or action is accepted by a policy or approval plugin. The function arguments are as follows:

plugin_name

The name of the plugin that accepted the command or “sudo” for the **sudo** front-end.

plugin_type

The type of plugin that accepted the command, currently either SUDO_POLICY_PLUGIN, SUDO_POLICY_APPROVAL, or SUDO_FRONT_END. The **accept()** function is called multiple times--once for each policy or approval plugin that succeeds and once for the sudo front-end. When called on behalf of the sudo front-end, *command_info* may include information from an I/O logging plugin as well.

Typically, an audit plugin is interested in either the accept status from the **sudo** front-end or from the various policy and approval plugins, but not both. It is possible for the policy plugin to accept a command that is later rejected by an approval plugin, in which case the audit plugin's **accept()** and **reject()** functions will *both* be called.

command_info

An optional vector of information describing the command being run in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing *command_info*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

run_argv

A NULL-terminated argument vector describing a command that will be run in the same form as what would be passed to the `execve(2)` system call.

run_envp

The environment the command will be run with in the form of a NULL-terminated vector of “name=value” strings.

When parsing *run_envp*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

errstr

If the **accept()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

reject

```
int (*reject)(const char *plugin_name, unsigned int plugin_type,
              const char *audit_msg, char * const command_info[],
              const char **errstr);
```

The **reject()** function is called when a command or action is rejected by a plugin. The function arguments are as follows:

plugin_name

The name of the plugin that rejected the command.

plugin_type

The type of plugin that rejected the command, currently either SUDO_POLICY_PLUGIN, SUDO_APPROVAL_PLUGIN, or SUDO_IO_PLUGIN.

Unlike the **accept()** function, the **reject()** function is not called on behalf of the **sudo** front-end.

audit_msg

An optional string describing the reason the command was rejected by the plugin. If the plugin did not provide a reason, *audit_msg* will be the NULL pointer.

command_info

An optional vector of information describing the command being run in the form of "name=value" strings. The vector is terminated by a NULL pointer.

When parsing *command_info*, the plugin should split on the **first** equal sign ('=') since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

errstr

If the **reject()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin's **close()** function is called.

error

```
int (*error)(const char *plugin_name, unsigned int plugin_type,
             const char *audit_msg, char * const command_info[],
             const char **errstr);
```

The **error()** function is called when a plugin or the **sudo** front-end returns an error. The function arguments are as follows:

plugin_name

The name of the plugin that generated the error or "sudo" for the **sudo** front-end.

plugin_type

The type of plugin that generated the error, or SUDO_FRONT_END for the **sudo** front-end.

audit_msg

An optional string describing the plugin error. If the plugin did not provide a description, *audit_msg* will be the NULL pointer.

command_info

An optional vector of information describing the command being run in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing *command_info*, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

errstr

If the **error()** function returns a value other than 1, the plugin may store a message describing the failure or error in *errstr*. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in *errstr* must remain valid until the plugin’s **close()** function is called.

show_version

```
int (*show_version)(int verbose);
```

The **show_version()** function is called by **sudo** when the user specifies the **-V** option. The plugin may display its version information to the user via the **conversation()** or **plugin_printf()** function using **SUDO_CONV_INFO_MSG**. If the user requests detailed version information, the **verbose** flag will be set.

Returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error, although the return value is currently ignored.

register_hooks

See the **Policy plugin API** section for a description of **register_hooks**.

deregister_hooks

See the **Policy plugin API** section for a description of **deregister_hooks**.

event_alloc

```
struct sudo_plugin_event * (*event_alloc)(void);
```

The **event_alloc()** function is used to allocate a **struct sudo_plugin_event** which provides access to the main **sudo** event loop. Unlike the other fields, the **event_alloc()** pointer is filled in by the **sudo** front-end, not by the plugin.

See the **Event API** section below for more information about events.

NOTE: the **event_alloc()** function is only available starting with API version 1.17. If the **sudo** front-end doesn’t support API version 1.17 or higher, **event_alloc()** will not be set.

Approval plugin API

```
struct approval_plugin {
#define SUDO_APPROVAL_PLUGIN 4
    unsigned int type; /* always SUDO_APPROVAL_PLUGIN */
    unsigned int version; /* always SUDO_API_VERSION */
    int (*open)(unsigned int version, sudo_conv_t conversation,
                sudo_printf_t sudo_printf, char * const settings[],
                char * const user_info[], int submit_optind,
                char * const submit_argv[], char * const submit_envp[],
                char * const plugin_options[], const char **errstr);
```

```

void (*close)(void);
int (*check)(char * const command_info[], char * const run_argv[],
             char * const run_envp[], const char **errstr);
int (*show_version)(int verbose);
} ;

```

An approval plugin can be used to apply extra constraints after a command has been accepted by the policy plugin. Unlike the other plugin types, it does not remain open until the command completes. The plugin is opened before a call to `check()` or `show_version()` and closed shortly thereafter (audit plugin functions must be called before the plugin is closed). Multiple approval plugins may be specified in `sudo.conf(5)`.

The `approval_plugin` struct has the following fields:

`type` The `type` field should always be set to `SUDO_APPROVAL_PLUGIN`.

`version`

The `version` field should be set to `SUDO_API_VERSION`.

This allows `sudo` to determine the API version the plugin was built against.

`open`

```

int (*open)(unsigned int version, sudo_conv_t conversation,
            sudo_printf_t sudo_printf, char * const settings[],
            char * const user_info[], int submit_optind,
            char * const submit_argv[], char * const submit_envp[],
            char * const plugin_options[], const char **errstr);

```

The approval `open()` function is run immediately before a call to the plugin's `check()` or `show_version()` functions. It is only called if the version is being requested or if the policy plugin's `check_policy()` function has returned successfully. It returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error. In the latter case, `sudo` will print a usage message before it exits. If an error occurs, the plugin may optionally call the `conversation()` or `plugin_printf()` function with `SUDO_CONF_ERROR_MSG` to present additional error information to the user.

The function arguments are as follows:

`version`

The version passed in by `sudo` allows the plugin to determine the major and minor version number of the plugin API supported by `sudo`.

`conversation`

A pointer to the `conversation()` function that can be used by the plugin to interact with the user (see **Conversation API** for details). Returns 0 on success and -1 on failure.

`plugin_printf`

A pointer to a `printf()`-style function that may be used to display informational or error messages (see **Conversation API** for details). Returns the number of characters printed on success and -1 on failure.

`settings`

A vector of user-supplied `sudo` settings in the form of "name=value" strings. The vector is terminated by a NULL pointer. These settings correspond to options the user specified when running `sudo`. As such, they will only be present when the corresponding option has been specified on the command line.

When parsing `settings`, the plugin should split on the **first** equal sign ('=') since the `name` field will never include one itself but the `value` might.

See the **Policy plugin API** section for a list of all possible settings.

`user_info`

A vector of information about the user running the command in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing `user_info`, the plugin should split on the **first** equal sign (‘=’) since the `name` field will never include one itself but the `value` might.

See the **Policy plugin API** section for a list of all possible strings.

`submit_optind`

The index into `submit_argv` that corresponds to the first entry that is not a command line option. If `submit_argv` only consists of options, which may be the case with the **-l** or **-v** options, `submit_argv[submit_optind]` will evaluate to the NULL pointer.

`submit_argv`

The argument vector **sudo** was invoked with, including all command line options. The `submit_optind` argument can be used to determine the end of the command line options.

`submit_envp`

The invoking user’s environment in the form of a NULL-terminated vector of “name=value” strings.

When parsing `submit_envp`, the plugin should split on the **first** equal sign (‘=’) since the `name` field will never include one itself but the `value` might.

`plugin_options`

Any (non-comment) strings immediately after the plugin path are treated as arguments to the plugin. These arguments are split on a white space boundary and are passed to the plugin in the form of a NULL-terminated array of strings. If no arguments were specified, `plugin_options` will be the NULL pointer.

`errstr`

If the `open()` function returns a value other than 1, the plugin may store a message describing the failure or error in `errstr`. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in `errstr` must remain valid until the plugin’s `close()` function is called.

`close`

```
void (*close)(void);
```

The `close()` function is called after the approval plugin’s `check()` or `show_version()` functions have been called. It takes no arguments. The `close()` function is typically used to perform plugin-specific cleanup, such as the freeing of memory objects allocated by the plugin. If the plugin does not need to perform any cleanup, `close()` may be set to the NULL pointer.

`check`

```
int (*check)(char * const command_info[], char * const run_argv[],
             char * const run_envp[], const char **errstr);
```

The approval `check()` function is run after the policy plugin `check_policy()` function and before any I/O logging plugins. If multiple approval plugins are loaded, they must all succeed for the command to be allowed. It returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error. In the latter case, **sudo** will print a usage message before it exits. If an error occurs, the plugin may optionally call the `conversation()` or `plugin_printf()` function with `SUDO_CONF_ERROR_MSG` to present additional error information to the user.

The function arguments are as follows:

`command_info`

A vector of information describing the command being run in the form of “name=value” strings. The vector is terminated by a NULL pointer.

When parsing `command_info`, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

See the **Policy plugin API** section for a list of all possible strings.

`run_argv`

A NULL-terminated argument vector describing a command that will be run in the same form as what would be passed to the `execve(2)` system call.

`run_envp`

The environment the command will be run with in the form of a NULL-terminated vector of “name=value” strings.

When parsing `run_envp`, the plugin should split on the **first** equal sign (‘=’) since the *name* field will never include one itself but the *value* might.

`errstr`

If the `open()` function returns a value other than 1, the plugin may store a message describing the failure or error in `errstr`. The **sudo** front-end will then pass this value to any registered audit plugins. The string stored in `errstr` must remain valid until the plugin’s `close()` function is called.

`show_version`

```
int (*show_version)(int verbose);
```

The `show_version()` function is called by **sudo** when the user specifies the **-v** option. The plugin may display its version information to the user via the `conversation()` or `plugin_printf()` function using `SUDO_CONV_INFO_MSG`. If the user requests detailed version information, the `verbose` flag will be set.

Returns 1 on success, 0 on failure, -1 if a general error occurred, or -2 if there was a usage error, although the return value is currently ignored.

Signal handlers

The **sudo** front-end installs default signal handlers to trap common signals while the plugin functions are run. The following signals are trapped by default before the command is executed:

- `SIGALRM`
- `SIGHUP`
- `SIGINT`
- `SIGPIPE`
- `SIGQUIT`
- `SIGTERM`
- `SIGTSTP`
- `SIGUSR1`
- `SIGUSR2`

If a fatal signal is received before the command is executed, **sudo** will call the plugin’s `close()` function with an exit status of 128 plus the value of the signal that was received. This allows for consistent logging of commands killed by a signal for plugins that log such information in their `close()` function. An exception to this is `SIGPIPE`, which is ignored until the command is executed.

A plugin may temporarily install its own signal handlers but must restore the original handler before the plugin function returns.

Hook function API

Beginning with plugin API version 1.2, it is possible to install hooks for certain functions called by the **sudo** front-end.

Currently, the only supported hooks relate to the handling of environment variables. Hooks can be used to intercept attempts to get, set, or remove environment variables so that these changes can be reflected in the version of the environment that is used to execute a command. A future version of the API will support hooking internal **sudo** front-end functions as well.

Hook structure

Hooks in **sudo** are described by the following structure:

```
typedef int (*sudo_hook_fn_t)();

struct sudo_hook {
    unsigned int hook_version;
    unsigned int hook_type;
    sudo_hook_fn_t hook_fn;
    void *closure;
};
```

The **sudo_hook** structure has the following fields:

hook_version

The **hook_version** field should be set to **SUDO_HOOK_VERSION**.

hook_type

The **hook_type** field may be one of the following supported hook types:

SUDO_HOOK_SETENV

The C library **setenv(3)** function. Any registered hooks will run before the C library implementation. The **hook_fn** field should be a function that matches the following typedef:

```
typedef int (*sudo_hook_fn_setenv_t)(const char *name,
                                     const char *value, int overwrite, void *closure);
```

If the registered hook does not match the typedef the results are unspecified.

SUDO_HOOK_UNSETENV

The C library **unsetenv(3)** function. Any registered hooks will run before the C library implementation. The **hook_fn** field should be a function that matches the following typedef:

```
typedef int (*sudo_hook_fn_unsetenv_t)(const char *name,
                                       void *closure);
```

SUDO_HOOK_GETENV

The C library **getenv(3)** function. Any registered hooks will run before the C library implementation. The **hook_fn** field should be a function that matches the following typedef:

```
typedef int (*sudo_hook_fn_getenv_t)(const char *name,
                                     char **value, void *closure);
```

If the registered hook does not match the typedef the results are unspecified.

SUDO_HOOK_PUTENV

The C library `putenv(3)` function. Any registered hooks will run before the C library implementation. The `hook_fn` field should be a function that matches the following typedef:

```
typedef int (*sudo_hook_fn_putenv_t)(char *string,
                                     void *closure);
```

If the registered hook does not match the typedef the results are unspecified.

hook_fn

```
sudo_hook_fn_t hook_fn;
```

The `hook_fn` field should be set to the plugin's hook implementation. The actual function arguments will vary depending on the `hook_type` (see `hook_type` above). In all cases, the `closure` field of struct `sudo_hook` is passed as the last function parameter. This can be used to pass arbitrary data to the plugin's hook implementation.

The function return value may be one of the following:

SUDO_HOOK_RET_ERROR

The hook function encountered an error.

SUDO_HOOK_RET_NEXT

The hook completed without error, go on to the next hook (including the system implementation if applicable). For example, a `getenv(3)` hook might return `SUDO_HOOK_RET_NEXT` if the specified variable was not found in the private copy of the environment.

SUDO_HOOK_RET_STOP

The hook completed without error, stop processing hooks for this invocation. This can be used to replace the system implementation. For example, a `setenv` hook that operates on a private copy of the environment but leaves `environ` unchanged.

Note that it is very easy to create an infinite loop when hooking C library functions. For example, a `getenv(3)` hook that calls the `snprintf(3)` function may create a loop if the `snprintf(3)` implementation calls `getenv(3)` to check the locale. To prevent this, you may wish to use a static variable in the hook function to guard against nested calls. For example:

```
static int in_progress = 0; /* avoid recursion */
if (in_progress)
    return SUDO_HOOK_RET_NEXT;
in_progress = 1;
...
in_progress = 0;
return SUDO_HOOK_RET_STOP;
```

Hook API Version Macros

```
/* Hook API version major/minor */
#define SUDO_HOOK_VERSION_MAJOR 1
#define SUDO_HOOK_VERSION_MINOR 0
#define SUDO_HOOK_VERSION SUDO_API_MKVERSION(SUDO_HOOK_VERSION_MAJOR, \
                                             SUDO_HOOK_VERSION_MINOR)
```

For getters and setters see the **Policy plugin API**.

Event API

When `sudo` runs a command, it uses an event loop to service signals and I/O. Events may be triggered based on time, a file or socket descriptor becoming ready, or due to receipt of a signal. Starting with API

version 1.15, it is possible for a plugin to participate in this event loop by calling the **event_alloc()** function.

Event structure

Events are described by the following structure:

```
typedef void (*sudo_plugin_ev_callback_t)(int fd, int what, void *closure);

struct sudo_plugin_event {
    int (*set)(struct sudo_plugin_event *pev, int fd, int events,
               sudo_plugin_ev_callback_t callback, void *closure);
    int (*add)(struct sudo_plugin_event *pev, struct timespec *timeout);
    int (*del)(struct sudo_plugin_event *pev);
    int (*pending)(struct sudo_plugin_event *pev, int events,
                   struct timespec *ts);
    int (*fd)(struct sudo_plugin_event *pev);
    void (*setbase)(struct sudo_plugin_event *pev, void *base);
    void (*loopbreak)(struct sudo_plugin_event *pev);
    void (*free)(struct sudo_plugin_event *pev);
};
```

The sudo_plugin_event struct contains the following function pointers:

```
set()
    int (*set)(struct sudo_plugin_event *pev, int fd, int events,
               sudo_plugin_ev_callback_t callback, void *closure);
```

The **set()** function takes the following arguments:

struct sudo_plugin_event *pev
A pointer to the struct sudo_plugin_event itself.

fd The file or socket descriptor for I/O-based events or the signal number for signal events. For time-based events, **fd** must be -1.

events

The following values determine what will trigger the event callback:

SUDO_PLUGIN_EV_TIMEOUT

callback is run after the specified timeout expires

SUDO_PLUGIN_EV_READ

callback is run when the file descriptor is readable

SUDO_PLUGIN_EV_WRITE

callback is run when the file descriptor is writable

SUDO_PLUGIN_EV_PERSIST

event is persistent and remains enabled until explicitly deleted

SUDO_PLUGIN_EV_SIGNAL

callback is run when the specified signal is received

The SUDO_PLUGIN_EV_PERSIST flag may be ORed with any of the event types. It is also possible to OR SUDO_PLUGIN_EV_READ and SUDO_PLUGIN_EV_WRITE together to run the callback when a descriptor is ready to be either read from or written to. All other event values are mutually exclusive.

```
sudo_plugin_ev_callback_t callback
    typedef void (*sudo_plugin_ev_callback_t)(int fd, int what,
        void *closure);
```

The function to call when an event is triggered. The **callback()** function is run with the following arguments:

fd The file or socket descriptor for I/O-based events or the signal number for signal events.

what

The event type that triggered that callback. For events that have multiple event types (for example SUDO_PLUGIN_EV_READ and SUDO_PLUGIN_EV_WRITE) or have an associated timeout, *what* can be used to determine why the callback was run.

closure

The generic pointer that was specified in the **set()** function.

closure

A generic pointer that will be passed to the callback function.

The **set()** function returns 1 on success, and -1 if a error occurred.

add()

```
int (*add)(struct sudo_plugin_event *pev, struct timespec *timeout);
```

The **add()** function adds the event *pev* to **sudo**'s event loop. The event must have previously been initialized via the **set()** function. If the *timeout* argument is not NULL, it should specify a (relative) timeout after which the event will be triggered if the main event criteria has not been met. This is often used to implement an I/O timeout where the event will fire if a descriptor is not ready within a certain time period. If the event is already present in the event loop, its *timeout* will be adjusted to match the new value, if any.

The **add()** function returns 1 on success, and -1 if a error occurred.

del()

```
int (*del)(struct sudo_plugin_event *pev);
```

The **del()** function deletes the event *pev* from **sudo**'s event loop. Deleted events can be added back via the **add()** function.

The **del()** function returns 1 on success, and -1 if a error occurred.

pending()

```
int (*pending)(struct sudo_plugin_event *pev, int events,
    struct timespec *ts);
```

The **pending()** function can be used to determine whether one or more events is pending. The *events* argument specifies which events to check for. See the **set()** function for a list of valid event types. If SUDO_PLUGIN_EV_TIMEOUT is specified in *events*, the event has an associated timeout and the *ts* pointer is non-NUL, it will be filled in with the remaining time.

fd()

```
int (*fd)(struct sudo_plugin_event *pev);
```

The **fd()** function returns the descriptor or signal number associated with the event *pev*.

setbase()

```
void (*setbase)(struct sudo_plugin_event *pev, void *base);
```

The **setbase()** function sets the underlying event *base* for *pev* to the specified value. This can be used to move an event created via **event_alloc()** to a new event loop allocated by sudo's event subsystem. If *base* is NULL, *pev*'s event base is reset to the default value, which corresponds to **sudo**'s main event loop. Using this function requires linking the plugin with the sudo_util library. It is unlikely to be used outside of the **sudoers** plugin.

```
loopbreak()
void (*loopbreak)(struct sudo_plugin_event *pev);
```

The **loopbreak()** function causes **sudo**'s event loop to exit immediately and the running command to be terminated.

```
free()
void (*free)(struct sudo_plugin_event *pev);
```

The **free()** function deletes the event *pev* from the event loop and frees the memory associated with it.

Remote command execution

The **sudo** front-end does not support running remote commands. However, starting with **sudo** 1.8.8, the **-h** option may be used to specify a remote host that is passed to the policy plugin. A plugin may also accept a *runas_user* in the form of “user@hostname” which will work with older versions of **sudo**. It is anticipated that remote commands will be supported by executing a “helper” program. The policy plugin should setup the execution environment such that the **sudo** front-end will run the helper which, in turn, will connect to the remote host and run the command.

For example, the policy plugin could utilize **ssh** to perform remote command execution. The helper program would be responsible for running **ssh** with the proper options to use a private key or certificate that the remote host will accept and run a program on the remote host that would setup the execution environment accordingly.

Note that remote **sudoedit** functionality must be handled by the policy plugin, not **sudo** itself as the front-end has no knowledge that a remote command is being executed. This may be addressed in a future revision of the plugin API.

Conversation API

If the plugin needs to interact with the user, it may do so via the **conversation()** function. A plugin should not attempt to read directly from the standard input or the user's tty (neither of which are guaranteed to exist). The caller must include a trailing newline in *msg* if one is to be printed.

A **printf()**-style function is also available that can be used to display informational or error messages to the user, which is usually more convenient for simple messages where no user input is required.

Conversation function structures

The conversation function takes as arguments pointers to the following structures:

```
struct sudo_conv_message {
#define SUDO_CONV_PROMPT_ECHO_OFF 0x0001 /* do not echo user input */
#define SUDO_CONV_PROMPT_ECHO_ON 0x0002 /* echo user input */
#define SUDO_CONV_ERROR_MSG 0x0003 /* error message */
#define SUDO_CONV_INFO_MSG 0x0004 /* informational message */
#define SUDO_CONV_PROMPT_MASK 0x0005 /* mask user input */
#define SUDO_CONV_PROMPT_ECHO_OK 0x1000 /* flag: allow echo if no tty */
#define SUDO_CONV_PREFER_TTY 0x2000 /* flag: use tty if possible */

    int msg_type;
    int timeout;
```

```

        const char *msg;
};

#define SUDO_CONV REPL_MAX      1023

struct sudo_conv_reply {
    char *reply;
};

typedef int (*sudo_conv_callback_fn_t)(int signo, void *closure);
struct sudo_conv_callback {
    unsigned int version;
    void *closure;
    sudo_conv_callback_fn_t on_suspend;
    sudo_conv_callback_fn_t on_resume;
};

```

Pointers to the **conversation()** and **printf()**-style functions are passed in to the plugin's **open()** function when the plugin is initialized. The following type definitions can be used in the declaration of the **open()** function:

```

typedef int (*sudo_conv_t)(int num_msgs,
    const struct sudo_conv_message msgs[],
    struct sudo_conv_reply replies[], struct sudo_conv_callback *callback);

typedef int (*sudo_printf_t)(int msg_type, const char *fmt, ...);

```

To use the **conversation()** function, the plugin must pass an array of **sudo_conv_message** and **sudo_conv_reply** structures. There must be a **struct sudo_conv_message** and **struct sudo_conv_reply** for each message in the conversation, that is, both arrays must have the same number of elements. Each **struct sudo_conv_reply** must have its *reply* member initialized to NULL. The **struct sudo_conv_callbackpointer**, if not NULL, should contain function pointers to be called when the **sudo** process is suspended and/or resumed during conversation input. The *on_suspend* and *on_resume* functions are called with the signal that caused **sudo** to be suspended and the *closure* pointer from the **struct sudo_conv_callback**. These functions should return 0 on success and -1 on error. On error, the conversation will end and the conversation function will return a value of -1. The intended use is to allow the plugin to release resources, such as locks, that should not be held indefinitely while suspended and then reacquire them when the process is resumed. Note that the functions are not actually invoked from within a signal handler.

The *msg_type* must be set to one of the following values:

SUDO_CONV_PROMPT_ECHO_OFF

Prompt the user for input with echo disabled; this is generally used for passwords. The reply will be stored in the *replies* array, and it will never be NULL.

SUDO_CONV_PROMPT_ECHO_ON

Prompt the user for input with echo enabled. The reply will be stored in the *replies* array, and it will never be NULL.

SUDO_CONV_ERROR_MSG

Display an error message. The message is written to the standard error unless the **SUDO_CONV_PREFER_TTY** flag is set, in which case it is written to the user's terminal if possible.

SUDO_CONV_INFO_MSG

Display a message. The message is written to the standard output unless the `SUDO_CONV_PREFER_TTY` flag is set, in which case it is written to the user's terminal if possible.

SUDO_CONV_PROMPT_MASK

Prompt the user for input but echo an asterisk character for each character read. The reply will be stored in the `replies` array, and it will never be `NULL`. This can be used to provide visual feedback to the user while reading sensitive information that should not be displayed.

In addition to the above values, the following flag bits may also be set:

SUDO_CONV_PROMPT_ECHO_OK

Allow input to be read when echo cannot be disabled when the message type is `SUDO_CONV_PROMPT_ECHO_OFF` or `SUDO_CONV_PROMPT_MASK`. By default, `sudo` will refuse to read input if the echo cannot be disabled for those message types.

SUDO_CONV_PREFER_TTY

When displaying a message via `SUDO_CONV_ERROR_MSG` or `SUDO_CONV_INFO_MSG`, try to write the message to the user's terminal. If the terminal is unavailable, the standard error or standard output will be used, depending upon whether `SUDO_CONV_ERROR_MSG` or `SUDO_CONV_INFO_MSG` was used. The user's terminal is always used when possible for input, this flag is only used for output.

The `timeout` in seconds until the prompt will wait for no more input. A zero value implies an infinite timeout.

The plugin is responsible for freeing the reply buffer located in each `struct sudo_conv_reply`, if it is not `NULL`. `SUDO_CONV REPL_MAX` represents the maximum length of the reply buffer (not including the trailing NUL character). In practical terms, this is the longest password `sudo` will support.

The `printf()`-style function uses the same underlying mechanism as the `conversation()` function but only supports `SUDO_CONV_INFO_MSG` and `SUDO_CONV_ERROR_MSG` for the `msg_type` parameter. It can be more convenient than using the `conversation()` function if no user reply is needed and supports standard `printf()` escape sequences.

See the sample plugin for an example of the `conversation()` function usage.

Plugin invocation order

As of `sudo` 1.9.0, the plugin `open()` and `close()` functions are called in the following order:

1. audit open
2. policy open
3. approval open
4. approval close
5. I/O log open
6. command runs
7. command exits
8. I/O log close
9. policy close
10. audit close

11. sudo exits

Prior to **sudo** 1.9.0, the I/O log **close()** function was called *after* the policy **close()** function.

Sudoers group plugin API

The **sudoers** plugin supports its own plugin interface to allow non-Unix group lookups. This can be used to query a group source other than the standard Unix group database. Two sample group plugins are bundled with **sudo**, *group_file*, and *system_group*, are detailed in *sudoers(5)*. Third party group plugins include a QAS AD plugin available from Quest Software.

A group plugin must declare and populate a *sudoers_group_plugin* struct in the global scope. This structure contains pointers to the functions that implement plugin initialization, cleanup, and group lookup.

```
struct sudoers_group_plugin {
    unsigned int version;
    int (*init)(int version, sudo_printf_t sudo_printf,
                char *const argv[]);
    void (*cleanup)(void);
    int (*query)(const char *user, const char *group,
                 const struct passwd *pwd);
};
```

The *sudoers_group_plugin* struct has the following fields:

version

The *version* field should be set to **GROUP_API_VERSION**.

This allows **sudoers** to determine the API version the group plugin was built against.

init

```
int (*init)(int version, sudo_printf_t plugin_printf,
            char *const argv[]);
```

The **init()** function is called after *sudoers* has been parsed but before any policy checks. It returns 1 on success, 0 on failure (or if the plugin is not configured), and -1 if an error occurred. If an error occurs, the plugin may call the **plugin_printf()** function with **SUDO_CONF_ERROR_MSG** to present additional error information to the user.

The function arguments are as follows:

version

The *version* passed in by **sudoers** allows the plugin to determine the major and minor version number of the group plugin API supported by **sudoers**.

plugin_printf

A pointer to a **printf()**-style function that may be used to display informational or error message to the user. Returns the number of characters printed on success and -1 on failure.

argv A NULL-terminated array of arguments generated from the *group_plugin* option in *sudoers*. If no arguments were given, *argv* will be NULL.

cleanup

```
void (*cleanup)();
```

The **cleanup()** function is called when **sudoers** has finished its group checks. The plugin should free any memory it has allocated and close open file handles.

query

```
int (*query)(const char *user, const char *group,
             const struct passwd *pwd);
```

The **query()** function is used to ask the group plugin whether *user* is a member of *group*.

The function arguments are as follows:

user The name of the user being looked up in the external group database.

group

The name of the group being queried.

pwd The password database entry for *user*, if any. If *user* is not present in the password database, *pwd* will be NULL.

Group API Version Macros

```
/* Sudoers group plugin version major/minor */
#define GROUP_API_VERSION_MAJOR 1
#define GROUP_API_VERSION_MINOR 0
#define GROUP_API_VERSION ((GROUP_API_VERSION_MAJOR << 16) | \
                         GROUP_API_VERSION_MINOR)
```

For getters and setters see the **Policy plugin API**.

PLUGIN API CHANGELOG

The following revisions have been made to the Sudo Plugin API.

Version 1.0

Initial API version.

Version 1.1 (sudo 1.8.0)

The I/O logging plugin's **open()** function was modified to take the `command_info` list as an argument.

Version 1.2 (sudo 1.8.5)

The Policy and I/O logging plugins' **open()** functions are now passed a list of plugin parameters if any are specified in `sudo.conf(5)`.

A simple hooks API has been introduced to allow plugins to hook in to the system's environment handling functions.

The `init_session` Policy plugin function is now passed a pointer to the user environment which can be updated as needed. This can be used to merge in environment variables stored in the PAM handle before a command is run.

Version 1.3 (sudo 1.8.7)

Support for the `exec_background` entry has been added to the `command_info` list.

The `max_groups` and `plugin_dir` entries were added to the `settings` list.

The `version()` and `close()` functions are now optional. Previously, a missing `version()` or `close()` function would result in a crash. If no policy plugin `close()` function is defined, a default `close()` function will be provided by the **sudo** front-end that displays a warning if the command could not be executed.

The **sudo** front-end now installs default signal handlers to trap common signals while the plugin functions are run.

Version 1.4 (sudo 1.8.8)

The *remote_host* entry was added to the *settings* list.

Version 1.5 (sudo 1.8.9)

The *preserve_fds* entry was added to the *command_info* list.

Version 1.6 (sudo 1.8.11)

The behavior when an I/O logging plugin returns an error (-1) has changed. Previously, the **sudo** front-end took no action when the **log_ttyin()**, **log_ttyout()**, **log_stdin()**, **log_stdout()**, or **log_stderr()** function returned an error.

The behavior when an I/O logging plugin returns 0 has changed. Previously, output from the command would be displayed to the terminal even if an output logging function returned 0.

Version 1.7 (sudo 1.8.12)

The *plugin_path* entry was added to the *settings* list.

The *debug_flags* entry now starts with a debug file path name and may occur multiple times if there are multiple plugin-specific Debug lines in the **sudo.conf(5)** file.

Version 1.8 (sudo 1.8.15)

The *sudoedit_checkdir* and *sudoedit_follow* entries were added to the *command_info* list. The default value of *sudoedit_checkdir* was changed to true in sudo 1.8.16.

The sudo *conversation* function now takes a pointer to a *struct sudo_conv_callback* as its fourth argument. The *sudo_conv_t* definition has been updated to match. The plugin must specify that it supports plugin API version 1.8 or higher to receive a conversation function pointer that supports this argument.

Version 1.9 (sudo 1.8.16)

The *execfd* entry was added to the *command_info* list.

Version 1.10 (sudo 1.8.19)

The *umask* entry was added to the *user_info* list. The *iolog_group*, *iolog_mode*, and *iolog_user* entries were added to the *command_info* list.

Version 1.11 (sudo 1.8.20)

The *timeout* entry was added to the *settings* list.

Version 1.12 (sudo 1.8.21)

The *change_winsize* field was added to the *io_plugin* struct.

Version 1.13 (sudo 1.8.26)

The *log_suspend* field was added to the *io_plugin* struct.

Version 1.14 (sudo 1.8.29)

The *umask_override* entry was added to the *command_info* list.

Version 1.15 (sudo 1.9.0)

The *cwd_optional* entry was added to the *command_info* list.

The *event_alloc* field was added to the *policy_plugin* and *io_plugin* structs.

The *errstr* argument was added to the policy and I/O plugin functions which the plugin function can use to return an error string. This string may be used by the audit plugin to report failure or error conditions set by the other plugins.

The **close()** function is now called regardless of whether or not a command was actually executed. This makes it possible for plugins to perform cleanup even when a command was not run.

SUDO_CONV_REPL_MAX has increased from 255 to 1023 bytes.

Support for audit and approval plugins was added.

Version 1.16 (sudo 1.9.3)

Initial resource limit values were added to the user_info list.

The *cmnd_chroot* and *cmnd_cwd* entries were added to the settings list.

Version 1.17 (sudo 1.9.4)

The *event_alloc* field was added to the audit_plugin and approval_plugin structs.

Version 1.18 (sudo 1.9.9)

The policy may now set resource limit values in the command_info list.

BUGS

If you feel you have found a bug in **sudo**, please submit a bug report at <https://bugzilla.sudo.ws/>

SUPPORT

Limited free support is available via the sudo-users mailing list, see <https://www.sudo.ws/mailman/listinfo/sudo-users> to subscribe or search the archives.

DISCLAIMER

sudo is provided “AS IS” and any express or implied warranties, including, but not limited to, the implied warranties of merchantability and fitness for a particular purpose are disclaimed. See the LICENSE file distributed with **sudo** or <https://www.sudo.ws/license.html> for complete details.

NAME

sudo_root – How to run administrative commands

SYNOPSIS

sudo *command*

sudo -i

INTRODUCTION

By default, the password for the user "root" (the system administrator) is locked. This means you cannot log in as root or use su. Instead, the installer will set up sudo to allow the user that is created during install to run all administrative commands.

This means that in the terminal you can use sudo for commands that require root privileges. All programs in the menu will use a graphical sudo to prompt for a password. When sudo asks for a password, it needs **your password**, this means that a root password is not needed.

To run a command which requires root privileges in a terminal, simply prepend **sudo** in front of it. To get an interactive root shell, use **sudo -i**.

ALLOWING OTHER USERS TO RUN SUDO

By default, only the user who installed the system is permitted to run sudo. To add more administrators, i. e. users who can run sudo, you have to add these users to the group 'sudo' by doing one of the following steps:

- * In a shell, do

sudo adduser *username* sudo

- * Use the graphical "Users & Groups" program in the "System settings" menu to add the new user to the **sudo** group.

BENEFITS OF USING SUDO

The benefits of leaving root disabled by default include the following:

- * Users do not have to remember an extra password, which they are likely to forget.
- * The installer is able to ask fewer questions.
- * It avoids the "I can do anything" interactive login by default – you will be prompted for a password before major changes can happen, which should make you think about the consequences of what you are doing.
- * Sudo adds a log entry of the command(s) run (in **/var/log/auth.log**).
- * Every attacker trying to brute-force their way into your box will know it has an account named root and will try that first. What they do not know is what the usernames of your other users are.
- * Allows easy transfer for admin rights, in a short term or long term period, by adding and removing users from the sudo group, while not compromising the root account.
- * sudo can be set up with a much more fine-grained security policy.
- * On systems with more than one administrator using sudo avoids sharing a password amongst them.

DOWNSIDES OF USING SUDO

Although for desktops the benefits of using sudo are great, there are possible issues which need to be noted:

- * Redirecting the output of commands run with sudo can be confusing at first. For instance consider

sudo ls > /root/somefile

will not work since it is the shell that tries to write to that file. You can use

ls | sudo tee /root/somefile

to get the behaviour you want.

- * In a lot of office environments the ONLY local user on a system is root. All other users are imported using NSS techniques such as nss-ldap. To setup a workstation, or fix it, in the case of a network failure where nss-ldap is broken, root is required. This tends to leave the system unusable. An extra local user, or an enabled root password is needed here.

GOING BACK TO A TRADITIONAL ROOT ACCOUNT

This is not recommended!

To enable the root account (i.e. set a password) use:

sudo passwd root

Afterwards, edit the sudo configuration with **sudo visudo** and comment out the line

%sudo ALL=(ALL) ALL

to disable sudo access to members of the sudo group.

NAME

sudo_sendlog — send sudo I/O log to log server

SYNOPSIS

```
sudo_sendlog [ -AnV ] [ -b ca_bundle ] [ -c cert_file ] [ -h host ] [ -i iolog-id ]
[ -k key_file ] [ -p port ] [ -r restart-point ] [ -R reject-reason ]
[ -s stop-point ] [ -t number ] path
```

DESCRIPTION

sudo_sendlog can be used to send the existing **sudoers** I/O log *path* to a remote log server such as **sudo_logsvrd(8)** for central storage.

The options are as follows:

-A, --accept-only

Only send the accept event, not the I/O associated with the log. This can be used to test the logging of accept events without any associated I/O.

-b, --ca-bundle

The path to a certificate authority bundle file, in PEM format, to use instead of the system's default certificate authority database when authenticating the log server. The default is to use the system's default certificate authority database.

-c, --cert

The path to the client's certificate file in PEM format. This setting is required when the connection to the remote log server is secured with TLS.

--help

Display a short help message to the standard output and exit.

-h, --host

Connect to the specified *host* instead of localhost.

-i, --iolog-id

Use the specified *iolog-id* when restarting a log transfer. The *iolog-id* is reported by the server when it creates the remote I/O log. This option may only be used in conjunction with the **-r** option.

-k, --key

The path to the client's private key file in PEM format. This setting is required when the connection to the remote log server is secured with TLS.

-n, --no-verify

If specified, the server's certificate will not be verified during the TLS handshake. By default, **sudo_sendlog** verifies that the server's certificate is valid and that it contains either the server's host name or its IP address. This setting is only supported when the connection to the remote log server is secured with TLS.

-p, --port

Use the specified network *port* when connecting to the log server instead of the default, port 30344.

-r, --restart

Restart an interrupted connection to the log server. The specified *restart-point* is used to tell the server the point in time at which to continue the log. The *restart-point* is specified in the form "seconds,nanoseconds" and is usually the last commit point received from the server. The **-i** option must also be specified when restarting a transfer .

-R, --reject

Send a reject event for the command using the specified *reject-reason*, even though it was actually accepted locally. This can be used to test the logging of reject events; no I/O will be sent.

-s, --stop-after

Stop sending log records and close the connection when *stop-point* is reached. This can be used for testing purposes to send a partial I/O log to the server. Partial logs can be restarted using the **-r** option. The *stop-point* is an elapsed time specified in the form “seconds,nanoseconds”.

-t, --test

Open *number* simultaneous connections to the log server and send the specified I/O log file on each one. This option is useful for performance testing.

-V, --version

Print the **sudo_sendlog** version and exit.

Debugging sendlog

sudo_sendlog supports a flexible debugging framework that is configured via Debug lines in the sudo.conf(5) file.

For more information on configuring sudo .conf(5), please refer to its manual.

NAME

sudo, sudoedit — execute a command as another user

SYNOPSIS

```
sudo -h | -K | -k | -v
sudo -v[ -ABknS] [-g group] [-h host] [-p prompt] [-u user]
sudo -l[ -ABknS] [-g group] [-h host] [-p prompt] [-U user] [-u user] [command]
sudo [ -ABbEHnPS] [-C num] [-D directory] [-g group] [-h host] [-p prompt]
      [-R directory] [-r role] [-t type] [-T timeout] [-u user] [VAR=value]
      [-i | -s] [command]
sudoedit [ -ABknS] [-C num] [-D directory] [-g group] [-h host] [-p prompt]
      [-R directory] [-r role] [-t type] [-T timeout] [-u user] file ...
```

DESCRIPTION

sudo allows a permitted user to execute a *command* as the superuser or another user, as specified by the security policy. The invoking user's real (*not effective*) user-ID is used to determine the user name with which to query the security policy.

sudo supports a plugin architecture for security policies, auditing, and input/output logging. Third parties can develop and distribute their own plugins to work seamlessly with the **sudo** front-end. The default security policy is *sudoers*, which is configured via the file /etc/sudoers, or via LDAP. See the **Plugins** section for more information.

The security policy determines what privileges, if any, a user has to run **sudo**. The policy may require that users authenticate themselves with a password or another authentication mechanism. If authentication is required, **sudo** will exit if the user's password is not entered within a configurable time limit. This limit is policy-specific; the default password prompt timeout for the *sudoers* security policy is 0 minutes.

Security policies may support credential caching to allow the user to run **sudo** again for a period of time without requiring authentication. By default, the *sudoers* policy caches credentials on a per-terminal basis for 15 minutes. See the *timestamp_type* and *timestamp_timeout* options in *sudoers*(5) for more information. By running **sudo** with the **-v** option, a user can update the cached credentials without running a *command*.

On systems where **sudo** is the primary method of gaining superuser privileges, it is imperative to avoid syntax errors in the security policy configuration files. For the default security policy, *sudoers*(5), changes to the configuration files should be made using the *visudo*(8) utility which will ensure that no syntax errors are introduced.

When invoked as **sudoedit**, the **-e** option (described below), is implied.

Security policies and audit plugins may log successful and failed attempts to run **sudo**. If an I/O plugin is configured, the running command's input and output may be logged as well.

The options are as follows:

-A, --askpass

Normally, if **sudo** requires a password, it will read it from the user's terminal. If the **-A** (*askpass*) option is specified, a (possibly graphical) helper program is executed to read the user's password and output the password to the standard output. If the **SUDO_ASKPASS** environment variable is set, it specifies the path to the helper program. Otherwise, if *sudo.conf*(5) contains a line specifying the *askpass* program, that value will be used. For example:

```
# Path to askpass helper program
Path askpass /usr/X11R6/bin/ssh-askpass
```

If no askpass program is available, **sudo** will exit with an error.

-B, --bell

Ring the bell as part of the password prompt when a terminal is present. This option has no effect if an askpass program is used.

-b, --background

Run the given command in the background. Note that it is not possible to use shell job control to manipulate background processes started by **sudo**. Most interactive commands will fail to work properly in background mode.

-C num, --close-from=num

Close all file descriptors greater than or equal to *num* before executing a command. Values less than three are not permitted. By default, **sudo** will close all open file descriptors other than standard input, standard output, and standard error when executing a command. The security policy may restrict the user's ability to use this option. The *sudoers* policy only permits use of the **-C** option when the administrator has enabled the *closefrom_override* option.

-D directory, --chdir=directory

Run the command in the specified *directory* instead of the current working directory. The security policy may return an error if the user does not have permission to specify the working directory.

-E, --preserve-env

Indicates to the security policy that the user wishes to preserve their existing environment variables. The security policy may return an error if the user does not have permission to preserve the environment.

--preserve-env=list

Indicates to the security policy that the user wishes to add the comma-separated list of environment variables to those preserved from the user's environment. The security policy may return an error if the user does not have permission to preserve the environment. This option may be specified multiple times.

-e, --edit

Edit one or more files instead of running a command. In lieu of a path name, the string "sudoeedit" is used when consulting the security policy. If the user is authorized by the policy, the following steps are taken:

1. Temporary copies are made of the files to be edited with the owner set to the invoking user.
2. The editor specified by the policy is run to edit the temporary files. The *sudoers* policy uses the *SUDO_EDITOR*, *VISUAL* and *EDITOR* environment variables (in that order). If none of *SUDO_EDITOR*, *VISUAL* or *EDITOR* are set, the first program listed in the *editor sudoers(5)* option is used.
3. If they have been modified, the temporary files are copied back to their original location and the temporary versions are removed.

To help prevent the editing of unauthorized files, the following restrictions are enforced unless explicitly allowed by the security policy:

- Symbolic links may not be edited (version 1.8.15 and higher).
- Symbolic links along the path to be edited are not followed when the parent directory is writable by the invoking user unless that user is root (version 1.8.16 and higher).

- Files located in a directory that is writable by the invoking user may not be edited unless that user is root (version 1.8.16 and higher).

Users are never allowed to edit device special files.

If the specified file does not exist, it will be created. Note that unlike most commands run by **sudo**, the editor is run with the invoking user's environment unmodified. If the temporary file becomes empty after editing, the user will be prompted before it is installed. If, for some reason, **sudo** is unable to update a file with its edited version, the user will receive a warning and the edited copy will remain in a temporary file.

-g group, --group=group

Run the command with the primary group set to *group* instead of the primary group specified by the target user's password database entry. The *group* may be either a group name or a numeric group-ID (GID) prefixed with the '#' character (e.g., #0 for GID 0). When running a command as a GID, many shells require that the '#' be escaped with a backslash ('\'). If no **-u** option is specified, the command will be run as the invoking user. In either case, the primary group will be set to *group*. The *sudoer*'s policy permits any of the target user's groups to be specified via the **-g** option as long as the **-P** option is not in use.

-H, --set-home

Request that the security policy set the HOME environment variable to the home directory specified by the target user's password database entry. Depending on the policy, this may be the default behavior.

-h, --help

Display a short help message to the standard output and exit.

-h host, --host=host

Run the command on the specified *host* if the security policy plugin supports remote commands. Note that the *sudoer*'s plugin does not currently support running remote commands. This may also be used in conjunction with the **-l** option to list a user's privileges for the remote host.

-i, --login

Run the shell specified by the target user's password database entry as a login shell. This means that login-specific resource files such as *.profile*, *.bash_profile*, or *.login* will be read by the shell. If a command is specified, it is passed to the shell as a simple command using the **-c** option. The command and any arguments are concatenated, separated by spaces, after escaping each character (including white space) with a backslash ('\') except for alphanumerics, underscores, hyphens, and dollar signs. If no command is specified, an interactive shell is executed. **sudo** attempts to change to that user's home directory before running the shell. The command is run with an environment similar to the one a user would receive at log in. Note that most shells behave differently when a command is specified as compared to an interactive session; consult the shell's manual for details. The *Command environment* section in the *sudoers(5)* manual documents how the **-i** option affects the environment in which a command is run when the *sudoers* policy is in use.

-K, --remove-timestamp

Similar to the **-k** option, except that it removes the user's cached credentials entirely and may not be used in conjunction with a command or other option. This option does not require a password. Not all security policies support credential caching.

-k, --reset-timestamp

When used without a command, invalidates the user's cached credentials. In other words, the next time **sudo** is run a password will be required. This option does not require a password,

and was added to allow a user to revoke **sudo** permissions from a .logout file.

When used in conjunction with a command or an option that may require a password, this option will cause **sudo** to ignore the user's cached credentials. As a result, **sudo** will prompt for a password (if one is required by the security policy) and will not update the user's cached credentials.

Not all security policies support credential caching.

-l, --list

If no *command* is specified, list the allowed (and forbidden) commands for the invoking user (or the user specified by the **-U** option) on the current host. A longer list format is used if this option is specified multiple times and the security policy supports a verbose output format.

If a *command* is specified and is permitted by the security policy, the fully-qualified path to the command is displayed along with any command line arguments. If a *command* is specified but not allowed by the policy, **sudo** will exit with a status value of 1.

-n, --non-interactive

Avoid prompting the user for input of any kind. If a password is required for the command to run, **sudo** will display an error message and exit.

-P, --preserve-groups

Preserve the invoking user's group vector unaltered. By default, the *sudoers* policy will initialize the group vector to the list of groups the target user is a member of. The real and effective group-IDs, however, are still set to match the target user.

-p *prompt*, --prompt=*prompt*

Use a custom password prompt with optional escape sequences. The following percent ('%') escape sequences are supported by the *sudoers* policy:

%H

expanded to the host name including the domain name (only if the machine's host name is fully qualified or the *fqdn* option is set in *sudoers*(5))

%h

expanded to the local host name without the domain name

%p

expanded to the name of the user whose password is being requested (respects the *rootpw*, *targetpw*, and *runaspw* flags in *sudoers*(5))

%U

expanded to the login name of the user the command will be run as (defaults to root unless the **-u** option is also specified)

%u

expanded to the invoking user's login name

%%

two consecutive '%' characters are collapsed into a single '%' character

The custom prompt will override the default prompt specified by either the security policy or the *SUDO_PROMPT* environment variable. On systems that use PAM, the custom prompt will also override the prompt specified by a PAM module unless the *passprompt_override* flag is disabled in *sudoers*.

-R directory, --chroot=directory

Change to the specified root *directory* (see *chroot(8)*) before running the command. The security policy may return an error if the user does not have permission to specify the root directory.

-r role, --role=role

Run the command with an SELinux security context that includes the specified *role*.

-s, --stdin

Write the prompt to the standard error and read the password from the standard input instead of using the terminal device.

-s, --shell

Run the shell specified by the SHELL environment variable if it is set or the shell specified by the invoking user's password database entry. If a command is specified, it is passed to the shell as a simple command using the **-c** option. The command and any arguments are concatenated, separated by spaces, after escaping each character (including white space) with a backslash ('\\') except for alphanumerics, underscores, hyphens, and dollar signs. If no command is specified, an interactive shell is executed. Note that most shells behave differently when a command is specified as compared to an interactive session; consult the shell's manual for details.

-t type, --type=type

Run the command with an SELinux security context that includes the specified *type*. If no *type* is specified, the default type is derived from the role.

-U user, --other-user=user

Used in conjunction with the **-l** option to list the privileges for *user* instead of for the invoking user. The security policy may restrict listing other users' privileges. The *sudoer*'s policy only allows root or a user with the ALL privilege on the current host to use this option.

-T timeout, --command-timeout=timeout

Used to set a timeout for the command. If the timeout expires before the command has exited, the command will be terminated. The security policy may restrict the ability to set command timeouts. The *sudoer*'s policy requires that user-specified timeouts be explicitly enabled.

-u user, --user=user

Run the command as a user other than the default target user (usually *root*). The *user* may be either a user name or a numeric user-ID (UID) prefixed with the '#' character (e.g.,#0 for UID 0). When running commands as a UID, many shells require that the '#' be escaped with a backslash ('\\'). Some security policies may restrict UIDs to those listed in the password database. The *sudoer*'s policy allows UIDs that are not in the password database as long as the *targetpw* option is not set. Other security policies may not support this.

-v, --version

Print the **sudo** version string as well as the version string of any configured plugins. If the invoking user is already root, the **-V** option will display the arguments passed to configure when **sudo** was built; plugins may display additional information such as default options.

-v, --validate

Update the user's cached credentials, authenticating the user if necessary. For the *sudoers* plugin, this extends the **sudo** timeout for another 15 minutes by default, but does not run a command. Not all security policies support cached credentials.

-- The **--** option indicates that **sudo** should stop processing command line arguments.

Options that take a value may only be specified once unless otherwise indicated in the description. This is to help guard against problems caused by poorly written scripts that invoke **sudo** with user-controlled input.

Environment variables to be set for the command may also be passed on the command line in the form of `VAR=value`, e.g., `LD_LIBRARY_PATH=/usr/local/pkg/lib`. Variables passed on the command line are subject to restrictions imposed by the security policy plugin. The *sudoers* policy subjects variables passed on the command line to the same restrictions as normal environment variables with one important exception. If the `setenv v` option is set in *sudoers*, the command to be run has the `SETENV` tag set or the command matched is `ALL`, the user may set variables that would otherwise be forbidden. See *sudoers*(5) for more information.

COMMAND EXECUTION

When **sudo** executes a command, the security policy specifies the execution environment for the command. Typically, the real and effective user and group and IDs are set to match those of the target user, as specified in the password database, and the group vector is initialized based on the group database (unless the `-P` option was specified).

The following parameters may be specified by security policy:

- real and effective user-ID
- real and effective group-ID
- supplementary group-IDs
- the environment list
- current working directory
- file creation mode mask (umask)
- SELinux role and type
- scheduling priority (aka nice value)

Process model

There are two distinct ways **sudo** can run a command.

If an I/O logging plugin is configured or if the security policy explicitly requests it, a new pseudo-terminal (“pty”) is allocated and `fork(2)` is used to create a second **sudo** process, referred to as the *monitor*. The *monitor* creates a new terminal session with itself as the leader and the pty as its controlling terminal, calls `fork(2)`, sets up the execution environment as described above, and then uses the `execve(2)` system call to run the command in the child process. The *monitor* exists to relay job control signals between the user’s existing terminal and the pty the command is being run in. This makes it possible to suspend and resume the command. Without the monitor, the command would be in what POSIX terms an “orphaned process group” and it would not receive any job control signals from the kernel. When the command exits or is terminated by a signal, the *monitor* passes the command’s exit status to the main **sudo** process and exits. After receiving the command’s exit status, the main **sudo** passes the command’s exit status to the security policy’s close function and exits.

If no pty is used, **sudo** calls `fork(2)`, sets up the execution environment as described above, and uses the `execve(2)` system call to run the command in the child process. The main **sudo** process waits until the command has completed, then passes the command’s exit status to the security policy’s close function and exits. As a special case, if the policy plugin does not define a close function, **sudo** will execute the command directly instead of calling `fork(2)` first. The *sudoers* policy plugin will only define a close function when I/O logging is enabled, a pty is required, an SELinux role is specified, the command has an associated timeout, or the `pam_session` or `pam_setcred` options are enabled. Note that `pam_session` and `pam_setcred` are enabled by default on systems using PAM.

On systems that use PAM, the security policy's close function is responsible for closing the PAM session. It may also log the command's exit status.

Signal handling

When the command is run as a child of the **sudo** process, **sudo** will relay signals it receives to the command. The SIGINT and SIGQUIT signals are only relayed when the command is being run in a new pty or when the signal was sent by a user process, not the kernel. This prevents the command from receiving SIGINT twice each time the user enters control-C. Some signals, such as SIGSTOP and SIGKILL, cannot be caught and thus will not be relayed to the command. As a general rule, SIGTSTP should be used instead of SIGSTOP when you wish to suspend a command being run by **sudo**.

As a special case, **sudo** will not relay signals that were sent by the command it is running. This prevents the command from accidentally killing itself. On some systems, the **reboot(8)** command sends SIGTERM to all non-system processes other than itself before rebooting the system. This prevents **sudo** from relaying the SIGTERM signal it received back to **reboot(8)**, which might then exit before the system was actually rebooted, leaving it in a half-dead state similar to single user mode. Note, however, that this check only applies to the command run by **sudo** and not any other processes that the command may create. As a result, running a script that calls **reboot(8)** or **shutdown(8)** via **sudo** may cause the system to end up in this undefined state unless the **reboot(8)** or **shutdown(8)** are run using the **exec()** family of functions instead of **system()** (which interposes a shell between the command and the calling process).

If no I/O logging plugins are loaded and the policy plugin has not defined a **close()** function, set a command timeout, or required that the command be run in a new pty, **sudo** may execute the command directly instead of running it as a child process.

Plugins

Plugins may be specified via Plugin directives in the **sudo.conf(5)** file. They may be loaded as dynamic shared objects (on systems that support them), or compiled directly into the **sudo** binary. If no **sudo.conf(5)** file is present, or if it doesn't contain any Plugin lines, **sudo** will use **sudoers(5)** for the policy, auditing, and I/O logging plugins. See the **sudo.conf(5)** manual for details of the **/etc/sudo.conf** file and the **sudo_plugin(5)** manual for more information about the **sudo** plugin architecture.

EXIT VALUE

Upon successful execution of a command, the exit status from **sudo** will be the exit status of the program that was executed. If the command terminated due to receipt of a signal, **sudo** will send itself the same signal that terminated the command.

If the **-l** option was specified without a command, **sudo** will exit with a value of 0 if the user is allowed to run **sudo** and they authenticated successfully (as required by the security policy). If a command is specified with the **-l** option, the exit value will only be 0 if the command is permitted by the security policy, otherwise it will be 1.

If there is an authentication failure, a configuration/permission problem, or if the given command cannot be executed, **sudo** exits with a value of 1. In the latter case, the error string is printed to the standard error. If **sudo** cannot stat(2) one or more entries in the user's PATH, an error is printed to the standard error. (If the directory does not exist or if it is not really a directory, the entry is ignored and no error is printed.) This should not happen under normal circumstances. The most common reason for stat(2) to return "permission denied" is if you are running an automounter and one of the directories in your PATH is on a machine that is currently unreachable.

SECURITY NOTES

sudo tries to be safe when executing external commands.

To prevent command spoofing, **sudo** checks "." and "" (both denoting current directory) last when searching for a command in the user's PATH (if one or both are in the PATH). Depending on the security policy, the user's PATH environment variable may be modified, replaced, or passed unchanged to the program that **sudo** executes.

Users should *never* be granted **sudo** privileges to execute files that are writable by the user or that reside in a directory that is writable by the user. If the user can modify or replace the command there is no way to limit what additional commands they can run.

Please note that **sudo** will normally only log the command it explicitly runs. If a user runs a command such as **sudo su** or **sudo sh**, subsequent commands run from that shell are not subject to **sudo**'s security policy. The same is true for commands that offer shell escapes (including most editors). If I/O logging is enabled, subsequent commands will have their input and/or output logged, but there will not be traditional logs for those commands. Because of this, care must be taken when giving users access to commands via **sudo** to verify that the command does not inadvertently give the user an effective root shell. For information on ways to address this, please see the *Preventing shell escapes* section in **sudoers(5)**.

To prevent the disclosure of potentially sensitive information, **sudo** disables core dumps by default while it is executing (they are re-enabled for the command that is run). This historical practice dates from a time when most operating systems allowed set-user-ID processes to dump core by default. To aid in debugging **sudo** crashes, you may wish to re-enable core dumps by setting "disable_coredump" to false in the **sudo.conf(5)** file as follows:

```
Set disable_coredump false
```

See the **sudo.conf(5)** manual for more information.

ENVIRONMENT

sudo utilizes the following environment variables. The security policy has control over the actual content of the command's environment.

EDITOR	Default editor to use in -e (sudoedit) mode if neither SUDO_EDITOR nor VISUAL is set.
MAIL	Set to the mail spool of the target user when the -i option is specified, or when env_reset is enabled in sudoers (unless MAIL is present in the env_keep list).
HOME	Set to the home directory of the target user when the -i or -H options are specified, when the -s option is specified and set_home is set in sudoers , when always_set_home is enabled in sudoers , or when env_reset is enabled in sudoers and HOME is not present in the env_keep list.
LOGNAME	Set to the login name of the target user when the -i option is specified, when the set_logname option is enabled in sudoers , or when the env_reset option is enabled in sudoers (unless LOGNAME is present in the env_keep list).
PATH	May be overridden by the security policy.
SHELL	Used to determine shell to run with -s option.
SUDO_ASKPASS	Specifies the path to a helper program used to read the password if no terminal is available or if the -A option is specified.
SUDO_COMMAND	Set to the command run by sudo, including command line arguments. The command line arguments are truncated at 4096 characters to prevent a potential execution error.

SUDO_EDITOR	Default editor to use in -e (sudoedit) mode.
SUDO_GID	Set to the group-ID of the user who invoked sudo.
SUDO_PROMPT	Used as the default password prompt unless the -p option was specified.
SUDO_PS1	If set, PS1 will be set to its value for the program being run.
SUDO_UID	Set to the user-ID of the user who invoked sudo.
SUDO_USER	Set to the login name of the user who invoked sudo.
USER	Set to the same value as LOGNAME, described above.
VISUAL	Default editor to use in -e (sudoedit) mode if SUDO_EDITOR is not set.

FILES

/etc/sudo.conf	sudo front-end configuration
----------------	-------------------------------------

EXAMPLES

Note: the following examples assume a properly configured security policy.

To get a file listing of an unreadable directory:

```
$ sudo ls /usr/local/protected
```

To list the home directory of user yaz on a machine where the file system holding ~yaz is not exported as root:

```
$ sudo -u yaz ls ~yaz
```

To edit the index.html file as user www:

```
$ sudoedit -u www ~www/htdocs/index.html
```

To view system logs only accessible to root and users in the adm group:

```
$ sudo -g adm more /var/log/syslog
```

To run an editor as jim with a different primary group:

```
$ sudoedit -u jim -g audio ~jim/sound.txt
```

To shut down a machine:

```
$ sudo shutdown -r +15 "quick reboot"
```

To make a usage listing of the directories in the /home partition. Note that this runs the commands in a sub-shell to make the cd and file redirection work.

```
$ sudo sh -c "cd /home ; du -s * | sort -rn > USAGE"
```

DIAGNOSTICS

Error messages produced by **sudo** include:

editing files in a writable directory is not permitted

By default, **sudoedit** does not permit editing a file when any of the parent directories are writable by the invoking user. This avoids a race condition that could allow the user to overwrite an arbitrary file. See the *sudoedit_c heckdir* option in sudoers(5) for more information.

editing symbolic links is not permitted

By default, **sudoedit** does not follow symbolic links when opening files. See the *sudoedit_follow* option in sudoers(5) for more information.

effective uid is not 0, is sudo installed setuid root?

sudo was not run with root privileges. The **sudo** binary must be owned by the root user and have the set-user-ID bit set. Also, it must not be located on a file system mounted with the ‘nosuid’ option or on an NFS file system that maps uid 0 to an unprivileged uid.

effective uid is not 0, is sudo on a file system with the ‘nosuid’ option set or an NFS file system without root privileges?

sudo was not run with root privileges. The **sudo** binary has the proper owner and permissions but it still did not run with root privileges. The most common reason for this is that the file system the **sudo** binary is located on is mounted with the ‘nosuid’ option or it is an NFS file system that maps uid 0 to an unprivileged uid.

fatal error, unable to load plugins

An error occurred while loading or initializing the plugins specified in **sudo.conf(5)**.

invalid environment variable name

One or more environment variable names specified via the **-E** option contained an equal sign (‘=’). The arguments to the **-E** option should be environment variable names without an associated value.

no password was provided

When **sudo** tried to read the password, it did not receive any characters. This may happen if no terminal is available (or the **-s** option is specified) and the standard input has been redirected from **/dev/null**.

a terminal is required to read the password

sudo needs to read the password but there is no mechanism available for it to do so. A terminal is not present to read the password from, **sudo** has not been configured to read from the standard input, the **-s** option was not used, and no askpass helper has been specified either via the **sudo.conf(5)** file or the **SUDO_ASKPASS** environment variable.

no writable temporary directory found

sudoedit was unable to find a usable temporary directory in which to store its intermediate files.

The “no new privileges” flag is set, which prevents sudo from running as root.

sudo was run by a process that has the Linux “no new privileges” flag is set. This causes the set-user-ID bit to be ignored when running an executable, which will prevent **sudo** from functioning. The most likely cause for this is running **sudo** within a container that sets this flag. Check the documentation to see if it is possible to configure the container such that the flag is not set.

sudo must be owned by uid 0 and have the setuid bit set

sudo was not run with root privileges. The **sudo** binary does not have the correct owner or permissions. It must be owned by the root user and have the set-user-ID bit set.

sudoedit is not supported on this platform

It is only possible to run **sudoedit** on systems that support setting the effective user-ID.

timed out reading password

The user did not enter a password before the password timeout (5 minutes by default) expired.

you do not exist in the passwd database

Your user-ID does not appear in the system passwd database.

you may not specify environment variables in edit mode

It is only possible to specify environment variables when running a command. When editing a file, the editor is run with the user’s environment unmodified.

AUTHORS

Many people have worked on `sudo` over the years; this version consists of code written primarily by:

Todd C. Miller

See the CONTRIBUTORS file in the `sudo` distribution (<https://www.sudo.ws/contributors.html>) for an exhaustive list of people who have contributed to `sudo`.

CAVEATS

There is no easy way to prevent a user from gaining a root shell if that user is allowed to run arbitrary commands via `sudo`. Also, many programs (such as editors) allow the user to run commands via shell escapes, thus avoiding `sudo`'s checks. However, on most systems it is possible to prevent shell escapes with the `sudoers(5)` plugin's `noexec` functionality.

It is not meaningful to run the `cd` command directly via `sudo`, e.g.,

```
$ sudo cd /usr/local/protected
```

since when the command exits the parent process (your shell) will still be the same. Please see the **EXAMPLES** section for more information.

Running shell scripts via `sudo` can expose the same kernel bugs that make set-user-ID shell scripts unsafe on some operating systems (if your OS has a `/dev/fd/` directory, set-user-ID shell scripts are generally safe).

BUGS

If you feel you have found a bug in `sudo`, please submit a bug report at <https://bugzilla.sudo.ws/>

SUPPORT

Limited free support is available via the `sudo-users` mailing list, see <https://www.sudo.ws/mailman/listinfo/sudo-users> to subscribe or search the archives.

DISCLAIMER

`sudo` is provided "AS IS" and any express or implied warranties, including, but not limited to, the implied warranties of merchantability and fitness for a particular purpose are disclaimed. See the LICENSE file distributed with `sudo` or <https://www.sudo.ws/license.html> for complete details.

NAME

sudoers — default sudo security policy plugin

DESCRIPTION

The **sudoers** policy plugin determines a user's **sudo** privileges. It is the default **sudo** policy plugin. The policy is driven by the /etc/sudoers file or, optionally, in LDAP. The policy format is described in detail in the **SUDOERS FILE FORMAT** section. For information on storing **sudoers** policy information in LDAP, please see sudoers.ldap(5).

Configuring sudo.conf for sudoers

sudo consults the sudo.conf(5) file to determine which plugins to load. If no sudo.conf(5) file is present, or if it contains no Plugin lines, **sudoers** will be used for auditing, policy decisions and I/O logging. To explicitly configure sudo.conf(5) to use the **sudoers** plugin, the following configuration can be used.

```
Plugin sudoers_audit sudoers.so
Plugin sudoers_policy sudoers.so
Plugin sudoers_io sudoers.so
```

Starting with **sudo** 1.8.5, it is possible to specify optional arguments to the **sudoers** plugin in the sudo.conf(5) file. Plugin arguments, if any, should be listed after the path to the plugin (i.e., after sudoers.so). The arguments are only effective for the plugin that opens (and parses) the sudoers file.

For **sudo** version 1.9.1 and higher, this is the *sudoers_audit* plugin. For older versions, it is the *sudoers_policy* plugin. Multiple arguments may be specified, separated by white space. For example:

```
Plugin sudoers_audit sudoers.so sudoers_mode=0400 error_recovery=false
```

The following plugin arguments are supported:

error_recovery=bool

The *error_recovery* argument can be used to control whether **sudoers** should attempt to recover from syntax errors in the sudoers file. If set to *true* (the default), **sudoers** will try to recover from a syntax error by discarding the portion of the line that contains the error until the end of the line. A value of *false* will disable error recovery. Prior to version 1.9.3, no error recovery was performed.

ldap_conf=pathname

The *ldap_conf* argument can be used to override the default path to the ldap.conf file.

ldap_secret=pathname

The *ldap_secret* argument can be used to override the default path to the ldap.secret file.

sudoers_file=pathname

The *sudoers_file* argument can be used to override the default path to the sudoers file.

sudoers_uid=user-ID

The *sudoers_uid* argument can be used to override the default owner of the sudoers file. It should be specified as a numeric user-ID.

sudoers_gid=group-ID

The *sudoers_gid* argument can be used to override the default group of the sudoers file. It must be specified as a numeric group-ID (not a group name).

sudoers_mode=mode

The *sudoers_mode* argument can be used to override the default file mode for the sudoers file. It should be specified as an octal value.

For more information on configuring `sudo.conf(5)`, please refer to its manual.

User Authentication

The **`sudoers`** security policy requires that most users authenticate themselves before they can use **`sudo`**. A password is not required if the invoking user is root, if the target user is the same as the invoking user, or if the policy has disabled authentication for the user or command. Unlike **`su(1)`**, when **`sudoers`** requires authentication, it validates the invoking user's credentials, not the target user's (or root's) credentials. This can be changed via the *rootpw*, *targetpw* and *runaspw* flags, described later.

If a user who is not listed in the policy tries to run a command via **`sudo`**, mail is sent to the proper authorities. The address used for such mail is configurable via the *mailto* Defaults entry (described later) and defaults to `root`.

Note that no mail will be sent if an unauthorized user tries to run **`sudo`** with the **`-l`** or **`-v`** option unless there is an authentication error and either the *mail_always* or *mail_badpass* flags are enabled. This allows users to determine for themselves whether or not they are allowed to use **`sudo`**. By default, all attempts to run **`sudo`** (successful or not) are logged, regardless of whether or not mail is sent.

If **`sudo`** is run by root and the `SUDO_USER` environment variable is set, the **`sudoers`** policy will use this value to determine who the actual user is. This can be used by a user to log commands through `sudo` even when a root shell has been invoked. It also allows the **`-e`** option to remain useful even when invoked via a sudo-run script or program. Note, however, that the *sudoers* file lookup is still done for root, not the user specified by `SUDO_USER`.

`sudoers` uses per-user time stamp files for credential caching. Once a user has been authenticated, a record is written containing the user-ID that was used to authenticate, the terminal session ID, the start time of the session leader (or parent process) and a time stamp (using a monotonic clock if one is available). The user may then use **`sudo`** without a password for a short period of time (15 minutes unless overridden by the *timestamp_timeout* option). By default, **`sudoers`** uses a separate record for each terminal, which means that a user's login sessions are authenticated separately. The *timestamp_type* option can be used to select the type of time stamp record **`sudoers`** will use.

Logging

By default, **`sudoers`** logs both successful and unsuccessful attempts (as well as errors). The *log_allowed* and *log_denied* flags can be used to control this behavior. Messages can be logged to `syslog(3)`, a log file, or both. The default is to log to `syslog(3)` but this is configurable via the `syslog` and `logfile` settings. See **LOG FORMAT** for a description of the log file format.

`sudoers` is also capable of running a command in a pseudo-terminal and logging all input and/or output. The standard input, standard output, and standard error can be logged even when not associated with a terminal. I/O logging is not on by default but can be enabled using the *log_input* and *log_output* options as well as the `LOG_INPUT` and `LOG_OUTPUT` command tags. See **I/O LOG FILES** for details on how I/O log files are stored.

Starting with version 1.9, the *log_servers* setting may be used to send event and I/O log data to a remote server running **`sudo_logsrvd`** or another service that implements the protocol described by `sudo_logsrv.proto(5)`.

Command environment

Since environment variables can influence program behavior, **`sudoers`** provides a means to restrict which variables from the user's environment are inherited by the command to be run. There are two distinct ways **`sudoers`** can deal with environment variables.

By default, the *env_reset* flag is enabled. This causes commands to be executed with a new, minimal environment. On AIX (and Linux systems without PAM), the environment is initialized with the contents of the

/etc/environment file. The HOME, MAIL, SHELL, LOGNAME and USER environment variables are initialized based on the target user and the SUDO_* variables are set based on the invoking user. Additional variables, such as DISPLAY, PATH and TERM, are preserved from the invoking user's environment if permitted by the *env_check*, or *env_keep* options. A few environment variables are treated specially. If the PATH and TERM variables are not preserved from the user's environment, they will be set to default values. The LOGNAME and USER are handled as a single entity. If one of them is preserved (or removed) from the user's environment, the other will be as well. If LOGNAME and USER are to be preserved but only one of them is present in the user's environment, the other will be set to the same value. This avoids an inconsistent environment where one of the variables describing the user name is set to the invoking user and one is set to the target user. Environment variables with a value beginning with () are removed unless both the name and value parts are matched by *env_keep* or *env_check*, as they may be interpreted as functions by the **bash** shell. Prior to version 1.8.11, such variables were always removed.

If, however, the *env_reset* flag is disabled, any variables not explicitly denied by the *env_check* and *env_delete* options are allowed and their values are inherited from the invoking process. Prior to version 1.8.21, environment variables with a value beginning with () were always removed. Beginning with version 1.8.21, a pattern in *env_delete* is used to match **bash** shell functions instead. Since it is not possible to block all potentially dangerous environment variables, use of the default *env_reset* behavior is encouraged.

Environment variables specified by *env_check*, *env_delete*, or *env_keep* may include one or more '*' characters which will match zero or more characters. No other wildcard characters are supported.

By default, environment variables are matched by name. However, if the pattern includes an equal sign ('='), both the variables name and value must match. For example, a **bash** shell function could be matched as follows:

```
env_keep += "BASH_FUNC_my_func%%=( )*"
```

Without the "=()*" suffix, this would not match, as **bash** shell functions are not preserved by default.

The complete list of environment variables that are preserved or removed, as modified by global Defaults parameters in *sudoers*, is displayed when **sudo** is run by root with the **-V** option. Please note that the list of environment variables to remove varies based on the operating system **sudo** is running on.

Other **sudoers** options may influence the command environment, such as *always_set_home*, *secure_path*, *set_logname*, and *set_home*.

On systems that support PAM where the **pam_env** module is enabled for **sudo**, variables in the PAM environment may be merged in to the environment. If a variable in the PAM environment is already present in the user's environment, the value will only be overridden if the variable was not preserved by **sudoers**. When *env_reset* is enabled, variables preserved from the invoking user's environment by the *env_keep* list take precedence over those in the PAM environment. When *v_reset* is disabled, variables present in the invoking user's environment take precedence over those in the PAM environment unless they match a pattern in the *env_delete* list.

Note that the dynamic linker on most operating systems will remove variables that can control dynamic linking from the environment of set-user-ID executables, including **sudo**. Depending on the operating system this may include _RLD*, DYLD_*, LD_*, LDR_*, LIBPATH, SHLIB_PATH, and others. These type of variables are removed from the environment before **sudo** even begins execution and, as such, it is not possible for **sudo** to preserve them.

As a special case, if the **-i** option (initial login) is specified, **sudoers** will initialize the environment regardless of the value of *env_reset*. The DISPLAY, PATH and TERM variables remain unchanged; HOME, MAIL, SHELL, USER, and LOGNAME are set based on the target user. On AIX (and Linux systems without PAM), the contents of /etc/environment are also included. All other environment variables are removed unless permitted by *env_keep* or *env_check*, described above.

Finally, the *restricted_env_file* and *env_file* files are applied, if present. The variables in *restricted_env_file* are applied first and are subject to the same restrictions as the invoking user's environment, as detailed above. The variables in *env_file* are applied last and are not subject to these restrictions. In both cases, variables present in the files will only be set to their specified values if they would not conflict with an existing environment variable.

SUDOERS FILE FORMAT

The *sudoers* file is composed of two types of entries: aliases (basically variables) and user specifications (which specify who may run what).

When multiple entries match for a user, they are applied in order. Where there are multiple matches, the last match is used (which is not necessarily the most specific match).

The *sudoers* file grammar will be described below in Extended Backus-Naur Form (EBNF). Don't despair if you are unfamiliar with EBNF; it is fairly simple, and the definitions below are annotated.

Resource limits

By default, **sudoers** uses the operating system's native method of setting resource limits for the target user. On Linux systems, resource limits are usually set by the *pam_limits.so* PAM module. On some BSD systems, the */etc/login.conf* file specifies resource limits for the user. On AIX systems, resource limits are configured in the */etc/security/limits* file. If there is no system mechanism to set per-user resource limits, the command will run with the same limits as the invoking user. The one exception to this is the core dump file size, which is set by **sudoers** to 0 by default. Disabling core dumps by default makes it possible to avoid potential security problems where the core file is treated as trusted input.

Resource limits may also be set in the *sudoers* file itself, in which case they override those set by the system. See the *rlimit_as*, *rlimit_core*, *rlimit_cpu*, *rlimit_data*, *rlimit_fsize*, *rlimit_locks*, *rlimit_memlock*, *rlimit_nofile*, *rlimit_nproc*, *rlimit_rss*, *rlimit_stack* options described below. Resource limits in **sudoers** may be specified in one of the following formats:

“value”

Both the soft and hard resource limits are set to the same value. The special value “infinity” can be used to indicate that the value is unlimited.

“soft,hard”

Two comma-separated values. The soft limit is set to the first value and the hard limit is set to the second. Both values must either be enclosed in a set of double quotes, or the comma must be escaped with a backslash (‘\’). The special value “infinity” may be used in place of either value.

“default”

The default resource limit for the user will be used. This may be a user-specific value (see above) or the value of the resource limit when **sudo** was invoked for systems that don't support per-user limits.

“user” The invoking user's resource limits will be preserved when running the command.

For example, to restore the historic core dump file size behavior, a line like the following may be used.

```
Defaults rlimit_core=default
```

Resource limits in **sudoers** are only supported by version 1.8.7 or higher.

Quick guide to EBNF

EBNF is a concise and exact way of describing the grammar of a language. Each EBNF definition is made up of *production rules*. E.g.,

```
symbol ::= definition | alternate1 | alternate2 . . .
```

Each *production rule* references others and thus makes up a grammar for the language. EBNF also contains the following operators, which many readers will recognize from regular expressions. Do not, however, confuse them with “wildcard” characters, which have different meanings.

- ? Means that the preceding symbol (or group of symbols) is optional. That is, it may appear once or not at all.
- * Means that the preceding symbol (or group of symbols) may appear zero or more times.
- + Means that the preceding symbol (or group of symbols) may appear one or more times.

Parentheses may be used to group symbols together. For clarity, we will use single quotes (‘ ’) to designate what is a verbatim character string (as opposed to a symbol name).

Aliases

There are four kinds of aliases: User_Alias, Runas_Alias, Host_Alias and Cmnd_Alias. Beginning with **sudo** 1.9.0, Cmd_Alias may be used in place of Cmnd_Alias if desired.

```
Alias ::= 'User_Alias' User_Alias_Spec (':' User_Alias_Spec)* |  
       'Runas_Alias' Runas_Alias_Spec (':' Runas_Alias_Spec)* |  
       'Host_Alias' Host_Alias_Spec (':' Host_Alias_Spec)* |  
       'Cmnd_Alias' Cmnd_Alias_Spec (':' Cmnd_Alias_Spec)* |  
       'Cmd_Alias' Cmnd_Alias_Spec (':' Cmnd_Alias_Spec)*
```

```
User_Alias ::= NAME
```

```
User_Alias_Spec ::= User_Alias '=' User_List
```

```
Runas_Alias ::= NAME
```

```
Runas_Alias_Spec ::= Runas_Alias '=' Runas_List
```

```
Host_Alias ::= NAME
```

```
Host_Alias_Spec ::= Host_Alias '=' Host_List
```

```
Cmnd_Alias ::= NAME
```

```
Cmnd_Alias_Spec ::= Cmnd_Alias '=' Cmnd_List
```

```
NAME ::= [A-Z]([A-Z][0-9]_)*
```

Each *alias* definition is of the form

```
Alias_Type NAME = item1, item2, ...
```

where *Alias_Type* is one of User_Alias, Runas_Alias, Host_Alias, or Cmnd_Alias. ANAME is a string of uppercase letters, numbers, and underscore characters (‘ _ ’). ANAME **must** start with an uppercase letter. It is possible to put several alias definitions of the same type on a single line, joined by a colon (‘ : ’). E.g.,

```
Alias_Type NAME = item1, item2, item3 : NAME = item4, item5
```

It is a syntax error to redefine an existing *alias*. It is possible to use the same name for *aliases* of different types, but this is not recommended.

The definitions of what constitutes a valid *alias* member follow.

```
User_List ::= User |
             User ',' User_List

User ::= '!'* user_name |
           '!'* #user-ID |
           '!'* %group |
           '!'* %#group-ID |
           '!'* +netgroup |
           '!'* %:nonunix_group |
           '!'* %:#nonunix_gid |
           '!'* User_Alias
```

A *User_List* is made up of one or more user names, user-IDs (prefixed with '#'), system group names and IDs (prefixed with '%' and '%#' respectively), netgroups (prefixed with '+'), non-Unix group names and IDs (prefixed with '%:' and%:# respecti vely), and *User_Aliases*. Each list item may be prefixed with zero or more '!' operators. An odd number of '!' operators negate the value of the item; an even number just cancel each other out. User netgroups are matched using the user and domain members only; the host member is not used when matching.

A *user_name*, *user-ID*, *group*, *group-ID*, *netgroup*, *nonunix_group* or *nonunix_gid* may be enclosed in double quotes to avoid the need for escaping special characters. Alternately, special characters may be specified in escaped hex mode, e.g., \x20 for space. When using double quotes, any prefix characters must be included inside the quotes.

The actual *nonunix_group* and *nonunix_gid* syntax depends on the underlying group provider plugin. For instance, the QAS AD plugin supports the following formats:

- Group in the same domain: "%:Group Name"
- Group in any domain: "%:Group Name@FULLY.QUALIFIED.DOMAIN"
- Group SID: "%:S-1-2-34-5678901234-5678901234-5678901234-567"

See **GROUP PROVIDER PLUGINS** for more information.

Note that quotes around group names are optional. Unquoted strings must use a backslash ('\') to escape spaces and special characters. See **Other special characters and reserved words** for a list of characters that need to be escaped.

```
Runas_List ::= Runas_Member |
               Runas_Member ',' Runas_List

Runas_Member ::= '!'* user_name |
                  '!'* #user-ID |
                  '!'* %group |
                  '!'* %#group-ID |
                  '!'* %:nonunix_group |
                  '!'* %:#nonunix_gid |
                  '!'* +netgroup |
                  '!'* Runas_Alias
```

A *Runas_List* is similar to a *User_List* except that instead of *User_Aliases* it can contain *Runas_Aliases*. Note that user names and groups are matched as strings. In other words, two users (groups) with the same user (group) ID are considered to be distinct. If you wish to match all user names with the same user-ID (e.g., root and toor), you can use a user-ID instead of a name (#0 in the example

given). Note that the user-ID or group-ID specified in a Runas_Member need not be listed in the password or group database.

```
Host_List ::= Host |
              Host ',' Host_List

Host ::= '!'* host name |
          '!'* ip_addr |
          '!'* network(/netmask)? |
          '!'* +netgroup |
          '!'* Host_Alias
```

A Host_List is made up of one or more host names, IP addresses, network numbers, netgroups (prefixed with '+'), and other aliases. Again, the value of an item may be negated with the '!' operator. Host netgroups are matched using the host (both qualified and unqualified) and domain members only; the user member is not used when matching. If you specify a network number without a netmask, **sudo** will query each of the local host's network interfaces and, if the network number corresponds to one of the hosts's network interfaces, will use the netmask of that interface. The netmask may be specified either in standard IP address notation (e.g., 255.255.255.0 or ffff:ffff:ffff:ffff::), or CIDR notation (number of bits, e.g., 24 or 64). A host name may include shell-style wildcards (see the **Wildcards** section below), but unless the host name command on your machine returns the fully qualified host name, you'll need to use the *fqdn* flag for wildcards to be useful. Note that **sudo** only inspects actual network interfaces; this means that IP address 127.0.0.1 (localhost) will never match. Also, the host name "localhost" will only match if that is the actual host name, which is usually only the case for non-networked systems.

```
digest ::= [A-Fa-f0-9]+ |
          [A-Za-z0-9\+/_]+

Digest_Spec ::= "sha224" ':: digest |
                  "sha256" ':: digest |
                  "sha384" ':: digest |
                  "sha512" ':: digest

Digest_List ::= Digest_Spec |
                  Digest_Spec ',' Digest_List

Cmnd_List ::= Cmnd |
                  Cmnd ',' Cmnd_List

command name ::= file name |
                  file name args |
                  file name '"'

Edit_Spec ::= "sudoedit" file name+

Cmnd ::= Digest_List? '!'* command name |
          '!'* directory |
          '!'* Edit_Spec |
          '!'* Cmnd_Alias
```

A Cmnd_List is a list of one or more command names, directories, and other aliases. A command name is a fully qualified file name which may include shell-style wildcards (see the **Wildcards** section below). A simple file name allows the user to run the command with any arguments they wish. However, you may also specify command line arguments (including wildcards). Alternately, you can specify "" to indicate that the

command may only be run **without** command line arguments. A directory is a fully qualified path name ending in a ‘/’. When you specify a directory in a Cmnd_List, the user will be able to run any file within that directory (but not in any sub-directories therein).

If a Cmnd has associated command line arguments, then the arguments in the Cmnd must match exactly those given by the user on the command line (or match the wildcards if there are any). Note that the following characters must be escaped with a ‘\’ if they are used in command arguments: ‘,’ ‘:’ ‘=’ ‘\’. The built-in command “**sudoedit**” is used to permit a user to run **sudo** with the **-e** option (or as **sudoedit**). It may take command line arguments just as a normal command does. Note that “**sudoedit**” is a command built into **sudo** itself and must be specified in the *sudoers* file **without** a leading path. If a leading path is present, for example /usr/bin/sudoedit, the path name will be silently converted to “**sudoedit**”. A fully-qualified path for **sudoedit** is treated as an error by **visudo**.

A command name may be preceded by a Digest_List, a comma-separated list of one or more Digest_Spec entries. If a Digest_List is present, the command will only match successfully if it can be verified using one of the SHA-2 digests in the list. Starting with version 1.9.0, the **ALL** reserved word can be used in conjunction with a Digest_List. The following digest formats are supported: sha224, sha256, sha384, and sha512. The string may be specified in either hex or base64 format (base64 is more compact). There are several utilities capable of generating SHA-2 digests in hex format such as openssl, shasum, sha224sum, sha256sum, sha384sum, sha512sum.

For example, using openssl:

```
$ openssl dgst -sha224 /bin/ls
SHA224(/bin/ls)= 118187da8364d490b4a7debbf483004e8f3e053ec954309de2c41a25
```

It is also possible to use openssl to generate base64 output:

```
$ openssl dgst -binary -sha224 /bin/ls | openssl base64
EYGH2oNk1JC0p9679IMATo8+BT7JVDCd4sQaJQ==
```

Warning, if the user has write access to the command itself (directly or via a **sudo** command), it may be possible for the user to replace the command after the digest check has been performed but before the command is executed. A similar race condition exists on systems that lack the **fexecve()** system call when the directory in which the command is located is writable by the user. See the description of the *fde_xec* setting for more information on how **sudo** executes commands that have an associated digest.

Command digests are only supported by version 1.8.7 or higher.

Defaults

Certain configuration options may be changed from their default values at run-time via one or more Default_Entry lines. These may affect all users on any host, all users on a specific host, a specific user, a specific command, or commands being run as a specific user. Note that per-command entries may not include command line arguments. If you need to specify arguments, define a Cmnd_Alias and reference that instead.

```
Default_Type ::= 'Defaults' |
                 'Defaults' '@' Host_List |
                 'Defaults' ':' User_List |
                 'Defaults' '!' Cmnd_List |
                 'Defaults' '>' Runas_List

Default_Entry ::= Default_Type Parameter_List

Parameter_List ::= Parameter |
                  Parameter ',' Parameter_List
```

```
Parameter ::= Parameter '=' Value |
             Parameter '+=' Value |
             Parameter '-=' Value |
             '!' * Parameter
```

Parameters may be **flags**, **integer** values, **strings**, or **lists**. Flags are implicitly boolean and can be turned off via the ‘!’ operator. Some integer, string and list parameters may also be used in a boolean context to disable them. Values may be enclosed in double quotes (“”) when they contain multiple words. Special characters may be escaped with a backslash (‘\’).

To include a literal backslash character in a command line argument you must escape the backslash twice. For example, to match ‘\n’ as part of a command line argument, you must use ‘\\n’ in the *sudoers* file. This is due to there being two levels of escaping, one in the *sudoers* parser itself and another when command line arguments are matched by the *fnmatch(3)* function.

Lists have two additional assignment operators, += and -=. These operators are used to add to and delete from a list respectively. It is not an error to use the-= operator to remove an element that does not exist in a list.

Defaults entries are parsed in the following order: generic, host, user, and runas Defaults first, then command defaults. If there are multiple Defaults settings of the same type, the last matching setting is used. The following Defaults settings are parsed before all others since they may affect subsequent entries: *fqdn*, *group_plugin*, *runas_default*, *sudoers_locale*.

See **SUDOERS OPTIONS** for a list of supported Defaults parameters.

User specification

```
User_Spec ::= User_List Host_List '=' Cmnd_Spec_List \
             (':' Host_List '=' Cmnd_Spec_List)*

Cmnd_Spec_List ::= Cmnd_Spec |
                   Cmnd_Spec ',' Cmnd_Spec_List

Cmnd_Spec ::= Runas_Spec? Option_Spec* Tag_Spec* Cmnd

Runas_Spec ::= '(' Runas_List? (':' Runas_List)? ')'

Option_Spec ::= (SELinux_Spec | Date_Spec | Timeout_Spec | Chdir_Spec | Chroot_Spec)

SELinux_Spec ::= ('ROLE=role' | 'TYPE=type')

Date_Spec ::= ('NOTBEFORE=timestamp' | 'NOTAFTER=timestamp')

Timeout_Spec ::= 'TIMEOUT=timeout'

Chdir_Spec ::= 'CWD=directory'

Chroot_Spec ::= 'CHROOT=directory'

Tag_Spec ::= ('EXEC:' | 'NOEXEC:' | 'FOLLOW:' | 'NOFOLLOW' |
              'LOG_INPUT:' | 'NOLOG_INPUT:' | 'LOG_OUTPUT:' |
              'NOLOG_OUTPUT:' | 'MAIL:' | 'NOMAIL:' | 'INTERCEPT:' |
              'NOINTERCEPT:' | 'PASSWD:' | 'NOPASSWD:' | 'SETENV:' |
              'NOSETENV:')
```

A **user specification** determines which commands a user may run (and as what user) on specified hosts. By default, commands are run as **root**, but this can be changed on a per-command basis.

The basic structure of a user specification is “who where = (as_whom) what”. Let’s break that down into its constituent parts:

Runas_Spec

A Runas_Spec determines the user and/or the group that a command may be run as. A fully-specified Runas_Spec consists of two Runas_Lists (as defined above) separated by a colon (‘:’) and enclosed in a set of parentheses. The first Runas_List indicates which users the command may be run as via the **-u** option. The second defines a list of groups that may be specified via the **-g** option (in addition to any of the target user’s groups). If both Runas_Lists are specified, the command may be run with any combination of users and groups listed in their respective Runas_Lists. If only the first is specified, the command may be run as any user in the list and, optionally, with any group the target user belongs to. If the first Runas_List is empty but the second is specified, the command may be run as the invoking user with the group set to any listed in the Runas_List. If both Runas_Lists are empty, the command may only be run as the invoking user and the group, if specified, must be one that the invoking user is a member of. If no Runas_Spec is specified, the command may only be run as **root** and the group, if specified, must be one that **root** is a member of.

A Runas_Spec sets the default for the commands that follow it. What this means is that for the entry:

```
dgb      boulder = (operator) /bin/ls, /bin/kill, /usr/bin/lprm
```

The user **dgb** may run `/bin/ls`, `/bin/kill`, and `/usr/bin/lprm` on the host `boulder`—but only as **operator**. E.g.,

```
$ sudo -u operator /bin/ls
```

It is also possible to override a Runas_Spec later on in an entry. If we modify the entry like so:

```
dgb      boulder = (operator) /bin/ls, (root) /bin/kill, /usr/bin/lprm
```

Then user **dgb** is now allowed to run `/bin/ls` as **operator**, but `/bin/kill` and `/usr/bin/lprm` as **root**.

We can extend this to allow **dgb** to run `/bin/ls` with either the user or group set to **operator**:

```
dgb      boulder = (operator : operator) /bin/ls, (root) /bin/kill,\n      /usr/bin/lprm
```

Note that while the group portion of the Runas_Spec permits the user to run as command with that group, it does not force the user to do so. If no group is specified on the command line, the command will run with the group listed in the target user’s password database entry. The following would all be permitted by the sudoers entry above:

```
$ sudo -u operator /bin/ls\n$ sudo -u operator -g operator /bin/ls\n$ sudo -g operator /bin/ls
```

In the following example, user **tcm** may run commands that access a modem device file with the dialer group.

```
tcm      boulder = (:dialer) /usr/bin/tip, /usr/bin/cu,\n      /usr/local/bin/minicom
```

Note that in this example only the group will be set, the command still runs as user **tcm**. E.g.

```
$ sudo -g dialer /usr/bin/cu
```

Multiple users and groups may be present in a Runas_Spec, in which case the user may select any combination of users and groups via the **-u** and **-g** options. In this example:

```
alan    ALL = (root, bin : operator, system) ALL
```

user **alan** may run any command as either user root or bin, optionally setting the group to operator or system.

Option_Spec

A Cmnd may have zero or more options associated with it. Options may consist of SELinux roles and/or types, start and/or end dates and command timeouts. Once an option is set for a Cmnd, subsequent Cmrnds in the Cmnd_Spec_List, inherit that option unless it is overridden by another option. Note that the option names are reserved words in *sudoers*. This means that none of the valid option names (see below) can be used when declaring an alias.

SELinux_Spec

On systems with SELinux support, *sudoers* file entries may optionally have an SELinux role and/or type associated with a command. This can be used to implement a form of role-based access control (RBAC). If a role or type is specified with the command it will override any default values specified in *sudoers*. A role or type specified on the command line, however, will supersede the values in *sudoers*.

Date_Spec

sudoers rules can be specified with a start and end date via the NOTBEFORE and NOTAFTER settings. The time stamp must be specified in *Generalized Time* as defined by RFC 4517. The format is effectively `yyyymmddHHMMSSZ` where the minutes and seconds are optional. The ‘z’ suffix indicates that the time stamp is in Coordinated Universal Time (UTC). It is also possible to specify a timezone offset from UTC in hours and minutes instead of a ‘z’. For example, `-0500` would correspond to Eastern Standard time in the US. As an extension, if no ‘z’ or timezone offset is specified, local time will be used.

The following are all valid time stamps:

```
20170214083000Z
2017021408Z
20160315220000-0500
20151201235900
```

Timeout_Spec

A command may have a timeout associated with it. If the timeout expires before the command has exited, the command will be terminated. The timeout may be specified in combinations of days, hours, minutes, and seconds with a single-letter case-insensitive suffix that indicates the unit of time. For example, a timeout of 7 days, 8 hours, 30 minutes, and 10 seconds would be written as `7d8h30m10s`. If a number is specified without a unit, seconds are assumed. Any of the days, minutes, hours, or seconds may be omitted. The order must be from largest to smallest unit and a unit may not be specified more than once.

The following are all *valid* timeout values: `7d8h30m10s`, `14d`, `8h30m`, `600s`, `3600`. The following are *invalid* timeout values: `12m2w1d`, `30s10m4h`, `1d2d3h`.

This setting is only supported by version 1.8.20 or higher.

Chdir_Spec

The working directory that the command will be run in can be specified using the CWD setting. The *directory* must be a fully-qualified path name beginning with a ‘/’ or ‘~’ character, or the special value “*”. A value of “*” indicates that the user may specify the working directory by running **sudo** with the **-D** option. By default, commands are run from the invoking user’s current working directory, unless the **-i** op-

tion is given. Path names of the form `~user/path/name` are interpreted as being relative to the named user's home directory. If the user name is omitted, the path will be relative to the runas user's home directory.

This setting is only supported by version 1.9.3 or higher.

Chroot_Spec

The root directory that the command will be run in can be specified using the CHROOT setting. The *directory* must be a fully-qualified path name beginning with a '/' or '~' character, or the special value '*'. A value of '*' indicates that the user may specify the root directory by running **sudo** with the **-R** option. This setting can be used to run the command in a chroot(2) "sandbox" similar to the chroot(8) utility. Path names of the form `~user/path/name` are interpreted as being relative to the named user's home directory. If the user name is omitted, the path will be relative to the runas user's home directory.

This setting is only supported by version 1.9.3 or higher.

Tag_Spec

A command may have zero or more tags associated with it. The following tag values are supported: EXEC, NOEXEC, FOLLOW, NOFOLLOW, LOG_INPUT, NOLOG_INPUT, LOG_OUTPUT, NOLOG_OUTPUT, MAIL, NOMAIL, INTERCEPT, NOINTERCEPT, PASSWD, NOPASSWD, SETENV, and NOSETENV. Once a tag is set on a Cmnd, subsequent Cmnds in the Cmnd_Spec_List, inherit the tag unless it is overridden by the opposite tag (in other words, PASSWD overrides NOPASSWD and NOEXEC overrides EXEC).

EXEC and *NOEXEC*

If **sudo** has been compiled with *noexec* support and the underlying operating system supports it, the NOEXEC tag can be used to prevent a dynamically-linked executable from running further commands itself.

In the following example, user **aaron** may run `/usr/bin/more` and `/usr/bin/vi` but shell escapes will be disabled.

```
aaron    shanty = NOEXEC: /usr/bin/more, /usr/bin/vi
```

See the **Preventing shell escapes** section below for more details on how NOEXEC works and whether or not it will work on your system.

FOLLOW and *NOFOLLOW* Starting with version 1.8.15, **sudoedit** will not open a file that is a symbolic link unless the *sudoedit_follow* flag is enabled. The *FOLLOW* and *NOFOLLOW* tags override the value of *sudoedit_follow* and can be used to permit (or deny) the editing of symbolic links on a per-command basis. These tags are only effective for the **sudoedit** command and are ignored for all other commands.

LOG_INPUT and *NOLOG_INPUT*

These tags override the value of the *log_input* flag on a per-command basis. For more information, see the description of *log_input* in the **SUDOERS OPTIONS** section below.

LOG_OUTPUT and *NOLOG_OUTPUT*

These tags override the value of the *log_output* flag on a per-command basis. For more information, see the description of *log_output* in the **SUDOERS OPTIONS** section below.

MAIL and *NOMAIL*

These tags provide fine-grained control over whether mail will be sent when a user runs a command by overriding the value of the *mail_all_cmnds* flag on a per-command basis. They have no effect when **sudo** is run with the **-1** or **-v** options. A *NOMAIL* tag will also override the *mail_always* and *mail_no_perms* options. For more information, see the descriptions of *mail_all_cmnds*, *mail_always*, and *mail_no_perms*.

in the **SUDOERS OPTIONS** section below.

PASSWD and *NOPASSWD*

By default, **sudo** requires that a user authenticate before running a command. This behavior can be modified via the **NOPASSWD** tag. Like a **Runas_Spec**, the **NOPASSWD** tag sets a default for the commands that follow it in the **Cmnd_Spec_List**. Conversely, the **PASSWD** tag can be used to reverse things. For example:

```
ray      rushmore = NOPASSWD: /bin/kill, /bin/ls, /usr/bin/lprm
```

would allow the user **ray** to run **/bin/kill**, **/bin/ls**, and **/usr/bin/lprm** as **root** on the machine “rushmore” without authenticating himself. If we only want **ray** to be able to run **/bin/kill** without a password the entry would be:

```
ray      rushmore = NOPASSWD: /bin/kill, PASSWD: /bin/ls, /usr/bin/lprm
```

Note, however, that the **PASSWD** tag has no effect on users who are in the group specified by the **exempt_group** setting.

By default, if the **NOPASSWD** tag is applied to any of a user’s entries for the current host, the user will be able to run “**sudo -l**” without a password. Additionally, a user may only run “**sudo -v**” without a password if all of the user’s entries for the current host have the **NOPASSWD** tag. This behavior may be overridden via the **verifypw** and **listpw** options.

SETENV and *NOSETENV*

These tags override the value of the *setenv* flag on a per-command basis. Note that if **SETENV** has been set for a command, the user may disable the *env_reset* flag from the command line via the **-E** option. Additionally, environment variables set on the command line are not subject to the restrictions imposed by *env_check*, *env_delete*, or *env_keep*. As such, only trusted users should be allowed to set variables in this manner. If the command matched **isALL**, the **SETENV** tag is implied for that command; this default may be overridden by use of the **NOSETENV** tag.

INTERCEPT and *NOINTERCEPT*

If **sudo** has been compiled with *intercept* support and the underlying operating system supports it, the **INTERCEPT** tag can be used to cause programs spawned by a command to be validated against *sudoers* and logged just like they would be if run through **sudo** directly. This is useful in conjunction with commands that allow shell escapes such as editors, shells, and paginators.

In the following example, user **chuck** may run any command on the machine “research” in intercept mode.

```
chuck  research = INTERCEPT: ALL
```

See the **Preventing shell escapes** section below for more details on how **INTERCEPT** works and whether or not it will work on your system.

Wildcards

sudo allows shell-style *wildcards* (aka meta or glob characters) to be used in host names, path names, and command line arguments in the *sudoers* file. Wildcard matching is done via the **glob(3)** and **fnmatch(3)** functions as specified by IEEE Std 1003.1 (“POSIX.1”).

- * Matches any set of zero or more characters (including white space).
- ? Matches any single character (including white space).

- [. . .] Matches any character in the specified range.
- [! . . .] Matches any character *not* in the specified range.
- \x For any character ‘x’, evaluates to ‘x’. This is used to escape special characters such as ‘*’, ‘?’, ‘[’, and ‘]’.

Note that these are not regular expressions. Unlike a regular expression there is no way to match one or more characters within a range.

Character classes may be used if your system’s `glob(3)` and `fnmatch(3)` functions support them. However, because the ‘:’ character has special meaning in *sudoers*, it must be escaped. For example:

```
/bin/ls [[\:alpha\:]]*
```

Would match any file name beginning with a letter.

Note that a forward slash (‘/’) will *not* be matched by wildcards used in the file name portion of the command. This is to make a path like:

```
/usr/bin/*
```

match /usr/bin/who but not /usr/bin/X11/xterm.

When matching the command line arguments, however, a slash *does* get matched by wildcards since command line arguments may contain arbitrary strings and not just path names.

Wildcards in command line arguments should be used with care.

Command line arguments are matched as a single, concatenated string. This means a wildcard character such as ‘?’ or ‘*’ will match across word boundaries, which may be unexpected. For example, while a sudoers entry like:

```
%operator ALL = /bin/cat /var/log/messages*
```

will allow command like:

```
$ sudo cat /var/log/messages.1
```

It will also allow:

```
$ sudo cat /var/log/messages /etc/shadow
```

which is probably not what was intended. In most cases it is better to do command line processing outside of the *sudoers* file in a scripting language.

Exceptions to wildcard rules

The following exceptions apply to the above rules:

- "" If the empty string “” is the only command line argument in the *sudoers* file entry it means that command is not allowed to be run with *any* arguments.
- sudoedit Command line arguments to the *sudoedit* built-in command should always be path names, so a forward slash (‘/’) will not be matched by a wildcard.

Including other files from within sudoers

It is possible to include other *sudoers* files from within the *sudoers* file currently being parsed using the `@include` and `@includedir` directives. For compatibility with sudo versions prior to 1.9.1, `#include` and `#includedir` are also accepted.

An include file can be used, for example, to keep a site-wide *sudoers* file in addition to a local, per-machine file. For the sake of this example the site-wide *sudoers* file will be `/etc/sudoers` and the per-machine one will be `/etc/sudoers.local`. To include `/etc/sudoers.local` from within

/etc/sudoers one would use the following line in /etc/sudoers:

```
@include /etc/sudoers.local
```

When **sudo** reaches this line it will suspend processing of the current file (/etc/sudoers) and switch to /etc/sudoers.local. Upon reaching the end of /etc/sudoers.local, the rest of /etc/sudoers will be processed. Files that are included may themselves include other files. A hard limit of 128 nested include files is enforced to prevent include file loops.

Starting with version 1.9.1, the path to the include file may contain white space if it is escaped with a backslash ('\'). Alternately, the entire path may be enclosed in double quotes (""), in which case no escaping is necessary. To include a literal backslash in the path, '\\\' should be used.

If the path to the include file is not fully-qualified (does not begin with a '/'), it must be located in the same directory as the sudoers file it was included from. For example, if /etc/sudoers contains the line:

```
@include sudoers.local
```

the file that will be included is /etc/sudoers.local.

The file name may also include the %h escape, signifying the short form of the host name. In other words, if the machine's host name is "xerxes", then

```
@include /etc/sudoers.%h
```

will cause **sudo** to include the file /etc/sudoers.xerxes.

The @includedir directive can be used to create a sudoers.d directory that the system package manager can drop sudoers file rules into as part of package installation. For example, given:

```
@includedir /etc/sudoers.d
```

sudo will suspend processing of the current file and read each file in /etc/sudoers.d, skipping file names that end in '~' or contain a '.' character to avoid causing problems with package manager or editor temporary/backup files. Files are parsed in sorted lexical order. That is, /etc/sudoers.d/01_first will be parsed before /etc/sudoers.d/10_second. Be aware that because the sorting is lexical, not numeric, /etc/sudoers.d/1_whoops would be loaded after /etc/sudoers.d/10_second. Using a consistent number of leading zeroes in the file names can be used to avoid such problems. After parsing the files in the directory, control returns to the file that contained the @includedir directive.

Note that unlike files included via @include, visudo will not edit the files in a @includedir directory unless one of them contains a syntax error. It is still possible to runvisudo with the -f flag to edit the files directly, but this will not catch the redefinition of an alias that is also present in a different file.

Other special characters and reserved words

The pound sign ('#') is used to indicate a comment (unless it is part of a #include directive or unless it occurs in the context of a user name and is followed by one or more digits, in which case it is treated as a user-ID). Both the comment character and any text after it, up to the end of the line, are ignored.

The reserved word **ALL** is a built-in alias that always causes a match to succeed. It can be used wherever one might otherwise use a Cmnd_Alias, User_Alias, Runas_Alias, or Host_Alias. Attempting to define an alias named **ALL** will result in a syntax error. Please note that using**ALL** can be dangerous since in a command context, it allows the user to run *any* command on the system.

The following option names permitted in an Option_Spec are also considered reserved words: CHROOT, ROLE, TYPE, TIMEOUT, CWD, NOTBEFORE and NOTAFTER. Attempting to define *alias* with the same name as one of the options will result in a syntax error.

An exclamation point ('!') can be used as a logical *not* operator in a list or *alias* as well as in front of a *Cmnd*. This allows one to exclude certain values. For the '!' operator to be effective, there must be something for it to exclude. For example, to match all users except for root one would use:

```
ALL, !root
```

If the **ALL**, is omitted, as in:

```
!root
```

it would explicitly deny root but not match any other users. This is different from a true “negation” operator.

Note, however, that using a '!' in conjunction with the built-in **ALL** alias to allow a user to run “all but a few” commands rarely works as intended (see **SECURITY NOTES** below).

Long lines can be continued with a backslash ('\') as the last character on the line.

White space between elements in a list as well as special syntactic characters in a *User Specification* ('=', ':', '(', ')') is optional.

The following characters must be escaped with a backslash ('\') when used as part of a word (e.g., a user name or host name): '!', '=', ':', ',', '(', ')', '\'.

SUDOERS OPTIONS

sudo's behavior can be modified by *Default_Entry* lines, as explained earlier. A list of all supported Defaults parameters, grouped by type, are listed below.

Boolean Flags:

always_query_group_plugin

If a *group_plugin* is configured, use it to resolve groups of the form %group as long as there is not also a system group of the same name. Normally, only groups of the form %:group are passed to the *group_plugin*. This flag is *off* by default.

always_set_home

If enabled, **sudo** will set the HOME environment variable to the home directory of the target user (which is the root user unless the **-u** option is used). This flag is largely obsolete and has no effect unless the *env_reset* flag has been disabled or HOME is present in the *env_keep* list, both of which are strongly discouraged. This flag is *off* by default.

authenticate

If set, users must authenticate themselves via a password (or other means of authentication) before they may run commands. This default may be overridden via the PASSWD and NOPASSWD tags. This flag is *on* by default.

case_insensitive_group

If enabled, group names in *sudoers* will be matched in a case insensitive manner. This may be necessary when users are stored in LDAP or AD. This flag is *on* by default.

case_insensitive_user

If enabled, user names in *sudoers* will be matched in a case insensitive manner. This may be necessary when groups are stored in LDAP or AD. This flag is *on* by default.

closefrom_override

If set, the user may use the **-C** option which overrides the default starting point at which **sudo** begins closing open file descriptors. This flag is *off* by default.

compress_io

If set, and **sudo** is configured to log a command's input or output, the I/O logs will be compressed using **zlib**. This flag is *on* by default when **sudo** is compiled with **zlib** support.

exec_background

By default, **sudo** runs a command as the foreground process as long as **sudo** itself is running in the foreground. When the *exec_background* flag is enabled and the command is being run in a pseudo-terminal (due to I/O logging or the *use_pty* flag), the command will be run as a background process. Attempts to read from the controlling terminal (or to change terminal settings) will result in the command being suspended with the SIGTTIN signal (or SIGTTOU in the case of terminal settings). If this happens when **sudo** is a foreground process, the command will be granted the controlling terminal and resumed in the foreground with no user intervention required. The advantage of initially running the command in the background is that **sudo** need not read from the terminal unless the command explicitly requests it. Otherwise, any terminal input must be passed to the command, whether it has required it or not (the kernel buffers terminals so it is not possible to tell whether the command really wants the input). This is different from historic *sudo* behavior or when the command is not being run in a pseudo-terminal.

For this to work seamlessly, the operating system must support the automatic restarting of system calls. Unfortunately, not all operating systems do this by default, and even those that do may have bugs. For example, macOS fails to restart the **tcgetattr()** and **tcsetattr()** system calls (this is a bug in macOS). Furthermore, because this behavior depends on the command stopping with the SIGTTIN or SIGTTOU signals, programs that catch these signals and suspend themselves with a different signal (usually SIGTOP) will not be automatically foregrounded. Some versions of the linux **su(1)** command behave this way. This flag is off by default.

This setting is only supported by version 1.8.7 or higher. It has no effect unless I/O logging is enabled or the *use_pty* flag is enabled.

env_editor

If set, **visudo** will use the value of the SUDO_EDITOR, VISUAL or EDITOR environment variables before falling back on the default editor list. Note that **visudo** is typically run as root so this flag may allow a user with **visudo** privileges to run arbitrary commands as root without logging. An alternative is to place a colon-separated list of “safe” editors int the *editor* setting. **visudo** will then only use SUDO_EDITOR, VISUAL or EDITOR if they match a value specified in *editor*. If the *v_reset* flag is enabled, the SUDO_EDITOR, VISUAL and/or EDITOR environment variables must be present in the *env_keep* list for the *env_editor* flag to function when **visudo** is invoked via **sudo**. This flag is on by default.

env_reset

If set, **sudo** will run the command in a minimal environment containing the TERM, PATH, HOME, MAIL, SHELL, LOGNAME, USER and SUDO_* variables. Any variables in the caller’s environment or in the file specified by the *restricted_env_file* setting that match the *env_keep* and *env_check* lists are then added, followed by any variables present in the file specified by the *env_file* setting (if any). The contents of the *env_keep* and *env_check* lists, as modified by global Defaults parameters in *sudoers*, are displayed when **sudo** is run by root with the **-v** option. If the *secure_path* setting is enabled, its value will be used for the PATH environment variable. This flag is off by default.

fast_glob

Normally, **sudo** uses the **glob(3)** function to do shell-style globbing when matching path names. However, since it accesses the file system, **glob(3)** can take a long time to complete for some patterns, especially when the pattern references a network file system that is mounted on demand (auto mounted). The *fast_glob* flag causes **sudo** to use the **fnmatch(3)** function, which does not access the file system to do its matching. The disadvantage of *fast_glob* is that it is unable to match relative path names such as *./ls* or *../bin/ls*. This has security implications when path names that include

globbing characters are used with the negation operator, ‘!’, as such rules can be trivially bypassed. As such, this flag should not be used when the *sudoers* file contains rules that contain negated path names which include globbing characters. This flag is *off* by default.

fqdn

Set this flag if you want to put fully qualified host names in the *sudoers* file when the local host name (as returned by the *hostname* command) does not contain the domain name. In other words, instead of myhost you would use myhost.mydomain.edu. You may still use the short form if you wish (and even mix the two). This flag is only effective when the “canonical” host name, as returned by the **getaddrinfo()** or **gethostbyname()** function, is a fully-qualified domain name. This is usually the case when the system is configured to use DNS for host name resolution.

If the system is configured to use the */etc/hosts* file in preference to DNS, the “canonical” host name may not be fully-qualified. The order that sources are queried for host name resolution is usually specified in the */etc/nsswitch.conf*, */etc/netsvc.conf*, */etc/host.conf*, or, in some cases, */etc/resolv.conf* file. In the */etc/hosts* file, the first host name of the entry is considered to be the “canonical” name; subsequent names are aliases that are not used by **sudoers**. For example, the following hosts file line for the machine “xyzzy” has the fully-qualified domain name as the “canonical” host name, and the short version as an alias.

```
192.168.1.1 xyzzy.sudo.ws xyzzy
```

If the machine’s hosts file entry is not formatted properly, the *fqdn* flag will not be effective if it is queried before DNS.

Beware that when using DNS for host name resolution, turning on *fqdn* requires **sudoers** to make DNS lookups which renders **sudo** unusable if DNS stops working (for example if the machine is disconnected from the network). Also note that just like with the hosts file, you must use the “canonical” name as DNS knows it. That is, you may not use a host alias (CNAME entry) due to performance issues and the fact that there is no way to get all aliases from DNS.

This flag is *on* by default.

ignore_audit_errors

Allow commands to be run even if **sudoers** cannot write to the audit log. If enabled, an audit log write failure is not treated as a fatal error. If disabled, a command may only be run after the audit event is successfully written. This flag is only effective on systems for which **sudoers** supports audit logging, including FreeBSD, Linux, macOS, and Solaris. This flag is *on* by default.

ignore_dot

If set, **sudo** will ignore “.” or “” (both denoting current directory) in the PATH environment variable; the PATH itself is not modified. This flag is *off* by default.

ignore_ilog_errors

Allow commands to be run even if **sudoers** cannot write to the I/O log (local or remote). If enabled, an I/O log write failure is not treated as a fatal error. If disabled, the command will be terminated if the I/O log cannot be written to. This flag is *off* by default.

ignore_logfile_errors

Allow commands to be run even if **sudoers** cannot write to the log file. If enabled, a log file write failure is not treated as a fatal error. If disabled, a command may only be run after the log file entry is successfully written. This flag only has an effect when **sudoers** is configured to use file-based logging via the *logfile* setting. This flag is *on*

by default.

`ignore_local_sudoers`

If set via LDAP, parsing of `/etc/sudoers` will be skipped. This is intended for Enterprises that wish to prevent the usage of local sudoers files so that only LDAP is used. This thwarts the efforts of rogue operators who would attempt to add roles to `/etc/sudoers`. When this flag is enabled, `/etc/sudoers` does not even need to exist. Since this flag tells `sudo` how to behave when no specific LDAP entries have been matched, this sudoOption is only meaningful for the `cn=defaults` section. This flag is *off* by default.

`ignore_unknown_defaults`

If set, `sudo` will not produce a warning if it encounters an unknown Defaults entry in the `sudoers` file or an unknown sudoOption in LDAP. This flag is *off* by default.

`insults`

If set, `sudo` will insult users when they enter an incorrect password. This flag is *off* by default.

`log_allowed`

If set, `sudoers` will log commands allowed by the policy to the system audit log (where supported) as well as to syslog and/or a log file. This flag is *on* by default.

This setting is only supported by version 1.8.29 or higher.

`log_denied`

If set, `sudoers` will log commands denied by the policy to the system audit log (where supported) as well as to syslog and/or a log file. This flag is *on* by default.

This setting is only supported by version 1.8.29 or higher.

`log_exit_status`

If set, `sudoers` will log the exit value of commands that are run to syslog and/or a log file. If a command was terminated by a signal, the signal name is logged as well. This flag is *off* by default.

This setting is only supported by version 1.9.8 or higher.

`log_host`

If set, the host name will be included in log entries written to the file configured by the `logfile` setting. This flag is *off* by default.

`log_input`

If set, `sudo` will run the command in a pseudo-terminal and log all user input. If the standard input is not connected to the user's tty, due to I/O redirection or because the command is part of a pipeline, that input is also captured and stored in a separate log file. Anything sent to the standard input will be consumed, regardless of whether or not the command run via `sudo` is actually reading the standard input. This may have unexpected results when using `sudo` in a shell script that expects to process the standard input. For more information about I/O logging, see the **I/O LOG FILES** section. This flag is *off* by default.

`log_output`

If set, `sudo` will run the command in a pseudo-terminal and log all output that is sent to the screen, similar to the `script(1)` command. For more information about I/O logging, see the **I/O LOG FILES** section. This flag is *off* by default.

`log_server_keepalive`

If set, `sudo` will enable the TCP keepalive socket option on the connection to the log server. This enables the periodic transmission of keepalive messages to the server. If the server does not respond to a message, the connection will be closed and the running command will be terminated unless the `ignore_iolog_errors` flag (I/O logging enabled) or the `ignore_log_errors` flag (I/O logging disabled) is set. This flag is *on* by default.

	This setting is only supported by version 1.9.0 or higher.
log_server_verify	If set, the server certificate received during the TLS handshake must be valid and it must contain either the server name (from <i>log_servers</i>) or its IP address. If either of these conditions is not met, the TLS handshake will fail. This flag is <i>on</i> by default.
	This setting is only supported by version 1.9.0 or higher.
log_subcmds	If set, sudoers will log when a command spawns a child process and executes a program using the exec1() , execle() , execlp() , execv() , execve() , execvp() , or execvpe() library functions. For example, if a shell is run by sudo , the individual commands run via the shell will be logged. This flag is <i>off</i> by default.
	The <i>log_subcmds</i> flag uses the same underlying mechanism as the <i>intercept</i> setting. See Preventing shell escapes for more information on what systems support this option and its limitations. This setting is only supported by version 1.9.8 or higher and is incompatible with SELinux RBAC support.
log_year	If set, the four-digit year will be logged in the (non-syslog) sudo log file. This flag is <i>off</i> by default.
long_otp_prompt	When validating with a One Time Password (OTP) scheme such as S/Key or OPIE , a two-line prompt is used to make it easier to cut and paste the challenge to a local window. It's not as pretty as the default but some people find it more convenient. This flag is <i>off</i> by default.
mail_all_cmnds	Send mail to the <i>mailto</i> user every time a user attempts to run a command via sudo (this includes sudoedit). No mail will be sent if the user runs sudo with the -l or -v option unless there is an authentication error and the <i>mail_badpass</i> flag is also set. This flag is <i>off</i> by default.
mail_always	Send mail to the <i>mailto</i> user every time a user runs sudo . This flag is <i>off</i> by default.
mail_badpass	Send mail to the <i>mailto</i> user if the user running sudo does not enter the correct password. If the command the user is attempting to run is not permitted by sudoers and one of the <i>mail_all_cmnds</i> , <i>mail_always</i> , <i>mail_no_host</i> , <i>mail_no_perms</i> or <i>mail_no_user</i> flags are set, this flag will have no effect. This flag is <i>off</i> by default.
mail_no_host	If set, mail will be sent to the <i>mailto</i> user if the invoking user exists in the <i>sudoers</i> file, but is not allowed to run commands on the current host. This flag is <i>off</i> by default.
mail_no_perms	If set, mail will be sent to the <i>mailto</i> user if the invoking user is allowed to use sudo but the command they are trying is not listed in their <i>sudoers</i> file entry or is explicitly denied. This flag is <i>off</i> by default.
mail_no_user	If set, mail will be sent to the <i>mailto</i> user if the invoking user is not in the <i>sudoers</i> file. This flag is <i>on</i> by default.
match_group_by_gid	By default, sudoers will look up each group the user is a member of by group-ID to determine the group name (this is only done once). The resulting list of the user's group names is used when matching groups listed in the <i>sudoers</i> file. This works well on systems where the number of groups listed in the <i>sudoers</i> file is larger than the number of groups a typical user belongs to. On systems where group lookups are slow, where users may belong to a large number of groups, and where the number of groups listed in the <i>sudoers</i> file is relatively small, it may be prohibitively expensive and running commands via sudo may take longer than normal. On such systems it may be faster to use the <i>match_group_by_gid</i> flag to avoid resolving the user's group-IDs to

group names. In this case, ***sudoers*** must look up any group name listed in the *sudoers* file and use the group-ID instead of the group name when determining whether the user is a member of the group.

Note that if *match_group_by_gid* is enabled, group database lookups performed by ***sudoers*** will be keyed by group name as opposed to group-ID. On systems where there are multiple sources for the group database, it is possible to have conflicting group names or group-IDs in the local */etc/group* file and the remote group database. On such systems, enabling or disabling *match_group_by_gid* can be used to choose whether group database queries are performed by name (enabled) or ID (disabled), which may aid in working around group entry conflicts.

The *match_group_by_gid* flag has no effect when *sudoers* data is stored in LDAP. This flag is *off* by default.

This setting is only supported by version 1.8.18 or higher.

intercept

If set, all commands run via ***sudo*** will behave as if the *INTERCEPT* tag has been set, unless overridden by an *NOINTERCEPT* tag. See the description of *INTERCEPT* and *NOINTERCEPT* above as well as the **Preventing shell escapes** section at the end of this manual. This flag is *off* by default.

This setting is only supported by version 1.9.8 or higher and is incompatible with SELinux RBAC support.

intercept_allow_setid

On most systems, the dynamic loader will ignore *LD_PRELOAD* (or the equivalent) when running set-user-ID and set-group-ID programs, effectively disabling intercept mode. To prevent this from happening, ***sudoers*** will not permit a set-user-ID or set-group-ID program to be run in intercept mode unless *intercept_allow_setid* is set. This flag has no effect unless the *intercept* flag is enabled or the *INTERCEPT* tag has been set for the command. This flag is *on* by default.

This setting is only supported by version 1.9.8 or higher.

intercept_authenticate

If set, commands run by an intercepted process must be authenticated when the user's time stamp is not current. For example, if a shell is run with *intercept* enabled, as soon as the invoking user's time stamp is out of date, subsequent commands will need to be authenticated. This flag has no effect unless the *intercept* flag is enabled or the *INTERCEPT* tag has been set for the command. This flag is *off* by default.

This setting is only supported by version 1.9.8 or higher.

netgroup_tuple

If set, netgroup lookups will be performed using the full netgroup tuple: host name, user name, and domain (if one is set). Historically, ***sudo*** only matched the user name and domain for netgroups used in a *User_List* and only matched the host name and domain for netgroups used in a *Host_List*. This flag is *off* by default.

noexec

If set, all commands run via ***sudo*** will behave as if the *NOEXEC* tag has been set, unless overridden by an *EXEC* tag. See the description of *EXEC* and *NOEXEC* above as well as the **Preventing shell escapes** section at the end of this manual. This flag is *off* by default.

pam_acct_mgmt

On systems that use PAM for authentication, ***sudo*** will perform PAM account validation for the invoking user by default. The actual checks performed depend on which PAM modules are configured. If enabled, account validation will be performed regardless of whether or not a password is required. This flag is *on* by default.

	This setting is only supported by version 1.8.28 or higher.
pam_rhost	On systems that use PAM for authentication, sudo will set the PAM remote host value to the name of the local host when the <i>pam_rhost</i> flag is enabled. On Linux systems, enabling <i>pam_rhost</i> may result in DNS lookups of the local host name when PAM is initialized. On Solaris versions prior to Solaris 8, <i>pam_rhost</i> must be enabled if <i>pam_ruser</i> is also enabled to avoid a crash in the Solaris PAM implementation. This flag is <i>off</i> by default on systems other than Solaris.
	This setting is only supported by version 1.9.0 or higher.
pam_ruser	On systems that use PAM for authentication, sudo will set the PAM remote user value to the name of the user that invoked sudo when the <i>pam_ruser</i> flag is enabled. This flag is <i>on</i> by default. This setting is only supported by version 1.9.0 or higher.
pam_session	On systems that use PAM for authentication, sudo will create a new PAM session for the command to be run in. Unless sudo is given the -i or -s options, PAM session modules are run with the “silent” flag enabled. This prevents last login information from being displayed for every command on some systems. Disabling <i>pam_session</i> may be needed on older PAM implementations or on operating systems where opening a PAM session changes the utmp or wtmp files. If PAM session support is disabled, resource limits may not be updated for the command being run. If <i>pam_session</i> , <i>pam_setcred</i> , and <i>use_pty</i> are disabled, <i>log_servers</i> has not been set and I/O logging has not been configured, sudo will execute the command directly instead of running it as a child process. This flag is <i>on</i> by default. This setting is only supported by version 1.8.7 or higher.
pam_setcred	On systems that use PAM for authentication, sudo will attempt to establish credentials for the target user by default, if supported by the underlying authentication system. One example of a credential is a Kerberos ticket. If <i>pam_session</i> , <i>pam_setcred</i> , and <i>use_pty</i> are disabled, <i>log_servers</i> has not been set and I/O logging has not been configured, sudo will execute the command directly instead of running it as a child process. This flag is <i>on</i> by default. This setting is only supported by version 1.8.8 or higher.
passprompt_override	If set, the prompt specified by <i>passprompt</i> or the SUDO_PROMPT environment variable will always be used and will replace the prompt provided by a PAM module or other authentication method. This flag is <i>off</i> by default.
path_info	Normally, sudo will tell the user when a command could not be found in their PATH environment variable. Some sites may wish to disable this as it could be used to gather information on the location of executables that the normal user does not have access to. The disadvantage is that if the executable is simply not in the user’s PATH, sudo will tell the user that they are not allowed to run it, which can be confusing. This flag is <i>on</i> by default.
preserve_groups	By default, sudo will initialize the group vector to the list of groups the target user is in. When <i>preserve_groups</i> is set, the user’s existing group vector is left unaltered. The real and effective group-IDs, however, are still set to match the target user. This flag is <i>off</i> by default.

pwfeedback	By default, sudo reads the password like most other Unix programs, by turning off echo until the user hits the return (or enter) key. Some users become confused by this as it appears to them that sudo has hung at this point. When <i>pwfeedback</i> is set, sudo will provide visual feedback when the user presses a key. Note that this does have a security impact as an onlooker may be able to determine the length of the password being entered. This flag is <i>off</i> by default.
requiretty	If set, sudo will only run when the user is logged in to a real tty. When this flag is set, sudo can only be run from a login session and not via other means such as cron(8) or cgi-bin scripts. This flag is <i>off</i> by default.
root_sudo	If set, root is allowed to run sudo too. Disabling this prevents users from “chaining” sudo commands to get a root shell by doing something like “ sudo sudo /bin/sh ”. Note, however, that turning off <i>root_sudo</i> will also prevent root from running sudoedit . Disabling <i>root_sudo</i> provides no real additional security; it exists purely for historical reasons. This flag is <i>on</i> by default.
rootpw	If set, sudo will prompt for the root password instead of the password of the invoking user when running a command or editing a file. This flag is <i>off</i> by default.
runas_allow_unknown_id	If enabled, allow matching of runas user and group IDs that are not present in the password or group databases. In addition to explicitly matching unknown user or group IDs in a Runas_List, this option also allows the ALL alias to match unknown IDs. This flag is <i>off</i> by default. This setting is only supported by version 1.8.30 or higher. Older versions of sudo always allowed matching of unknown user and group IDs.
runas_check_shell	If enabled, sudo will only run commands as a user whose shell appears in the <i>/etc/shells</i> file, even if the invoking user’s Runas_List would otherwise permit it. If no <i>/etc/shells</i> file is present, a system-dependent list of built-in default shells is used. On many operating systems, system users such as “bin”, do not have a valid shell and this flag can be used to prevent commands from being run as those users. This flag is <i>off</i> by default. This setting is only supported by version 1.8.30 or higher.
runaspw	If set, sudo will prompt for the password of the user defined by the <i>runas_default</i> option (defaults to <i>root</i>) instead of the password of the invoking user when running a command or editing a file. This flag is <i>off</i> by default.
selinux	If enabled, the user may specify an SELinux role and/or type to use when running the command, as permitted by the SELinux policy. If SELinux is disabled on the system, this flag has no effect. This flag is <i>on</i> by default.
set_home	If enabled and sudo is invoked with the -s option, the HOME environment variable will be set to the home directory of the target user (which is the root user unless the -u option is used). This flag is largely obsolete and has no effect unless the <i>env_reset</i> flag has been disabled or HOME is present in the <i>env_keep</i> list, both of which are strongly discouraged. This flag is <i>off</i> by default.
set_logname	Normally, sudo will set the LOGNAME and USER environment variables to the name of the target user (usually root unless the -u option is given). However, since some programs (including the RCS revision control system) use LOGNAME to determine the real identity of the user, it may be desirable to change this behavior. This can be done by negating the <i>set_logname</i> option. Note that <i>set_logname</i> will have no effect if the

	<i>env_reset</i> option has not been disabled and the <i>env_keep</i> list contains LOGNAME or USER. This flag is <i>on</i> by default.
set_utmp	When enabled, sudo will create an entry in the utmp (or utmpx) file when a pseudo-terminal is allocated. A pseudo-terminal is allocated by sudo when it is running in a terminal and one or more of the <i>log_input</i> , <i>log_output</i> , or <i>use_pty</i> flags is enabled. By default, the new entry will be a copy of the user's existing utmp entry (if any), with the tty, time, type, and pid fields updated. This flag is <i>on</i> by default.
setenv	Allow the user to disable the <i>env_reset</i> option from the command line via the -E option. Additionally, environment variables set via the command line are not subject to the restrictions imposed by <i>env_check</i> , <i>env_delete</i> , or <i>env_keep</i> . As such, only trusted users should be allowed to set variables in this manner. This flag is <i>off</i> by default.
shell_noargs	If set and sudo is invoked with no arguments it acts as if the -s option had been given. That is, it runs a shell as root (the shell is determined by the <i>SHELL</i> environment variable if it is set, falling back on the shell listed in the invoking user's /etc/passwd entry if not). This flag is <i>off</i> by default.
stay_setuid	Normally, when sudo executes a command the real and effective user-IDs are set to the target user (root by default). This option changes that behavior such that the real user-ID is left as the invoking user's user-ID. In other words, this makes sudo act as a set-user-ID wrapper. This can be useful on systems that disable some potentially dangerous functionality when a program is run set-user-ID. This option is only effective on systems that support either the <i>setreuid(2)</i> or <i>setresuid(2)</i> system call. This flag is <i>off</i> by default.
sudoedit_checkdir	If set, sudoedit will check all directory components of the path to be edited for writability by the invoking user. Symbolic links will not be followed in writable directories and sudoedit will refuse to edit a file located in a writable directory. These restrictions are not enforced when sudoedit is run by root. On some systems, if all directory components of the path to be edited are not readable by the target user, sudoedit will be unable to edit the file. This flag is <i>on</i> by default. This setting was first introduced in version 1.8.15 but initially suffered from a race condition. The check for symbolic links in writable intermediate directories was added in version 1.8.16.
sudoedit_follow	By default, sudoedit will not follow symbolic links when opening files. The <i>sudoedit_follow</i> option can be enabled to allow sudoedit to open symbolic links. It may be overridden on a per-command basis by the <i>FOLLOW</i> and <i>NOFOLLOW</i> tags. This flag is <i>off</i> by default. This setting is only supported by version 1.8.15 or higher.
syslog_pid	When logging via <i>syslog(3)</i> , include the process ID in the log entry. This flag is <i>off</i> by default.
	This setting is only supported by version 1.8.21 or higher.
targetpw	If set, sudo will prompt for the password of the user specified by the -u option (defaults to <i>root</i>) instead of the password of the invoking user when running a command or editing a file. Note that this flag precludes the use of a user-ID not listed in the passwd database as an argument to the -u option. This flag is <i>off</i> by default.
tty_tickets	If set, users must authenticate on a per-tty basis. With this flag enabled, sudo will use a separate record in the time stamp file for each terminal. If disabled, a single record is used for all login sessions.

	This option has been superseded by the <i>timestamp_type</i> option.
umask_override	If set, sudo will set the umask as specified in the <i>sudoers</i> file without modification. This makes it possible to specify a umask in the <i>sudoers</i> file that is more permissive than the user's own umask and matches historical behavior. If <i>umask_override</i> is not set, sudo will set the umask to be the union of the user's umask and what is specified in <i>sudoers</i> . This flag is <i>off</i> by default.
use_netgroups	If set, netgroups (prefixed with '+'), may be used in place of a user or host. For LDAP-based sudoers, netgroup support requires an expensive sub-string match on the server unless the NETGROUP_BASE directive is present in the <i>/etc/ldap.conf</i> file. If netgroups are not needed, this option can be disabled to reduce the load on the LDAP server. This flag is <i>on</i> by default.
use_pty	If set, and sudo is running in a terminal, the command will be run in a pseudo-terminal (even if no I/O logging is being done). If the sudo process is not attached to a terminal, <i>use_pty</i> has no effect.
	A malicious program run under sudo may be capable of injecting commands into the user's terminal or running a background process that retains access to the user's terminal device even after the main program has finished executing. By running the command in a separate pseudo-terminal, this attack is no longer possible. This flag is <i>off</i> by default.
user_command_timeouts	If set, the user may specify a timeout on the command line. If the timeout expires before the command has exited, the command will be terminated. If a timeout is specified both in the <i>sudoers</i> file and on the command line, the smaller of the two timeouts will be used. See the Timeout_Spec section for a description of the timeout syntax. This flag is <i>off</i> by default.
	This setting is only supported by version 1.8.20 or higher.
utmp_runas	If set, sudo will store the name of the runas user when updating the utmp (or utmpx) file. By default, sudo stores the name of the invoking user. This flag is <i>off</i> by default.
visiblepw	By default, sudo will refuse to run if the user must enter a password but it is not possible to disable echo on the terminal. If the <i>visiblepw</i> flag is set, sudo will prompt for a password even when it would be visible on the screen. This makes it possible to run things like "ssh somehost sudo ls" since by default, ssh(1) does not allocate a tty when running a command. This flag is <i>off</i> by default.
Integers:	
closefrom	Before it executes a command, sudo will close all open file descriptors other than standard input, standard output, and standard error (file descriptors 0-2). The <i>closefrom</i> option can be used to specify a different file descriptor at which to start closing. The default is 3.
command_timeout	The maximum amount of time a command is allowed to run before it is terminated. See the Timeout_Spec section for a description of the timeout syntax.
	This setting is only supported by version 1.8.20 or higher.
log_server_timeout	The maximum amount of time to wait when connecting to a log server or waiting for a server response. See the Timeout_Spec section for a description of the timeout syntax. The default value is 30 seconds.

	This setting is only supported by version 1.9.0 or higher.
maxseq	The maximum sequence number that will be substituted for the “%{seq}” escape in the I/O log file (see the <i>iolog_dir</i> description below for more information). While the value substituted for “%{seq}” is in base 36, <i>maxseq</i> itself should be expressed in decimal. Values larger than 2176782336 (which corresponds to the base 36 sequence number “ZZZZZZ”) will be silently truncated to 2176782336. The default value is 2176782336.
	Once the local sequence number reaches the value of <i>maxseq</i> , it will “roll over” to zero, after which sudoers will truncate and re-use any existing I/O log path names.
	This setting is only supported by version 1.8.7 or higher.
passwd_tries	The number of tries a user gets to enter his/her password before sudo logs the failure and exits. The default is 3.
syslog_maxlen	On many systems, <i>syslog</i> (3) has a relatively small log buffer. IETF RFC 5424 states that syslog servers must support messages of at least 480 bytes and should support messages up to 2048 bytes. By default, sudoers creates log messages up to 980 bytes which corresponds to the historic BSD syslog implementation which used a 1024 byte buffer to store the message, date, hostname, and program name. To prevent syslog messages from being truncated, sudoers will split up log messages that are larger than <i>syslog_maxlen</i> bytes. When a message is split, additional parts will include the string “(command continued)” after the user name and before the continued command line arguments.
	This setting is only supported by version 1.8.19 or higher.
Integers that can be used in a boolean context:	
loglinelen	Number of characters per line for the file log. This value is used to decide when to wrap lines for nicer log files. This has no effect on the syslog log file, only the file log. The default is 80 (use 0 or negate the option to disable word wrap).
passwd_timeout	Number of minutes before the sudo password prompt times out, or 0 for no timeout. The timeout may include a fractional component if minute granularity is insufficient, for example 2.5. The default is 0.
timestamp_timeout	Number of minutes that can elapse before sudo will ask for a passwd again. The timeout may include a fractional component if minute granularity is insufficient, for example 2.5. The default is 15. Set this to 0 to always prompt for a password. If set to a value less than 0 the user’s time stamp will not expire until the system is rebooted. This can be used to allow users to create or delete their own time stamps via “ sudo -v ” and “ sudo -k ” respectively.
umask	File mode creation mask to use when running the command. Negate this option or set it to 0777 to prevent sudoers from changing the umask. Unless the <i>umask_override</i> flag is set, the actual umask will be the union of the user’s umask and the value of the <i>umask</i> setting, which defaults to 0022. This guarantees that sudo never lowers the umask when running a command.
	If <i>umask</i> is explicitly set in <i>sudoers</i> , it will override any umask setting in PAM or login.conf. If <i>umask</i> is not set in <i>sudoers</i> , the umask specified by PAM or login.conf will take precedence. The umask setting in PAM is not used for sudoedit , which does not create a new PAM session.

Strings:

authfail_message	Message that is displayed after a user fails to authenticate. The message may include the ‘%d’ escape which will expand to the number of failed password attempts. If set, it overrides the default message, %d incorrect password attempt(s).
badpass_message	Message that is displayed if a user enters an incorrect password. The default is Sorry, try again.unless insults are enabled.
editor	A colon (‘:’) separated list of editors path names used by sudoedit and visudo . For sudoedit , this list is used to find an editor when none of the SUDO_EDITOR, VISUAL or EDITOR environment variables are set to an editor that exists and is executable. For visudo , it is used as a white list of allowed editors; visudo will choose the editor that matches the user’s SUDO_EDITOR, VISUAL or EDITOR environment variable if possible, or the first editor in the list that exists and is executable if not. Unless invoked as sudoedit , sudo does not preserve the SUDO_EDITOR, VISUAL or EDITOR environment variables unless they are present in the <i>env_keep</i> list or the <i>env_reset</i> option is disabled. The default is /usr/bin/editor.
ilog_dir	The top-level directory to use when constructing the path name for the input/output log directory. Only used if the <i>log_input</i> or <i>log_output</i> options are enabled or when the LOG_INPUT or LOG_OUTPUT tags are present for a command. The session sequence number, if any, is stored in the directory. The default is /var/log/sudo-io. The following percent (‘%’) escape sequences are supported: %{seq} expanded to a monotonically increasing base-36 sequence number, such as 0100A5, where every two digits are used to form a new directory, e.g., 01/00/A5 %{user} expanded to the invoking user’s login name %{group} expanded to the name of the invoking user’s real group-ID %{runas_user} expanded to the login name of the user the command will be run as (e.g., root) %{runas_group} expanded to the group name of the user the command will be run as (e.g., wheel) %{hostname} expanded to the local host name without the domain name %{command} expanded to the base name of the command being run In addition, any escape sequences supported by the system’s strftime(3) function will be expanded. To include a literal ‘%’ character, the string ‘%%’ should be used. ilog_file The path name, relative to <i>ilog_dir</i> , in which to store input/output logs when the <i>log_input</i> or <i>log_output</i> options are enabled or when the LOG_INPUT or LOG_OUTPUT tags are present for a command. Note that <i>ilog_file</i> may contain directory components. The default is “%{seq}”.

	See the <i>iolog_dir</i> option above for a list of supported percent ('%') escape sequences. In addition to the escape sequences, path names that end in six or more Xs will have the Xs replaced with a unique combination of digits and letters, similar to the <code>mktemp(3)</code> function.
<i>iolog_flush</i>	If the path created by concatenating <i>iolog_dir</i> and <i>iolog_file</i> already exists, the existing I/O log file will be truncated and overwritten unless <i>iolog_file</i> ends in six or more Xs.
<i>iolog_group</i>	If set, sudo will flush I/O log data to disk after each write instead of buffering it. This makes it possible to view the logs in real-time as the program is executing but may significantly reduce the effectiveness of I/O log compression. This flag is <i>off</i> by default.
	This setting is only supported by version 1.8.20 or higher.
<i>iolog_mode</i>	The group name to look up when setting the group-ID on new I/O log files and directories. If <i>iolo g_group</i> is not set, the primary group-ID of the user specified by <i>iolog_user</i> is used. If neither <i>iolog_group</i> nor <i>iolog_user</i> are set, I/O log files and directories are created with group-ID 0.
	This setting is only supported by version 1.8.19 or higher.
<i>iolog_user</i>	The file mode to use when creating I/O log files. Mode bits for read and write permissions for owner, group, or other are honored, everything else is ignored. The file permissions will always include the owner read and write bits, even if they are not present in the specified mode. When creating I/O log directories, search (execute) bits are added to match the read and write bits specified by <i>iolog_mode</i> . Defaults to 0600 (read and write by user only).
	This setting is only supported by version 1.8.19 or higher.
<i>lecture_status_dir</i>	The user name to look up when setting the user and group-IDs on new I/O log files and directories. If <i>iolo g_group</i> is set, it will be used instead of the user's primary group-ID. By default, I/O log files and directories are created with user and group-ID 0.
	This setting can be useful when the I/O logs are stored on a Network File System (NFS) share. Having a dedicated user own the I/O log files means that sudoers does not write to the log files as user-ID 0, which is usually not permitted by NFS.
	This setting is only supported by version 1.8.19 or higher.
<i>log_server_cabundle</i>	The directory in which sudo stores per-user lecture status files. Once a user has received the lecture, a zero-length file is created in this directory so that sudo will not lecture the user again. This directory should not be cleared when the system reboots. The default is <code>/var/lib/sudo/lectured</code> .
	The path to a certificate authority bundle file, in PEM format, to use instead of the system's default certificate authority database when authenticating the log server. The default is to use the system's default certificate authority database. This setting has no effect unless <i>log_servers</i> is set and the remote log server is secured with TLS.
	This setting is only supported by version 1.9.0 or higher.
<i>log_server_peer_cert</i>	The path to the sudo client's certificate file, in PEM format. This setting is required when the remote log server is secured with TLS and client certificate validation is enabled. For sudo_logsvrd , client certificate validation is controlled by the <i>tls_checkpeer</i> option, which defaults to <i>false</i> .

This setting is only supported by version 1.9.0 or higher.

log_server_peer_key

The path to the **sudo** client's private key file, in PEM format. This setting is required when the remote log server is secured with TLS and client certificate validation is enabled. For **sudo_logsvrd**, client certificate validation is controlled by the *tls_checkpeer* option, which defaults to *false*.

This setting is only supported by version 1.9.0 or higher.

mailsub

Subject of the mail sent to the *mailto* user. The escape%*h* will expand to the host name of the machine. Default is “*** SECURITY information for %*h* ***”.

noexec_file

As of **sudo** version 1.8.1 this option is no longer supported. The path to the noexec file should now be set in the **sudo.conf(5)** file.

pam_askpass_service

On systems that use PAM for authentication, this is the service name used when the **-A** option is specified. The default value is either “@pam_service@” or “**sudo-i**”, depending on whether or not the **-i** option is also specified. See the description of **pam_service** for more information.

This setting is only supported by version 1.9.9 or higher.

pam_login_service

On systems that use PAM for authentication, this is the service name used when the **-i** option is specified. The default value is “**sudo-i**”. See the description of **pam_service** for more information.

This setting is only supported by version 1.8.8 or higher.

pam_service

On systems that use PAM for authentication, the service name specifies the PAM policy to apply. This usually corresponds to an entry in the **pam.conf** file or a file in the **/etc/pam.d** directory. The default value is “**sudo**”.

This setting is only supported by version 1.8.8 or higher.

passprompt

The default prompt to use when asking for a password; can be overridden via the **-p** option or the **SUDO_PROMPT** environment variable. The following percent ('%') escape sequences are supported:

%H expanded to the local host name including the domain name (only if the machine's host name is fully qualified or the *fqdn* option is set)

%h expanded to the local host name without the domain name

%p expanded to the user whose password is being asked for (respects the *rootpw*, *targetpw* and *runaspw* flags in **sudoers**)

%U expanded to the login name of the user the command will be run as (defaults to root)

%u expanded to the invoking user's login name

%% two consecutive % characters are collapsed into a single % character

On systems that use PAM for authentication, *passprompt* will only be used if the prompt provided by the PAM module matches the string “Password: ” or “username's Password: ”. This ensures that the *passprompt* setting does not interfere with challenge-response style authentication. The *passprompt_override* flag can be used to change this behavior.

	The default value is “[sudo] password for %p: ”.
role	The default SELinux role to use when constructing a new security context to run the command. The default role may be overridden on a per-command basis in the <i>sudoers</i> file or via command line options. This option is only available when sudo is built with SELinux support.
runas_default	The default user to run commands as if the -u option is not specified on the command line. This defaults to <code>root</code> .
sudoers_locale	Locale to use when parsing the sudoers file, logging commands, and sending email. Note that changing the locale may affect how sudoers is interpreted. Defaults to “C”.
timestamp_type	sudoers uses per-user time stamp files for credential caching. The <i>timestamp_type</i> option can be used to specify the type of time stamp record used. It has the following possible values:
global	A single time stamp record is used for all of a user’s login sessions, regardless of the terminal or parent process ID. An additional record is used to serialize password prompts when sudo is used multiple times in a pipeline, but this does not affect authentication.
ppid	A single time stamp record is used for all processes with the same parent process ID (usually the shell). Commands run from the same shell (or other common parent process) will not require a password for <i>timestamp_timeout</i> minutes (15 by default). Commands run via sudo with a different parent process ID, for example from a shell script, will be authenticated separately.
tty	One time stamp record is used for each terminal, which means that a user’s login sessions are authenticated separately. If no terminal is present, the behavior is the same as <i>ppid</i> . Commands run from the same terminal will not require a password for <i>timestamp_timeout</i> minutes (15 by default).
kernel	The time stamp is stored in the kernel as an attribute of the terminal device. If no terminal is present, the behavior is the same as <i>ppid</i> . Negative <i>timestamp_timeout</i> values are not supported and positive values are limited to a maximum of 60 minutes. This is currently only supported on OpenBSD.
	The default value is <code>tty</code> .
	This setting is only supported by version 1.8.21 or higher.
timestampdir	The directory in which sudo stores its time stamp files. This directory should be cleared when the system reboots. The default is <code>/run/sudo/ts</code> .
timestampowner	The owner of the lecture status directory, time stamp directory and all files stored therein. The default is <code>root</code> .
type	The default SELinux type to use when constructing a new security context to run the command. The default type may be overridden on a per-command basis in the <i>sudoers</i> file or via command line options. This option is only available when sudo is built with SELinux support.

Strings that can be used in a boolean context:

admin_flag	The <i>admin_flag</i> option specifies the path to a file that is created the first time a user that is a member of the <i>sudo</i> or <i>admin</i> groups runs sudo . Only available if sudo is configured with the <code>--enable-admin-flag</code> option. The default value is <code>~/.sudo_as_admin_successful</code> .
------------	---

env_file	The <i>env_file</i> option specifies the fully qualified path to a file containing variables to be set in the environment of the program being run. Entries in this file should either be of the form “VARIABLE=value” or “export VARIABLE=value”. The value may optionally be enclosed in single or double quotes. Variables in this file are only added if the variable does not already exist in the environment. This file is considered to be part of the security policy, its contents are not subject to other sudo environment restrictions such as <i>env_keep</i> and <i>env_check</i> .
exempt_group	Users in this group are exempt from password and PATH requirements. The group name specified should not include a % prefix. This is not set by default.
fdexec	Determines whether sudo will execute a command by its path or by an open file descriptor. It has the following possible values: always Always execute by file descriptor. never Never execute by file descriptor. digest_only Only execute by file descriptor if the command has an associated digest in the <i>sudoers</i> file. The default value is <i>digest_only</i> . This avoids a time of check versus time of use race condition when the command is located in a directory writable by the invoking user. Note that <i>fdexec</i> will change the first element of the argument vector for scripts (\$0 in the shell) due to the way the kernel runs script interpreters. Instead of being a normal path, it will refer to a file descriptor. For example, /dev/fd/4 on Solaris and /proc/self/fd/4 on Linux. A workaround is to use the SUDO_COMMAND environment variable instead. The <i>fdexec</i> setting is only used when the command is matched by path name. It has no effect if the command is matched by the built-in ALL alias. This setting is only supported by version 1.8.20 or higher. If the operating system does not support the fexecve() system call, this setting has no effect.
group_plugin	A string containing a sudoers group plugin with optional arguments. The string should consist of the plugin path, either fully-qualified or relative to the /usr/libexec/sudo directory, followed by any configuration arguments the plugin requires. These arguments (if any) will be passed to the plugin’s initialization function. If arguments are present, the string must be enclosed in double quotes (""). For more information see GROUP PROVIDER PLUGINS .
lecture	This option controls when a short lecture will be printed along with the password prompt. It has the following possible values: always Always lecture the user. never Never lecture the user. once Only lecture the user the first time they run sudo . If no value is specified, a value of <i>once</i> is implied. Negating the option results in a value of <i>never</i> being used. The default value is <i>never</i> .
lecture_file	Path to a file containing an alternate sudo lecture that will be used in place of the standard lecture if the named file exists. By default, sudo uses a built-in lecture.

listpw	This option controls when a password will be required when a user runs sudo with the -l option. It has the following possible values:
all	All the user's <i>sudoers</i> file entries for the current host must have the NOPASSWD flag set to avoid entering a password.
always	The user must always enter a password to use the -l option.
any	At least one of the user's <i>sudoers</i> file entries for the current host must have the NOPASSWD flag set to avoid entering a password.
never	The user need never enter a password to use the -l option.
	If no value is specified, a value of <i>any</i> is implied. Negating the option results in a value of <i>never</i> being used. The default value is <i>any</i> .
log_format	The event log format. Supported log formats are:
json	Logs in JSON format. JSON log entries contain the full user details as well as the execution environment if the command was allowed. Due to limitations of the protocol, JSON events sent via <i>syslog</i> may be truncated.
sudo	Traditional sudo-style logs, see LOG FORMAT for a description of the log file format.
	This setting affects logs sent via <i>syslog(3)</i> as well as the file specified by the <i>logfile</i> setting, if any. The default value is <i>sudo</i> .
logfile	Path to the sudo log file (not the syslog log file). Setting a path turns on logging to a file; negating this option turns it off. By default, sudo logs via syslog.
mailerflags	Flags to use when invoking mailer. Defaults to -t .
mailerpath	Path to mail program used to send warning mail. Defaults to the path to sendmail found at configure time.
mailfrom	Address to use for the "from" address when sending warning and error mail. The address should be enclosed in double quotes ("") to protect against sudo interpreting the @ sign. Defaults to the name of the user running sudo .
mailto	Address to send warning and error mail to. The address should be enclosed in double quotes ("") to protect against sudo interpreting the @ sign. Defaults to root .
rlimit_as	The maximum size to which the process's address space may grow (in bytes), if supported by the operating system. See Resource limits for more information.
rlimit_core	The largest size core dump file that may be created (in bytes). See Resource limits for more information. Defaults to 0 (no core dump created).
rlimit_cpu	The maximum amount of CPU time that the process may use (in seconds). See Resource limits for more information.
rlimit_data	The maximum size of the data segment for the process (in bytes). See Resource limits for more information.
rlimit_fsize	The largest size file that the process may create (in bytes). See Resource limits for more information.
rlimit_locks	The maximum number of locks that the process may establish, if supported by the operating system. See Resource limits for more information.

rlimit_memlock

The maximum size that the process may lock in memory (in bytes), if supported by the operating system. See **Resource limits** for more information.

rlimit_nofile

The maximum number of files that the process may have open. See **Resource limits** for more information.

rlimit_nproc

The maximum number of processes that the user may run simultaneously. See **Resource limits** for more information.

rlimit_rss

The maximum size to which the process's resident set size may grow (in bytes). See **Resource limits** for more information.

rlimit_stack

The maximum size to which the process's stack may grow (in bytes). See **Resource limits** for more information.

restricted_env_file

The *restricted_env_file* option specifies the fully qualified path to a file containing variables to be set in the environment of the program being run. Entries in this file should either be of the form “`VARIABLE=value`” or “`export VARIABLE=value`”. The value may optionally be enclosed in single or double quotes. Variables in this file are only added if the variable does not already exist in the environment. Unlike *env_file*, the file's contents are not trusted and are processed in a manner similar to that of the invoking user's environment. If *env_reset* is enabled, variables in the file will only be added if they are matched by either the *env_check* or *env_keep* list. If *env_reset* is disabled, variables in the file are added as long as they are not matched by the *env_delete* list. In either case, the contents of *restricted_env_file* are processed before the contents of *env_file*.

runchroot

If set, **sudo** will use this value for the root directory when running a command. The special value “`*`” will allow the user to specify the root directory via **sudo**'s **-R** option. See the **Chroot_Spec** section for more details.

It is only possible to use *runchroot* as a command-specific Defaults setting if the command exists with the same path both inside and outside the chroot jail. This restriction does not apply to generic, host, or user-based Defaults settings or to a *Cmnd_Spec* that includes a *Chroot_Spec*.

This setting is only supported by version 1.9.3 or higher.

runcwd

If set, **sudo** will use this value for the working directory when running a command. The special value “`*`” will allow the user to specify the working directory via **sudo**'s **-D** option. See the **Chdir_Spec** section for more details.

This setting is only supported by version 1.9.3 or higher.

secure_path

If set, **sudo** will use this value in place of the user's PATH environment variable. This option can be used to reset the PATH to a known good value that contains directories for system administrator commands such as `/usr/sbin`.

Users in the group specified by the *exempt_group* option are not affected by *secure_path*. This option is not set by default.

syslog

Syslog facility if syslog is being used for logging (negate to disable syslog logging). Defaults to authpriv.

The following syslog facilities are supported: **authpriv** (if your OS supports it), **auth**, **daemon**, **user**, **local0**, **local1**, **local2**, **local3**, **local4**, **local5**, **local6**, and **local7**.

syslog_badpri Syslog priority to use when the user is not allowed to run a command or when authentication is unsuccessful. Defaults to **alert**.

The following syslog priorities are supported: **alert**, **crit**, **debug**, **emerg**, **err**, **info**, **notice**, **warning**, and **none**. Negating the option or setting it to a value of **none** will disable logging of unsuccessful commands.

syslog_goodpri

Syslog priority to use when the user is allowed to run a command and authentication is successful. Defaults to **notice**.

See *syslog_badpri* for the list of supported syslog priorities. Negating the option or setting it to a value of **none** will disable logging of successful commands.

verifypw

This option controls when a password will be required when a user runs **sudo** with the **-v** option. It has the following possible values:

- all** All the user's *sudoers* file entries for the current host must have the NOPASSWD flag set to avoid entering a password.
- always** The user must always enter a password to use the **-v** option.
- any** At least one of the user's *sudoers* file entries for the current host must have the NOPASSWD flag set to avoid entering a password.
- never** The user need never enter a password to use the **-v** option.

If no value is specified, a value of *all* is implied. Negating the option results in a value of *never* being used. The default value is *all*.

Lists that can be used in a boolean context:

env_check

Environment variables to be removed from the user's environment unless they are considered "safe". For all variables except TZ, "safe" means that the variable's value does not contain any '%' or '/' characters. This can be used to guard against printf-style format vulnerabilities in poorly-written programs. The TZ variable is considered unsafe if any of the following are true:

- It consists of a fully-qualified path name, optionally prefixed with a colon (':'), that does not match the location of the *zoneinfo* directory.
- It contains a . . path element.
- It contains white space or non-printable characters.
- It is longer than the value of PATH_MAX.

The argument may be a double-quoted, space-separated list or a single value without double-quotes. The list can be replaced, added to, deleted from, or disabled by using the =, +=, -=, and ! operators respectively. Regardless of whether the *env_reset* option is enabled or disabled, variables specified by *env_check* will be preserved in the environment if they pass the aforementioned check. The global list of environment variables to check is displayed when **sudo** is run by root with the **-V** option.

env_delete

Environment variables to be removed from the user's environment when the *env_reset* option is not in effect. The argument may be a double-quoted, space-separated list or a single value without double-quotes. The list can be replaced, added to, deleted from, or disabled by using the =, +=, -=, and ! operators respectively. The global list of environment variables to remove is displayed when **sudo** is run by root with the **-V** option. Note that many operating systems will remove potentially dangerous variables from the

	environment of any set-user-ID process (such as sudo).
env_keep	Environment variables to be preserved in the user's environment when the <i>env_reset</i> option is in effect. This allows fine-grained control over the environment sudo -spawned processes will receive. The argument may be a double-quoted, space-separated list or a single value without double-quotes. The list can be replaced, added to, deleted from, or disabled by using the <code>=</code> , <code>+ =</code> , <code>- =</code> , and <code>!</code> operators respectively. The global list of variables to keep is displayed when sudo is run by root with the <code>-V</code> option.
	Preserving the <code>HOME</code> environment variable has security implications since many programs use it when searching for configuration or data files. Adding <code>HOME</code> to <i>env_keep</i> may enable a user to run unrestricted commands via sudo and is strongly discouraged. Users wishing to edit files with sudo should run sudoedit (or sudo -e) to get their accustomed editor configuration instead of invoking the editor directly.
log_servers	A list of one or more servers to use for remote event and I/O log storage, separated by white space. Log servers must be running sudo_logsrvd or another service that implements the protocol described by sudo_logsrv.proto(5) . Server addresses should be of the form “host[:port][(tls)]”. The host portion may be a host name, an IPv4 address, or an IPv6 address in square brackets. If the optional <i>tls</i> flag is present, the connection will be secured with Transport Layer Security (TLS) version 1.2 or 1.3. Versions of TLS prior to 1.2 are not supported. If a port is specified, it may either be a port number or a well-known service name as defined by the system service name database. If no port is specified, port 30343 will be used for plaintext connections and port 30344 will be used for TLS connections. When <i>log_servers</i> is set, event log data will be logged both locally (see the <i>syslog</i> and <i>log_file</i> settings) as well as remotely, but I/O log data will only be logged remotely. If multiple hosts are specified, they will be attempted in reverse order. If no log servers are available, the user will not be able to run a command unless either the <i>ignore_iolog_errors</i> flag (I/O logging enabled) or the <i>ignore_log_errors</i> flag (I/O logging disabled) is set. Likewise, if the connection to the log server is interrupted while sudo is running, the command will be terminated unless the <i>ignore_iolog_errors</i> flag (I/O logging enabled) or the <i>ignore_log_errors</i> flag (I/O logging disabled) is set. This setting is only supported by version 1.9.0 or higher.

GROUP PROVIDER PLUGINS

The **sudoers** plugin supports its own plugin interface to allow non-Unix group lookups which can query a group source other than the standard Unix group database. This can be used to implement support for the `nonunix_group` syntax described earlier.

Group provider plugins are specified via the *group_plugin* setting. The argument to *group_plugin* should consist of the plugin path, either fully-qualified or relative to the `/usr/libexec/sudo` directory, followed by any configuration options the plugin requires. These options (if specified) will be passed to the plugin's initialization function. If options are present, the string must be enclosed in double quotes ("").

The following group provider plugins are installed by default:

group_file

The *group_file* plugin supports an alternate group file that uses the same syntax as the `/etc/group` file. The path to the group file should be specified as an option to the plugin. For example, if the group file to be used is `/etc/sudo-group`:

```
Defaults group_plugin="group_file.so /etc/sudo-group"
```

system_group

The *system_group* plugin supports group lookups via the standard C library functions **getgrnam()** and **getgrid()**. This plugin can be used in instances where the user belongs to groups not present in the user's supplemental group vector. This plugin takes no options:

```
Defaults group_plugin=system_group.so
```

The group provider plugin API is described in detail in [sudo_plugin\(5\)](#).

LOG FORMAT

sudoers can log events in either JSON or *sudo* format, this section describes the *sudo* log format. Depending on *sudoers* configuration, **sudoers** can log events via [syslog\(3\)](#), to a local log file, or both. The log format is almost identical in both cases.

Accepted command log entries

Commands that *sudo* runs are logged using the following format (split into multiple lines for readability):

```
date hostname progname: username : TTY=ttyname ; PWD=cwd ; \
USER=runasuser ; GROUP=runasgroup ; TSID=loginid ; \
ENV=env_vars COMMAND=command
```

Where the fields are as follows:

date	The date the command was run. Typically, this is in the format “MMM, DD, HH:MM:SS”. If logging via syslog(3) , the actual date format is controlled by the syslog daemon. If logging to a file and the <i>log_year</i> option is enabled, the date will also include the year.
hostname	The name of the host sudo was run on. This field is only present when logging via syslog(3) .
progname	The name of the program, usually <i>sudo</i> or <i>sudoedit</i> . This field is only present when logging via syslog(3) .
username	The login name of the user who ran sudo .
ttyname	The short name of the terminal (e.g., “console”, “tty01”, or “pts/0”) sudo was run on, or “unknown” if there was no terminal present.
cwd	The current working directory that sudo was run in.
runasuser	The user the command was run as.
runasgroup	The group the command was run as if one was specified on the command line.
loginid	An I/O log identifier that can be used to replay the command's output. This is only present when the <i>log_input</i> or <i>log_output</i> option is enabled.
env_vars	A list of environment variables specified on the command line, if specified.
command	The actual command that was executed.

Messages are logged using the locale specified by *sudoers_locale*, which defaults to the “C” locale.

Denied command log entries

If the user is not allowed to run the command, the reason for the denial will follow the user name. Possible reasons include:

user NOT in sudoers

The user is not listed in the *sudoers* file.

user NOT authorized on host

The user is listed in the *sudoers* file but is not allowed to run commands on the host.

command not allowed

The user is listed in the *sudoers* file for the host but they are not allowed to run the specified command.

3 incorrect password attempts

The user failed to enter their password after 3 tries. The actual number of tries will vary based on the number of failed attempts and the value of the *passwd_tries* option.

a password is required

The **-n** option was specified but a password was required.

sorry, you are not allowed to set the following environment variables

The user specified environment variables on the command line that were not allowed by *sudoers*.

Error log entries

If an error occurs, **sudoers** will log a message and, in most cases, send a message to the administrator via email. Possible errors include:

parse error in /etc/sudoers near line N

sudoers encountered an error when parsing the specified file. In some cases, the actual error may be one line above or below the line number listed, depending on the type of error.

problem with defaults entries

The *sudoers* file contains one or more unknown Defaults settings. This does not prevent **sudo** from running, but the *sudoers* file should be checked using **visudo**.

timestamp owner (username): No such user

The time stamp directory owner, as specified by the *timestampowner* setting, could not be found in the password database.

unable to open/read /etc/sudoers

The *sudoers* file could not be opened for reading. This can happen when the *sudoers* file is located on a remote file system that maps user-ID 0 to a different value. Normally, **sudoers** tries to open the *sudoers* file using group permissions to avoid this problem. Consider either changing the ownership of /etc/sudoers or adding an argument like “*sudoers_uid=N*” (where ‘N’ is the user-ID that owns the *sudoers* file) to the end of the **sudoers** Plugin line in the *sudo.conf(5)* file.

unable to stat /etc/sudoers

The /etc/sudoers file is missing.

/etc/sudoers is not a regular file

The /etc/sudoers file exists but is not a regular file or symbolic link.

/etc/sudoers is owned by uid N, should be 0

The *sudoers* file has the wrong owner. If you wish to change the *sudoer* s file owner, please add “*sudoers_uid=N*” (where ‘N’ is the user-ID that owns the *sudoers* file) to the **sudoers** Plugin line in the *sudo.conf(5)* file.

/etc/sudoers is world writable

The permissions on the *sudoers* file allow all users to write to it. The *sudoers* file must not be world-writable, the default file mode is 0440 (readable by owner and group, writable by none). The default mode may be changed via the “*sudoers_mode*” option to the **sudoers** Plugin line in the *sudo.conf(5)* file.

/etc/sudoers is owned by gid N, should be 1

The **sudoers** file has the wrong group ownership. If you wish to change the **sudoers** file group ownership, please add “**sudoers_gid=N**” (where ‘N’ is the group-ID that owns the **sudoers** file) to the **sudoers** **Plugin** line in the **sudo.conf(5)** file.

unable to open /run/sudo/ts/username

sudoers was unable to read or create the user’s time stamp file. This can happen when *timestampowner* is set to a user other than root and the mode on **/run/ sudo** is not searchable by group or other. The default mode for **/run/ sudo** is 0711.

unable to write to /run/sudo/ts/username

sudoers was unable to write to the user’s time stamp file.

/run/ sudo/ ts is owned by uid X, should be Y

The time stamp directory is owned by a user other than *timestampowner*. This can occur when the value of *timestampowner* has been changed. **sudoers** will ignore the time stamp directory until the owner is corrected.

/run/ sudo/ ts is group writable

The time stamp directory is group-writable; it should be writable only by *timestampowner*. The default mode for the time stamp directory is 0700. **sudoers** will ignore the time stamp directory until the mode is corrected.

Notes on logging via syslog

By default, **sudoers** logs messages via **syslog(3)**. The *date*, *hostname*, and *programname* fields are added by the system’s **syslog()** function, not **sudoers** itself. As such, they may vary in format on different systems.

The maximum size of syslog messages varies from system to system. The *syslog_maxlen* setting can be used to change the maximum syslog message size from the default value of 980 bytes. For more information, see the description of *syslog_maxlen*.

Notes on logging to a file

If the *logfile* option is set, **sudoers** will log to a local file, such as **/var/ log/ sudo**. When logging to a file, **sudoers** uses a format similar to **syslog(3)**, with a few important differences:

1. The *programname* and *hostname* fields are not present.
2. If the *log_year* option is enabled, the date will also include the year.
3. Lines that are longer than *loglinelen* characters (80 by default) are word-wrapped and continued on the next line with a four character indent. This makes entries easier to read for a human being, but makes it more difficult to use **grep(1)** on the log files. If the *loglinelen* option is set to 0 (or negated with a ‘!’), word wrap will be disabled.

I/O LOG FILES

When I/O logging is enabled, **sudo** will run the command in a pseudo-terminal and log all user input and/or output, depending on which options are enabled. I/O can be logged either to the local machine or to a remote log server. For local logs, I/O is logged to the directory specified by the *iolog_dir* option (**/var/ log/ sudo- io** by default) using a unique session ID that is included in the **sudo** log line, prefixed with “*TSID=*”. The *iolog_file* option may be used to control the format of the session ID. For remote logs, the *log_servers* setting is used to specify one or more log servers running **sudo_logsrvd** or another server that implements the protocol described by **sudo_logsrv.proto(5)**.

For both local and remote I/O logs, each log is stored in a separate directory that contains the following files:

<code>log</code>	A text file containing information about the command. The first line consists of the following colon-delimited fields: the time the command was run, the name of the user who ran sudo , the name of the target user, the name of the target group (optional), the terminal that sudo was run from, and the number of lines and columns of the terminal. The second and third lines contain the working directory the command was run from and the path name of the command itself (with arguments if present).
<code>log.json</code>	A JSON-formatted file containing information about the command. This is similar to the <code>log</code> file but contains additional information and is easily extensible. The <code>log.json</code> file will be used by sudoreplay(8) in preference to the <code>log</code> file if it exists. The file may contain the following elements:
<code>timestamp</code>	A JSON object containing time the command was run. It consists of two values, <code>seconds</code> and <code>nanoseconds</code> .
<code>columns</code>	The number of columns of the terminal the command ran on, or zero if no terminal was present.
<code>command</code>	The fully-qualified path of the command that was run.
<code>lines</code>	The number of lines of the terminal the command ran on, or zero if no terminal was present.
<code>runargv</code>	A JSON array representing the command's argument vector as passed to the execve() system call.
<code>runenv</code>	A JSON array representing the command's environment as passed to the execve() system call.
<code>rungid</code>	The group ID the command ran as. This element is only present when the user specifies a group on the command line.
<code>rungroup</code>	The name of the group the command ran as. This element is only present when the user specifies a group on the command line.
<code>runuid</code>	The user ID the command ran as.
<code>runuser</code>	The name of the user the command ran as.
<code>submit cwd</code>	The current working directory at the time sudo was run.
<code>submit host</code>	The name of the host the command was run on.
<code>submit user</code>	The name of the user who ran the command via sudo .
<code>ttyname</code>	The path name of the terminal the user invoked sudo from. If the command was run in a pseudo-terminal, <code>ttyname</code> will be different from the terminal the command actually ran in.
<code>timing</code>	Timing information used to replay the session. Each line consists of the I/O log entry type and amount of time since the last entry, followed by type-specific data. The I/O log entry types and their corresponding type-specific data are:

0	standard input, number of bytes in the entry
1	standard output, number of bytes in the entry
2	standard error, number of bytes in the entry
3	terminal input, number of bytes in the entry
4	terminal output, number of bytes in the entry
5	window change, new number lines and columns
6	bug compatibility for sudo 1.8.7 terminal output
7	command suspend or resume, signal received
ttyin	Raw input from the user's terminal, exactly as it was received. No post-processing is performed. For manual viewing, you may wish to convert carriage return characters in the log to line feeds. For example: gunzip -c ttyin tr "\r" "\n"
stdin	The standard input when no terminal is present, or input redirected from a pipe or file.
ttyout	Output from the pseudo-terminal (what the command writes to the screen). Note that terminal-specific post-processing is performed before the data is logged. This means that, for example, line feeds are usually converted to line feed/carriage return pairs and tabs may be expanded to spaces.
stdout	The standard output when no terminal is present, or output redirected to a pipe or file.
stderr	The standard error redirected to a pipe or file.

All files other than **log** are compressed in gzip format unless the *compress_io* flag has been disabled. Due to buffering, it is not normally possible to display the I/O logs in real-time as the program is executing. The I/O log data will not be complete until the program run by **sudo** has exited or has been terminated by a signal. The *iolo g_flush* flag can be used to disable buffering, in which case I/O log data is written to disk as soon as it is available. The output portion of an I/O log file can be viewed with the **sudoreplay(8)** utility, which can also be used to list or search the available logs.

Note that user input may contain sensitive information such as passwords (even if they are not echoed to the screen), which will be stored in the log file unencrypted. In most cases, logging the command output via *log_output* or **LOG_OUTPUT** is all that is required.

Since each session's I/O logs are stored in a separate directory, traditional log rotation utilities cannot be used to limit the number of I/O logs. The simplest way to limit the number of I/O is by setting the *maxseq* option to the maximum number of logs you wish to store. Once the I/O log sequence number reaches *maxseq*, it will be reset to zero and **sudoers** will truncate and re-use any existing I/O logs.

FILES

/etc/sudo.conf	Sudo front-end configuration
/etc/sudoers	List of who can run what
/etc/group	Local groups file
/etc/netgroup	List of network groups
/var/log/sudo-io	I/O log files
/run/sudo/ts	Directory containing time stamps for the sudoers security policy
/var/lib/sudo/lectured	Directory containing lecture status files for the sudoers security policy
/etc/environment	Initial environment for -i mode on AIX and Linux systems

EXAMPLES

Below are example *sudoers* file entries. Admittedly, some of these are a bit contrived. First, we allow a few environment variables to pass and then define our *aliases*:

```
# Run X applications through sudo; HOME is used to find the
# .Xauthority file. Note that other programs use HOME to find
# configuration files and this may lead to privilege escalation!
Defaults env_keep += "DISPLAY HOME"

# User alias specification
User_Alias      FULLTIMERS = millert, mikef, dowdy
User_Alias      PARTTIMERS = bostley, jwfox, crawl
User_Alias      WEBADMIN = will, wendy, wim

# Runas alias specification
Runas_Alias    OP = root, operator
Runas_Alias    DB = oracle, sybase
Runas_Alias    ADMINGRP = adm, oper

# Host alias specification
Host_Alias     SPARC = bigtime, eclipse, moet, anchor :\
                SGI = grolsch, dandelion, black :\
                ALPHA = widget, thalamus, foobar :\
                HPPA = boa, nag, python
Host_Alias     CUNETS = 128.138.0.0/255.255.0.0
Host_Alias     CSNETS = 128.138.243.0, 128.138.204.0/24, 128.138.242.0
Host_Alias     SERVERS = primary, mail, www, ns
Host_Alias     CDROM = orion, perseus, hercules

# Cmnd alias specification
Cmnd_Alias    DUMPS = /usr/bin/mt, /usr/sbin/dump, /usr/sbin/rdump, \
                /usr/sbin/restore, /usr/sbin/rrestore, \
                sha224:0GomF8mNN3wlDt1HD9XldjJ3SNgpFdbj01+NsQ== \
                /home/operator/bin/start_backups
Cmnd_Alias    KILL = /usr/bin/kill
Cmnd_Alias    PRINTING = /usr/sbin/lpc, /usr/bin/lprm
Cmnd_Alias    SHUTDOWN = /usr/sbin/shutdown
Cmnd_Alias    HALT = /usr/sbin/halt
Cmnd_Alias    REBOOT = /usr/sbin/reboot
Cmnd_Alias    SHELLS = /usr/bin/sh, /usr/bin/csh, /usr/bin/ksh, \
                /usr/local/bin/tcsh, /usr/bin/rsh, \
                /usr/local/bin/zsh
Cmnd_Alias    SU = /usr/bin/su
Cmnd_Alias    PAGERS = /usr/bin/more, /usr/bin/pg, /usr/bin/less
```

Here we override some of the compiled in default values. We want **sudo** to log via `syslog(3)` using the *auth* facility in all cases and for commands to be run with the target user's home directory as the working directory. We don't want to subject the full time staff to the **sudo** lecture and we want to allow them to run commands in a `chroot(2)` "sandbox" via the **-R** option. User **millert** need not provide a password and we don't want to reset the `LOGNAME` or `USER` environment variables when running commands as root. Additionally, on the machines in the *SERVERS* `Host_Alias`, we keep an additional local log file and make sure we log the year in each log line since the log entries will be kept around for several years. Lastly, we disable shell escapes for the commands in the *PAGERS* `Cmnd_Alias` (`/usr/bin/more`, `/usr/bin/pg` and

`/usr/bin/less`). Note that this will not effectively constrain users with **sudo ALL** privileges.

```
# Override built-in defaults
Defaults           syslog=auth,runcwd=~
Defaults>root      !set_logname
Defaults:FULLTIMERS !lecture,runchroot=*
Defaults:millert   !authenticate
Defaults@SERVERS   log_year, logfile=/var/log/sudo.log
Defaults!PAGERS    noexec
```

The *User specification* is the part that actually determines who may run what.

```
root          ALL = (ALL) ALL
%wheel        ALL = (ALL) ALL
```

We let **root** and any user in group **wheel** run any command on any host as any user.

```
FULLTIMERS     ALL = NOPASSWD: ALL
```

Full time sysadmins (**millert**, **mik ef**, and **dowdy**) may run any command on any host without authenticating themselves.

```
PARTTIMERS    ALL = ALL
```

Part time sysadmins (**bostley**, **jwfox**, and **crawl**) may run any command on any host but they must authenticate themselves first (since the entry lacks the NOPASSWD tag).

```
jack          CSNETS = ALL
```

The user **jack** may run any command on the machines in the *CSNETS* alias (the networks 128.138.243.0, 128.138.204.0, and 128.138.242.0). Of those networks, only 128.138.204.0 has an explicit netmask (in CIDR notation) indicating it is a class C network. For the other networks in *CSNETS*, the local machine's netmask will be used during matching.

```
lisa          CUNETS = ALL
```

The user **lisa** may run any command on any host in the *CUNETS* alias (the class B network 128.138.0.0).

```
operator       ALL = DUMPS, KILL, SHUTDOWN, HALT, REBOOT, PRINTING, \
                sudoedit /etc/printcap, /usr/oper/bin/
```

The **operator** user may run commands limited to simple maintenance. Here, those are commands related to backups, killing processes, the printing system, shutting down the system, and any commands in the directory `/usr/oper/bin/`. Note that one command in the `DUMPS` Cmnd_Alias includes a sha224 digest, `/home/operator/bin/start_backups`. This is because the directory containing the script is writable by the operator user. If the script is modified (resulting in a digest mismatch) it will no longer be possible to run it via **sudo**.

```
joe          ALL = /usr/bin/su operator
```

The user **joe** may only `su(1)` to operator.

```
pete          HPPA = /usr/bin/passwd [A-Za-z]*, !/usr/bin/passwd *root*
%opers        ALL = (: ADMINGRP) /usr/sbin/
```

Users in the **opers** group may run commands in `/usr/sbin/` as themselves with any group in the `ADMINGRP` Runas_Alias (the **adm** and **oper** groups).

The user **pete** is allowed to change anyone's password except for root on the *HPPA* machines. Because command line arguments are matched as a single, concatenated string, the '*' wildcard will match *multiple* words. This example assumes that `passwd(1)` does not take multiple user names on the command line. Note that on GNU systems, options to `passwd(1)` may be specified after the user argument. As a result, this rule will also allow:

```
passwd username --expire
```

which may not be desirable.

```
bob           SPARC = (OP) ALL : SGI = (OP) ALL
```

The user **bob** may run anything on the *SPARC* and *SGI* machines as any user listed in the *OP Runas_Alias* (**root** and **operator**.)

```
jim           +biglab = ALL
```

The user **jim** may run any command on machines in the *biglab* netgroup. **sudo** knows that "biglab" is a netgroup due to the '+' prefix.

```
+secretaries  ALL = PRINTING, /usr/bin/adduser, /usr/bin/rmuser
```

Users in the **secretaries** netgroup need to help manage the printers as well as add and remove users, so they are allowed to run those commands on all machines.

```
fred          ALL = (DB) NOPASSWD: ALL
```

The user **fred** can run commands as any user in the *DB Runas_Alias* (**oracle** or **sybase**) without giving a password.

```
john          ALPHA = /usr/bin/su [!-]*, !/usr/bin/su *root*
```

On the *ALPHA* machines, user **john** may su to anyone except root but he is not allowed to specify any options to the `su(1)` command.

```
jen           ALL, !SERVERS = ALL
```

The user **jen** may run any command on any machine except for those in the *SERVERS Host_Alias* (primary, mail, www, and ns).

```
jill          SERVERS = /usr/bin/, !SU, !SHELLS
```

For any machine in the *SERVERS Host_Alias*, **jill** may run any commands in the directory `/usr/bin/` except for those commands belonging to the *SU* and *SHELLS Cmnd_Aliases*. While not specifically mentioned in the rule, the commands in the *PAGERS Cmnd_Alias* all reside in `/usr/bin` and have the *noexec* option set.

```
steve         CSNETS = (operator) /usr/local/op_commands/
```

The user **steve** may run any command in the directory `/usr/local/op_commands/` but only as user operator.

```
matt          valkyrie = KILL
```

On his personal workstation, **valkyrie**, **matt** needs to be able to kill hung processes.

```
WEBADMIN      www = (www) ALL, (root) /usr/bin/su www
```

On the host `www`, any user in the *WEBADMIN User_Alias* (will, wendy, and wim), may run any command as user `www` (which owns the web pages) or simply `su(1)` to `www`.

```
ALL          CDROM = NOPASSWD: /sbin/umount /CDROM,\n           /sbin/mount -o nosuid\,,nodev /dev/cd0a /CDROM
```

Any user may mount or unmount a CD-ROM on the machines in the CDROM Host_Alias (orion, perseus, hercules) without entering a password. This is a bit tedious for users to type, so it is a prime candidate for encapsulating in a shell script.

SECURITY NOTES

Limitations of the ‘!’ operator

It is generally not effective to “subtract” commands from **ALL** using the ‘!’ operator. A user can trivially circumvent this by copying the desired command to a different name and then executing that. For example:

```
bill    ALL = ALL, !SU, !SHELLS
```

Doesn’t really prevent **bill** from running the commands listed in **SU** or **SHELLS** since he can simply copy those commands to a different name, or use a shell escape from an editor or other program. Therefore, these kind of restrictions should be considered advisory at best (and reinforced by policy).

In general, if a user has sudo **ALL** there is nothing to prevent them from creating their own program that gives them a root shell (or making their own copy of a shell) regardless of any ‘!’ elements in the user specification.

Security implications of *fast_glob*

If the *fast_glob* option is in use, it is not possible to reliably negate commands where the path name includes globbing (aka wildcard) characters. This is because the C library’s `fnmatch(3)` function cannot resolve relative paths. While this is typically only an inconvenience for rules that grant privileges, it can result in a security issue for rules that subtract or revoke privileges.

For example, given the following *sudoers* file entry:

```
john    ALL = /usr/bin/passwd [a-zA-Z0-9]*, /usr/bin/chsh [a-zA-Z0-9]*, \
          /usr/bin/chfn [a-zA-Z0-9]*, !/usr/bin/* root
```

User **john** can still run `/usr/bin/passwd root` if *fast_glob* is enabled by changing to `/usr/bin` and running `./passwd root` instead.

Preventing shell escapes

Once **sudo** executes a program, that program is free to do whatever it pleases, including run other programs. This can be a security issue since it is not uncommon for a program to allow shell escapes, which lets a user bypass **sudo**’s access control and logging. Common programs that permit shell escapes include shells (obviously), editors, paginators, mail, and terminal programs.

There are four basic approaches to this problem:

restrict Avoid giving users access to commands that allow the user to run arbitrary commands. Many editors have a restricted mode where shell escapes are disabled, though **sudoedit** is a better solution to running editors via **sudo**. Due to the large number of programs that offer shell escapes, restricting users to the set of programs that do not is often unworkable.

intercept Many systems that support shared libraries have the ability to override default library functions by pointing an environment variable (usually `LD_PRELOAD`) to an alternate shared library. On such systems, **sudo**’s *intercept* functionality can be used to transparently intercept an attempt to run a new command, allow or deny it based on *sudoers* rules, and log the result. For example, this can be used to restrict the commands run from within a privileged shell. Note, however, that this applies only to dynamically-linked executables. Statically-linked executables and executables running under binary emulation are not affected. Also, most shells support built-in commands and the ability to read or write sensitive files that cannot be intercepted by **sudo**.

Currently, **sudo**'s *intercept* functionality only works for programs that use the **exec1()**, **execle()**, **execlp()**, **execv()**, **execve()**, **execvp()**, or **execvpe()** library functions to run the new command. This may be expanded in a future release of **sudo**. Because most dynamic loaders ignore **LD_PRELOAD** (or the equivalent) when running set-user-ID and set-group-ID programs, **sudoers** will not permit such programs to be run in *intercept* mode.

The *intercept* feature is known to work on Solaris, *BSD, Linux, macOS, HP-UX 11.x and AIX 5.3 and above. It should be supported on most operating systems that support the **LD_PRELOAD** environment variable. Check your operating system's manual pages for the dynamic linker (usually **ld.so**, **ld.so.1**, **dyld**, **dld.sl**, **rld**, or **loader**) to see if **LD_PRELOAD** is supported. It is *not* supported when **sudo**'s SELinux RBAC support is in use due to a fundamental incompatibility.

To enable intercept mode on a per-command basis, use the **INTERCEPT** tag as documented in the User Specification section above. Here is that example again:

```
chuck research = INTERCEPT: ALL
```

This allows user **chuck** to run any command on the machine "research" in intercept mode. Any commands run via shell escapes will be validated and logged by **sudo**. If you are unsure whether or not your system is capable of supporting *intercept*, you can always just try it out and check whether or not external commands run via a shell are logged when *intercept* is enabled.

log

There are two separate but related ways to log additional commands. The first is to enable I/O logging using the **log_output** flag. This will log the command's output but will not create an event log entry when the additional command is run. The second is to enable the **log_subcmds** flag in **sudoers** which will create an event log entry every time a new command is run. If I/O logging is also enabled, the log entry will include a time offset into the I/O log to indicate when the command was run. This offset can be passed to the **sudoreplay(8)** utility to replay the I/O log at the exact moment when the command was run. The **log_subcmds** flag uses the same mechanism as *intercept* (see above) and has the same limitations.

noexec

sudo's *noexec* functionality can be used to prevent a program run by **sudo** from executing any other programs. On most systems, it uses the same mechanism as *intercept* (see above) and thus the same caveats apply. The *noexec* functionality is capable of blocking execution of commands run via the **exec1()**, **execle()**, **execlp()**, **exec()**, **execv()**, **execve()**, **execveat()**, **execvP()**, **execvp()**, **execvpe()**, **fexecve()**, **popen()**, **posix_spawn()**, **posix_spawnp()**, **system()**, and **wordexp()** functions. On Linux, a **seccomp()** filter is used to implement *noexec*. On Solaris 10 and higher, *noexec* uses Solaris privileges instead of the **LD_PRELOAD** environment variable.

To enable *noexec* for a command, use the **NOEXEC** tag as documented in the User Specification section above. Here is that example again:

```
aaron shanty = NOEXEC: /usr/bin/more, /usr/bin/vi
```

This allows user **aaron** to run **/usr/bin/more** and **/usr/bin/vi** with *noexec* enabled. This will prevent those two commands from executing other commands (such as a shell). If you are unsure whether or not your system is capable of supporting *noexec* you can always just try it out and check whether shell escapes work when *noexec* is enabled.

Note that restricting shell escapes is not a panacea. Programs running as root are still capable of many potentially hazardous operations (such as changing or overwriting files) that could lead to unintended privilege escalation. In the specific case of an editor, a safer approach is to give the user permission to run **sudoedit** (see below).

Secure editing

The **sudoers** plugin includes **sudoedit** support which allows users to securely edit files with the editor of their choice. As **sudoedit** is a built-in command, it must be specified in the *sudoers* file without a leading path. However, it may take command line arguments just as a normal command does. Wildcards used in **sudoedit** command line arguments are expected to be path names, so a forward slash ('/') will not be matched by a wildcard.

Unlike other **sudo** commands, the editor is run with the permissions of the invoking user and with the environment unmodified. More information may be found in the description of the **-e** option in **sudo(8)**.

For example, to allow user operator to edit the “message of the day” file:

```
operator      sudoedit /etc/motd
```

The operator user then runs **sudoedit** as follows:

```
$ sudoedit /etc/motd
```

The editor will run as the operator user, not root, on a temporary copy of */etc/motd*. After the file has been edited, */etc/motd* will be updated with the contents of the temporary copy.

Users should *never* be granted **sudoedit** permission to edit a file that resides in a directory the user has write access to, either directly or via a wildcard. If the user has write access to the directory it is possible to replace the legitimate file with a link to another file, allowing the editing of arbitrary files. To prevent this, starting with version 1.8.16, symbolic links will not be followed in writable directories and **sudoedit** will refuse to edit a file located in a writable directory unless the *sudoedit_checkdir* option has been disabled or the invoking user is root. Additionally, in version 1.8.15 and higher, **sudoedit** will refuse to open a symbolic link unless either the *sudoedit_follow* option is enabled or the *sudoedit* command is prefixed with the FOLLOW tag in the *sudoers* file.

Time stamp file checks

sudoers will check the ownership of its time stamp directory (*/run/sudo/ts* by default) and ignore the directory’s contents if it is not owned by root or if it is writable by a user other than root. Older versions of **sudo** stored time stamp files in */tmp*; this is no longer recommended as it may be possible for a user to create the time stamp themselves on systems that allow unprivileged users to change the ownership of files they create.

While the time stamp directory *should* be cleared at reboot time, not all systems contain a */run* or */var/run* directory. To avoid potential problems, **sudoers** will ignore time stamp files that date from before the machine booted on systems where the boot time is available.

Some systems with graphical desktop environments allow unprivileged users to change the system clock. Since **sudoers** relies on the system clock for time stamp validation, it may be possible on such systems for a user to run **sudo** for longer than *timestamp_timeout* by setting the clock back. To combat this, **sudoers** uses a monotonic clock (which never moves backwards) for its time stamps if the system supports it.

sudoers will not honor time stamps set far in the future. Time stamps with a date greater than *current_time + 2 * TIMEOUT* will be ignored and **sudoers** will log and complain.

If the *timestamp_type* option is set to “tty”, the time stamp record includes the device number of the terminal the user authenticated with. This provides per-terminal granularity but time stamp records may still outlive the user’s session.

Unless the *timestamp_type* option is set to “global”, the time stamp record also includes the session ID of the process that last authenticated. This prevents processes in different terminal sessions from using the same time stamp record. On systems where a process’s start time can be queried, the start time of the session leader is recorded in the time stamp record. If no terminal is present or the *timestamp_type* option is set to “ppid”, the start time of the parent process is used instead. In most cases this will prevent a time stamp

record from being re-used without the user entering a password when logging out and back in again.

DEBUGGING

Versions 1.8.4 and higher of the **sudoers** plugin support a flexible debugging framework that can help track down what the plugin is doing internally if there is a problem. This can be configured in the **sudo.conf(5)** file.

The **sudoers** plugin uses the same debug flag format as the **sudo** front-end: *subsystem@priority*.

The priorities used by **sudoers**, in order of decreasing severity, are: *crit, err, warn, notice, diag, info, trace*, and *debug*. Each priority, when specified, also includes all priorities higher than it. For example, a priority of *notice* would include debug messages logged at *notice* and higher.

The following subsystems are used by the **sudoers** plugin:

<i>alias</i>	User_Alias, Runas_Alias, Host_Alias and Cmnd_Alias processing
<i>all</i>	matches every subsystem
<i>audit</i>	BSM and Linux audit code
<i>auth</i>	user authentication
<i>defaults</i>	<i>sudoers</i> file Defaults settings
<i>env</i>	environment handling
<i>ldap</i>	LDAP-based sudoers
<i>logging</i>	logging support
<i>match</i>	matching of users, groups, hosts, and netgroups in the <i>sudoers</i> file
<i>netif</i>	network interface handling
<i>nss</i>	network service switch handling in sudoers
<i>parser</i>	<i>sudoers</i> file parsing
<i>perms</i>	permission setting
<i>plugin</i>	The equivalent of <i>main</i> for the plugin.
<i>pty</i>	pseudo-terminal related code
<i>rbtree</i>	redblack tree internals
<i>sssd</i>	SSSD-based sudoers
<i>util</i>	utility functions

For example:

```
Debug sudoers.so /var/log/sudoers_debug match@info,nss@info
```

For more information, see the **sudo.conf(5)** manual.

See the CONTRIBUTORS file in the **sudo** distribution (<https://www.sudo.ws/contributors.html>) for an exhaustive list of people who have contributed to **sudo**.

CAVEATS

The *sudoers* file should **always** be edited by the **visudo** utility which locks the file and checks for syntax errors. If *sudoer.s* contains syntax errors, **sudo** may refuse to run, which is a serious problem if **sudo** is your only method of obtaining superuser privileges. Recent versions of **sudoers** will attempt to recover after a syntax error by ignoring the rest of the line after encountering an error. Older versions of **sudo** will not run if *sudoers* contains a syntax error.

When using netgroups of machines (as opposed to users), if you store fully qualified host name in the netgroup (as is usually the case), you either need to have the machine's host name be fully qualified as returned by the `hostname` command or use the *fqdn* option in *sudoers*.

BUGS

If you feel you have found a bug in **sudo**, please submit a bug report at <https://bugzilla.sudo.ws/>

SUPPORT

Limited free support is available via the sudo-users mailing list, see <https://www.sudo.ws/mailman/listinfo/sudo-users> to subscribe or search the archives.

DISCLAIMER

NAME

sudoers_timestamp — Sudoers Time Stamp Format

DESCRIPTION

The **sudoers** plugin uses per-user time stamp files for credential caching. Once a user has been authenticated, they may use **sudo** without a password for a short period of time (15 minutes unless overridden by the *timestamp_timeout* option). By default, **sudoers** uses a separate record for each terminal, which means that a user's login sessions are authenticated separately. The *timestamp_type* option can be used to select the type of time stamp record **sudoers** will use.

A multi-record time stamp file format was introduced in **sudo** 1.8.10 that uses a single file per user. Previously, a separate file was used for each user and terminal combination unless tty-based time stamps were disabled. The new format is extensible and records of multiple types and versions may coexist within the same file.

All records, regardless of type or version, begin with a 16-bit version number and a 16-bit record size.

Time stamp records have the following structure:

```
/* Time stamp entry types */
#define TS_GLOBAL          0x01 /* not restricted by tty or ppid */
#define TS_TTY              0x02 /* restricted by tty */
#define TS_PPID             0x03 /* restricted by ppid */
#define TS_LOCKEXCL         0x04 /* special lock record */

/* Time stamp flags */
#define TS_DISABLED          0x01 /* entry disabled */
#define TS_ANYUID            0x02 /* ignore uid, only valid in key */

struct timestamp_entry {
    unsigned short version;      /* version number */
    unsigned short size;         /* entry size */
    unsigned short type;         /* TS_GLOBAL, TS_TTY, TS_PPID */
    unsigned short flags;        /* TS_DISABLED, TS_ANYUID */
    uid_t auth_uid;             /* uid to authenticate as */
    pid_t sid;                  /* session ID associated with tty/ppid */
    struct timespec start_time; /* session/ppid start time */
    struct timespec ts;          /* time stamp (CLOCK_MONOTONIC) */
    union {
        dev_t ttydev;           /* tty device number */
        pid_t ppid;              /* parent pid */
    } u;
};
```

The `timestamp_entry` struct fields are as follows:

`version`

The version number of the `timestamp_entry` struct. New entries are created with a version number of 2. Records with different version numbers may coexist in the same file but are not inter-operable.

`size` The size of the record in bytes.

`type` The record type, currently `TS_GLOBAL`, `TS_TTY`, or `TS_PPID`.

flags Zero or more record flags which can be bit-wise ORed together. Supported flags are `TS_DISABLED`, for records disabled via `sudo -k` and `TS_ANYUID`, which is used only when matching records.

auth_uid

The user-ID that was used for authentication. Depending on the value of the `rootpw`, `runaspw` and `targetpw` options, the user-ID may be that of the invoking user, the root user, the default runas user or the target user.

sid The ID of the user's terminal session, if present. The session ID is only used when matching records of type `TS_TTY`.

start_time

The start time of the session leader for records of type `TS_TTY` or of the parent process for records of type `TS_PPID`. The `start_time` is used to help prevent re-use of a time stamp record after a user has logged out. Not all systems support a method to easily retrieve a process's start time. The `start_time` field was added in **sudoers** version 1.8.22 for the second revision of the `timestamp_entry` struct.

ts The actual time stamp. A monotonic time source (which does not move backward) is used if the system supports it. Where possible, **sudoers** uses a monotonic timer that increments even while the system is suspended. The value of `ts` is updated each time a command is run via `sudo`. If the difference between `ts` and the current time is less than the value of the `timestamp_timeout` option, no password is required.

u.ttydev

The device number of the terminal associated with the session for records of type `TS_TTY`.

u.ppid

The ID of the parent process for records of type `TS_PPID`.

LOCKING

In **sudoers** versions 1.8.10 through 1.8.14, the entire time stamp file was locked for exclusive access when reading or writing to the file. Starting in **sudoers** 1.8.15, individual records are locked in the time stamp file instead of the entire file and the lock is held for a longer period of time. This scheme is described below.

The first record in the time stamp file is of type `TS_LOCKEXCL` and is used as a `lock` record to prevent more than one `sudo` process from adding a new record at the same time. Once the desired time stamp record has been located or created (and locked), the `TS_LOCKEXCL` record is unlocked. The lock on the individual time stamp record, however, is held until authentication is complete. This allows **sudoers** to avoid prompting for a password multiple times when it is used more than once in a pipeline.

Records of type `TS_GLOBAL` cannot be locked for a long period of time since doing so would interfere with other `sudo` processes. Instead, a separate lock record is used to prevent multiple `sudo` processes using the same terminal (or parent process ID) from prompting for a password at the same time.

SEE ALSO

`sudoers(5)`, `sudo(8)`

HISTORY

Originally, `sudo` used a single zero-length file per user and the file's modification time was used as the time stamp. Later versions of `sudo` added restrictions on the ownership of the time stamp files and directory as well as checks on the validity of the time stamp itself. Notable changes were introduced in the following `sudo` versions:

1.4.0 Support for tty-based time stamp file was added by appending the terminal name to the time stamp file name.

1.6.2 The time stamp file was replaced by a per-user directory which contained any tty-based time stamp files.

1.6.3p2

The target user name was added to the time stamp file name when the *targetpw* option was set.

1.7.3 Information about the terminal device was stored in tty-based time stamp files for validity checks. This included the terminal device numbers, inode number and, on systems where it was not updated when the device was written to, the inode change time. This helped prevent re-use of the time stamp file after logout.

1.8.6p7

The terminal session ID was added to tty-based time stamp files to prevent re-use of the time stamp by the same user in a different terminal session. It also helped prevent re-use of the time stamp file on systems where the terminal device's inode change time was updated by writing.

1.8.10

A new, multi-record time stamp file format was introduced that uses a single file per user. The terminal device's change time was not included since most systems now update the change time after a write is performed as required by POSIX.

1.8.15

Individual records are locked in the time stamp file instead of the entire file and the lock is held until authentication is complete.

1.8.22

The start time of the terminal session leader or parent process is now stored in non-global time stamp records. This prevents re-use of the time stamp file after logout in most cases.

Support was added for the kernel-based tty time stamps available in OpenBSD which do not use an on-disk time stamp file.

NAME

sudoreplay — replay sudo session logs

SYNOPSIS

```
sudoreplay [ -FhnRS ] [-d dir] [-f filter] [-m num] [-s num] ID[@offset]
sudoreplay [ -h ] [-d dir] -l [search expression]
```

DESCRIPTION

sudoreplay plays back or lists the output logs created by **sudo**. When replaying, **sudoreplay** can play the session back in real-time, or the playback speed may be adjusted (faster or slower) based on the command line options.

The *ID* should either be a six character sequence of digits and upper case letters, e.g., 0100A5 or a path name. The *ID* may include an optional @*offset* suffix which may be used to start replaying at a specific time offset. The @*offset* is specified as a number in seconds since the start of the session with an optional decimal fraction.

Path names may be relative to the I/O log directory /var/log/sudo-io (unless overridden by the **-d** option) or fully qualified, beginning with a ‘/’ character. When a command is run via **sudo** with *log_output* enabled in the *sudoers* file, a TSID=ID string is logged via syslog or to the **sudo** log file. The *ID* may also be determined using **sudoreplay**'s list mode.

In list mode, **sudoreplay** can be used to find the ID of a session based on a number of criteria such as the user, tty, or command run.

In replay mode, if the standard input and output are connected to a terminal and the **-n** option is not specified, **sudoreplay** will operate interactively. In interactive mode, **sudoreplay** will attempt to adjust the terminal size to match that of the session and write directly to the terminal (not all terminals support this). Additionally, it will poll the keyboard and act on the following keys:

- ‘\n’ or ‘\r’ Skip to the next replay event; useful for long pauses.
- ‘ ’ (space) Pause output; press any key to resume.
- ‘<’ Reduce the playback speed by one half.
- ‘>’ Double the playback speed.

The session can be interrupted via control-C. When the session has finished, the terminal is restored to its original size if it was changed during playback.

The options are as follows:

- d dir, --directory=dir**
Store session logs in *dir* instead of the default, /var/log/sudo-io.
- f filter, --filter=filter**
Select which I/O type(s) to display. By default, **sudoreplay** will display the command's standard output, standard error, and tty output. The *filter* argument is a comma-separated list, consisting of one or more of following: *stdin*, *stdout*, *stderr*, *ttyin*, and *ttyout*.
- F, --follow**
Enable “follow mode”. When replaying a session, **sudoreplay** will ignore end-of-file and keep replaying until the log is complete. This can be used to replay a session that is still in progress, similar to “tail -f”. An I/O log file is considered to be complete when the write bits have been cleared on the session's timing file. Note that versions of **sudo** prior to 1.9.1 do not clear the write bits upon completion.

-h, --help

Display a short help message to the standard output and exit.

-l, --list [search expression]

Enable “list mode”. In this mode, **sudoreplay** will list available sessions in a format similar to the **sudo** log file format, sorted by file name (or sequence number). If a *search expression* is specified, it will be used to restrict the IDs that are displayed. An expression is composed of the following predicates:

command pattern

Evaluates to true if the command run matches the POSIX extended regular expression *pattern*.

cwd directory

Evaluates to true if the command was run with the specified current working directory.

fromdate date

Evaluates to true if the command was run on or after *date*. See**Date and time format** for a description of supported date and time formats.

group runas_group

Evaluates to true if the command was run with the specified *runas_group*. Note that unless a *runas_group* was explicitly specified when **sudo** was run this field will be empty in the log.

host hostname

Evaluates to true if the command was run on the specified *hostname*.

runas runas_user

Evaluates to true if the command was run as the specified *runas_user*. Note that **sudo** runs commands as user *root* by default.

todate date

Evaluates to true if the command was run on or prior to *date*. See**Date and time format** for a description of supported date and time formats.

tty tty name

Evaluates to true if the command was run on the specified terminal device. The *tty* *name* should be specified without the */dev/* prefix, e.g., *tty01* instead of */dev/tty01*.

user user name

Evaluates to true if the ID matches a command run by *user name*.

Predicates may be abbreviated to the shortest unique string.

Predicates may be combined using *and*, *or*, and *!* operators as well as ‘(’ and ‘)’ grouping (note that parentheses must generally be escaped from the shell). The *and* operator is optional, adjacent predicates have an implied *and* unless separated by an *or*.

-m, --max-wait max_wait

Specify an upper bound on how long to wait between key presses or output data. By default, **sudoreplay** will accurately reproduce the delays between key presses or program output. However, this can be tedious when the session includes long pauses. When the **-m** option is specified, **sudoreplay** will limit these pauses to at most *max_wait* seconds. The value may be specified as a floating point number, e.g., 2.5. A *max_wait* of zero or less will eliminate the pauses entirely.

-n, --non-interactive

Do not prompt for user input or attempt to re-size the terminal. The session is written to the standard output, not directly to the user's terminal.

-R, --no-resize

Do not attempt to re-size the terminal to match the terminal size of the session.

-S, --suspend-wait

Wait while the command was suspended. By default, **sudoreplay** will ignore the time interval between when the command was suspended and when it was resumed. If the **-S** option is specified, **sudoreplay** will wait instead.

-s, --speed speed_factor

This option causes **sudoreplay** to adjust the number of seconds it will wait between key presses or program output. This can be used to slow down or speed up the display. For example, a *speed_factor* of 2 would make the output twice as fast whereas a *speed_factor* of .5 would make the output twice as slow.

-v, --version

Print the **sudoreplay** versions version number and exit.

Date and time format

The time and date may be specified multiple ways, common formats include:

HH:MM:SS am MM/DD/CCYY timezone

24 hour time may be used in place of am/pm.

HH:MM:SS am Month, Day Year timezone

24 hour time may be used in place of am/pm, and month and day names may be abbreviated. Note that month and day of the week names must be specified in English.

CCYY-MM-DD HH:MM:SS

ISO time format

DD Month CCYY HH:MM:SS

The month name may be abbreviated.

Either time or date may be omitted, the am/pm and timezone are optional. If no date is specified, the current day is assumed; if no time is specified, the first second of the specified date is used. The less significant parts of both time and date may also be omitted, in which case zero is assumed.

The following are all valid time and date specifications:

now The current time and date.

tomorrow

Exactly one day from now.

yesterday

24 hours ago.

2 hours ago

2 hours ago.

next Friday

The first second of the Friday in the next (upcoming) week. Not to be confused with "this Friday" which would match the Friday of the current week.

last week

The current time but 7 days ago. This is equivalent to “a week ago”.

a fortnight ago

The current time but 14 days ago.

10:01 am 9/17/2009

10:01 am, September 17, 2009.

10:01 am

10:01 am on the current day.

10 10:00 am on the current day.

9/17/2009

00:00 am, September 17, 2009.

10:01 am Sep 17, 2009

10:01 am, September 17, 2009.

Note that relative time specifications do not always work as expected. For example, the “next” qualifier is intended to be used in conjunction with a day such as “next Monday”. When used with units of weeks, months, years, etc the result will be one more than expected. For example, “next week” will result in a time exactly two weeks from now, which is probably not what was intended. This will be addressed in a future version of **sudoreplay**.

Debugging sudoreplay

sudoreplay versions 1.8.4 and higher support a flexible debugging framework that is configured via Debug lines in the **sudo.conf(5)** file.

For more information on configuring **sudo.conf(5)**, please refer to its manual.

FILES

/etc/sudo.conf	Debugging framework configuration
/var/log/sudo-io	The default I/O log directory.
/var/log/sudo-io/00/00/01/log	Example session log info.
/var/log/sudo-io/00/00/01/log.json	Example session log info (JSON format).
/var/log/sudo-io/00/00/01/stdin	Example session standard input log.
/var/log/sudo-io/00/00/01/stdout	Example session standard output log.
/var/log/sudo-io/00/00/01/stderr	Example session standard error log.
/var/log/sudo-io/00/00/01/ttyin	Example session tty input file.
/var/log/sudo-io/00/00/01/ttyout	Example session tty output file.

```
/var/log/sudo-io/00/00/01/timing  
Example session timing file.
```

Note that the *stdin*, *stdout* and *stderr* files will be empty unless **sudo** was used as part of a pipeline for a particular command.

EXAMPLES

List sessions run by user *millert*:

```
# sudoreplay -l user millert
```

List sessions run by user *bob* with a command containing the string vi:

```
# sudoreplay -l user bob command vi
```

List sessions run by user *jeff* that match a regular expression:

```
# sudoreplay -l user jeff command '/bin/[a-z]*sh'
```

List sessions run by *jeff* or *bob* on the console:

```
# sudoreplay -l ( user jeff or user bob ) tty console
```

NAME

swapon, swapoff – start/stop swapping to file/device

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/swap.h>
int swapon(const char *path, int swapflags);
int swapoff(const char *path);
```

DESCRIPTION

swapon() sets the swap area to the file or block device specified by *path*. **swapoff()** stops swapping to the file or block device specified by *path*.

If the **SWAP_FLAG_PREFER** flag is specified in the **swapon()** *swapflags* argument, the new swap area will have a higher priority than default. The priority is encoded within *swapflags* as:

```
(prio << SWAP_FLAG_PRIO_SHIFT) & SWAP_FLAG_PRIO_MASK
```

If the **SWAP_FLAG_DISCARD** flag is specified in the **swapon()** *swapflags* argument, freed swap pages will be discarded before they are reused, if the swap device supports the discard or trim operation. (This may improve performance on some Solid State Devices, but often it does not.) See also NOTES.

These functions may be used only by a privileged process (one having the **CAP_SYS_ADMIN** capability).

Priority

Each swap area has a priority, either high or low. The default priority is low. Within the low-priority areas, newer areas are even lower priority than older areas.

All priorities set with *swapflags* are high-priority, higher than default. They may have any nonnegative value chosen by the caller. Higher numbers mean higher priority.

Swap pages are allocated from areas in priority order, highest priority first. For areas with different priorities, a higher-priority area is exhausted before using a lower-priority area. If two or more areas have the same priority, and it is the highest priority available, pages are allocated on a round-robin basis between them.

As of Linux 1.3.6, the kernel usually follows these rules, but there are exceptions.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

EBUSY

(for **swapon()**) The specified *path* is already being used as a swap area.

EINVAL

The file *path* exists, but refers neither to a regular file nor to a block device;

EINVAL

(**swapon()**) The indicated path does not contain a valid swap signature or resides on an in-memory filesystem such as **tmpfs**(5).

EINVAL (since Linux 3.4)

(**swapon()**) An invalid flag value was specified in *swapflags*.

EINVAL

(**swapoff()**) *path* is not currently a swap area.

ENFILE

The system-wide limit on the total number of open files has been reached.

ENOENT

The file *path* does not exist.

ENOMEM

The system has insufficient memory to start swapping.

EPERM

The caller does not have the **CAP_SYS_ADMIN** capability. Alternatively, the maximum number of swap files are already in use; see NOTES below.

STANDARDS

These functions are Linux-specific and should not be used in programs intended to be portable. The second *swapflags* argument was introduced in Linux 1.3.2.

NOTES

The partition or path must be prepared with **mkswap(8)**.

There is an upper limit on the number of swap files that may be used, defined by the kernel constant **MAX_SWAPFILES**. Before Linux 2.4.10, **MAX_SWAPFILES** has the value 8; since Linux 2.4.10, it has the value 32. Since Linux 2.6.18, the limit is decreased by 2 (thus: 30) if the kernel is built with the **CONFIG_MIGRATION** option (which reserves two swap table entries for the page migration features of **mbind(2)** and **migrate_pages(2)**). Since Linux 2.6.32, the limit is further decreased by 1 if the kernel is built with the **CONFIG_MEMORY_FAILURE** option. Since Linux 5.14, the limit is further decreased by 4 if the kernel is built with the **CONFIG_DEVICE_PRIVATE** option.

Discard of swap pages was introduced in Linux 2.6.29, then made conditional on the **SWAP_FLAG_DISCARD** flag in Linux 2.6.36, which still discards the entire swap area when **swapon()** is called, even if that flag bit is not set.

NAME

swapon, **swapoff** – enable/disable devices and files for paging and swapping

SYNOPSIS

swapon [options] [*specialfile...*]

swapoff [**-va**] [*specialfile...*]

DESCRIPTION

swapon is used to specify devices on which paging and swapping are to take place.

The device or file used is given by the *specialfile* parameter. It may be of the form **-L** *label* or **-U** *uuid* to indicate a device by label or uuid.

Calls to **swapon** normally occur in the system boot scripts making all swap devices available, so that the paging and swapping activity is interleaved across several devices and files.

swapoff disables swapping on the specified devices and files. When the **-a** flag is given, swapping is disabled on all known swap devices and files (as found in */proc/swaps* or */etc/fstab*).

OPTIONS**-a, --all**

All devices marked as "swap" in */etc/fstab* are made available, except for those with the "noauto" option. Devices that are already being used as swap are silently skipped.

-d, --discard[=policy]

Enable swap discards, if the swap backing device supports the discard or trim operation. This may improve performance on some Solid State Devices, but often it does not. The option allows one to select between two available swap discard policies:

--discard=once

to perform a single-time discard operation for the whole swap area at swapon; or

--discard=pages

to asynchronously discard freed swap pages before they are available for reuse.

If no policy is selected, the default behavior is to enable both discard types. The */etc/fstab* mount options **discard**, **discard=once**, or **discard=pages** may also be used to enable discard flags.

-e, --ifexists

Silently skip devices that do not exist. The */etc/fstab* mount option **nofail** may also be used to skip non-existing device.

-f, --fixpgsz

Reinitialize (exec **mkswap**) the swap space if its page size does not match that of the current running kernel. **mkswap(8)** initializes the whole device and does not check for bad blocks.

-L *label*

Use the partition that has the specified *label*. (For this, access to */proc/partitions* is needed.)

-o, --options *opts*

Specify swap options by an *fstab*-compatible comma-separated string. For example:

swapon -o pri=1,discard=pages,nofail /dev/sda2

The *opts* string is evaluated last and overrides all other command line options.

-p, --priority *priority*

Specify the priority of the swap device. *priority* is a value between -1 and 32767. Higher numbers indicate higher priority. See **swapon(2)** for a full description of swap priorities. Add **pri=value** to the option field of */etc/fstab* for use with **swapon -a**. When no priority is defined, it defaults to -1.

-s, --summary

Display swap usage summary by device. Equivalent to **cat /proc/swaps**. This output format is DEPRECATED in favour of **--show** that provides better control on output data.

--show[=column...]

Display a definable table of swap areas. See the **--help** output for a list of available columns.

--output-all

Output all available columns.

--noheadings

Do not print headings when displaying **--show** output.

--raw

Display **--show** output without aligning table columns.

--bytes

Display swap size in bytes in **--show** output instead of in user-friendly units.

-U *uuid*

Use the partition that has the specified *uuid*.

-v, --verbose

Be verbose.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

EXIT STATUS

swapoff has the following exit status values since v2.36:

0

success

2

system has insufficient memory to stop swapping (OOM)

4

swapoff(2) syscall failed for another reason

8

non-**swapoff(2)** syscall system error (out of memory, ...)

16

usage or syntax error

32

all swapoff failed on **--all**

64

some swapoff succeeded on **--all**

The command **swapoff --all** returns 0 (all succeeded), 32 (all failed), or 64 (some failed, some succeeded).

+ The old versions before v2.36 has no documented exit status, 0 means success in all versions.

ENVIRONMENT

LIBMOUNT_DEBUG=all

enables **libmount** debug output.

LIBBLKID_DEBUG=all

enables **libblkid** debug output.

FILES

/dev/sd??

standard paging devices

/etc/fstab

ascii filesystem description table

NOTES

Files with holes

The swap file implementation in the kernel expects to be able to write to the file directly, without the assistance of the filesystem. This is a problem on files with holes or on copy-on-write files on filesystems like Btrfs.

Commands like **cp(1)** or **truncate(1)** create files with holes. These files will be rejected by **swapon**.

Preallocated files created by **fallocate(1)** may be interpreted as files with holes too depending of the filesystem. Preallocated swap files are supported on XFS since Linux 4.18.

The most portable solution to create a swap file is to use **dd(1)** and */dev/zero*.

Btrfs

Swap files on Btrfs are supported since Linux 5.0 on files with **nocow** attribute. See the **btrfs(5)** manual page for more details.

NFS

Swap over **NFS** may not work.

Suspend

swapon automatically detects and rewrites a swap space signature with old software suspend data (e.g., **S1SUSPEND**, **S2SUSPEND**, ...). The problem is that if we don't do it, then we get data corruption the next time an attempt at unsuspending is made.

HISTORY

The **swapon** command appeared in 4.0BSD.

SEE ALSO

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **swapon** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](#) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

swapon, swapoff – start/stop swapping to file/device

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/swap.h>
int swapon(const char *path, int swapflags);
int swapoff(const char *path);
```

DESCRIPTION

swapon() sets the swap area to the file or block device specified by *path*. **swapoff()** stops swapping to the file or block device specified by *path*.

If the **SWAP_FLAG_PREFER** flag is specified in the **swapon()** *swapflags* argument, the new swap area will have a higher priority than default. The priority is encoded within *swapflags* as:

```
(prio << SWAP_FLAG_PRIO_SHIFT) & SWAP_FLAG_PRIO_MASK
```

If the **SWAP_FLAG_DISCARD** flag is specified in the **swapon()** *swapflags* argument, freed swap pages will be discarded before they are reused, if the swap device supports the discard or trim operation. (This may improve performance on some Solid State Devices, but often it does not.) See also NOTES.

These functions may be used only by a privileged process (one having the **CAP_SYS_ADMIN** capability).

Priority

Each swap area has a priority, either high or low. The default priority is low. Within the low-priority areas, newer areas are even lower priority than older areas.

All priorities set with *swapflags* are high-priority, higher than default. They may have any nonnegative value chosen by the caller. Higher numbers mean higher priority.

Swap pages are allocated from areas in priority order, highest priority first. For areas with different priorities, a higher-priority area is exhausted before using a lower-priority area. If two or more areas have the same priority, and it is the highest priority available, pages are allocated on a round-robin basis between them.

As of Linux 1.3.6, the kernel usually follows these rules, but there are exceptions.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

EBUSY

(for **swapon()**) The specified *path* is already being used as a swap area.

EINVAL

The file *path* exists, but refers neither to a regular file nor to a block device;

EINVAL

(**swapon()**) The indicated path does not contain a valid swap signature or resides on an in-memory filesystem such as **tmpfs**(5).

EINVAL (since Linux 3.4)

(**swapon()**) An invalid flag value was specified in *swapflags*.

EINVAL

(**swapoff()**) *path* is not currently a swap area.

ENFILE

The system-wide limit on the total number of open files has been reached.

ENOENT

The file *path* does not exist.

ENOMEM

The system has insufficient memory to start swapping.

EPERM

The caller does not have the **CAP_SYS_ADMIN** capability. Alternatively, the maximum number of swap files are already in use; see NOTES below.

STANDARDS

These functions are Linux-specific and should not be used in programs intended to be portable. The second *swapflags* argument was introduced in Linux 1.3.2.

NOTES

The partition or path must be prepared with **mkswap(8)**.

There is an upper limit on the number of swap files that may be used, defined by the kernel constant **MAX_SWAPFILES**. Before Linux 2.4.10, **MAX_SWAPFILES** has the value 8; since Linux 2.4.10, it has the value 32. Since Linux 2.6.18, the limit is decreased by 2 (thus: 30) if the kernel is built with the **CONFIG_MIGRATION** option (which reserves two swap table entries for the page migration features of **mbind(2)** and **migrate_pages(2)**). Since Linux 2.6.32, the limit is further decreased by 1 if the kernel is built with the **CONFIG_MEMORY_FAILURE** option. NAME

swapon, **swapoff** – enable/disable devices and files for paging and swapping

SYNOPSIS

swapon [options] [*specialfile...*]

swapoff [-va] [*specialfile...*]

DESCRIPTION

swapon is used to specify devices on which paging and swapping are to take place.

The device or file used is given by the *specialfile* parameter. It may be of the form **-L** *label* or **-U** *uuid* to indicate a device by label or uuid.

Calls to **swapon** normally occur in the system boot scripts making all swap devices available, so that the paging and swapping activity is interleaved across several devices and files.

swapoff disables swapping on the specified devices and files. When the **-a** flag is given, swapping is disabled on all known swap devices and files (as found in */proc/swaps* or */etc/fstab*).

OPTIONS**-a, --all**

All devices marked as "swap" in */etc/fstab* are made available, except for those with the "noauto" option. Devices that are already being used as swap are silently skipped.

-d, --discard[=policy]

Enable swap discards, if the swap backing device supports the discard or trim operation. This may improve performance on some Solid State Devices, but often it does not. The option allows one to select between two available swap discard policies:

--discard=once

to perform a single-time discard operation for the whole swap area at swapon; or

--discard=pages

to asynchronously discard freed swap pages before they are available for reuse.

If no policy is selected, the default behavior is to enable both discard types. The */etc/fstab* mount options **discard**, **discard=once**, or **discard=pages** may also be used to enable discard flags.

-e, --ifexists

Silently skip devices that do not exist. The */etc/fstab* mount option **nofail** may also be used to skip non-existing device.

-f, --fixpgsz

Reinitialize (exec **mkswap**) the swap space if its page size does not match that of the current running kernel. **mkswap(8)** initializes the whole device and does not check for bad blocks.

-L *label*

Use the partition that has the specified *label*. (For this, access to */proc/partitions* is needed.)

-o, --options *opts*

Specify swap options by an *fstab*-compatible comma-separated string. For example:

swapon -o pri=1,discard=pages,nofail /dev/sda2

The *opts* string is evaluated last and overrides all other command line options.

-p, --priority *priority*

Specify the priority of the swap device. *priority* is a value between -1 and 32767. Higher numbers indicate higher priority. See **swapon(2)** for a full description of swap priorities. Add **pri=value** to the option field of */etc/fstab* for use with **swapon -a**. When no priority is defined, it defaults to -1.

-s, --summary

Display swap usage summary by device. Equivalent to **cat /proc/swaps**. This output format is DEPRECATED in favour of **--show** that provides better control on output data.

--show[=column...]

Display a definable table of swap areas. See the **--help** output for a list of available columns.

--output-all

Output all available columns.

--noheadings

Do not print headings when displaying **--show** output.

--raw

Display **--show** output without aligning table columns.

--bytes

Display swap size in bytes in **--show** output instead of in user-friendly units.

-U *uuid*

Use the partition that has the specified *uuid*.

-v, --verbose

Be verbose.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

EXIT STATUS

swapoff has the following exit status values since v2.36:

0

success

2

system has insufficient memory to stop swapping (OOM)

4

swapoff(2) syscall failed for another reason

8

non-**swapoff(2)** syscall system error (out of memory, ...)

16

usage or syntax error

32

all swapoff failed on **--all**

64

some swapoff succeeded on **--all**

The command **swapoff --all** returns 0 (all succeeded), 32 (all failed), or 64 (some failed, some succeeded).

+ The old versions before v2.36 has no documented exit status, 0 means success in all versions.

ENVIRONMENT

LIBMOUNT_DEBUG=all

enables **libmount** debug output.

LIBBLKID_DEBUG=all

enables **libblkid** debug output.

NAME

sysinfo – return system information

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/sysinfo.h>
int sysinfo(struct sysinfo *info);
```

DESCRIPTION

sysinfo() returns certain statistics on memory and swap usage, as well as the load average.

Until Linux 2.3.16, **sysinfo()** returned information in the following structure:

```
struct sysinfo {
    long uptime;           /* Seconds since boot */
    unsigned long loads[3]; /* 1, 5, and 15 minute load averages */
    unsigned long totalram; /* Total usable main memory size */
    unsigned long freeram; /* Available memory size */
    unsigned long sharedram; /* Amount of shared memory */
    unsigned long bufferram; /* Memory used by buffers */
    unsigned long totalswap; /* Total swap space size */
    unsigned long freeswap; /* Swap space still available */
    unsigned short procs; /* Number of current processes */
    char _f[22];           /* Pads structure to 64 bytes */
};
```

In the above structure, the sizes of the memory and swap fields are given in bytes.

Since Linux 2.3.23 (i386) and Linux 2.3.48 (all architectures) the structure is:

```
struct sysinfo {
    long uptime;           /* Seconds since boot */
    unsigned long loads[3]; /* 1, 5, and 15 minute load averages */
    unsigned long totalram; /* Total usable main memory size */
    unsigned long freeram; /* Available memory size */
    unsigned long sharedram; /* Amount of shared memory */
    unsigned long bufferram; /* Memory used by buffers */
    unsigned long totalswap; /* Total swap space size */
    unsigned long freeswap; /* Swap space still available */
    unsigned short procs; /* Number of current processes */
    unsigned long totalhigh; /* Total high memory size */
    unsigned long freehigh; /* Available high memory size */
    unsigned int mem_unit; /* Memory unit size in bytes */
    char _f[20-2*sizeof(long)-sizeof(int)]; /* Padding to 64 bytes */
};
```

In the above structure, sizes of the memory and swap fields are given as multiples of *mem_unit* bytes.

RETURN VALUE

On success, **sysinfo()** returns zero. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS**EFAULT**

info is not a valid address.

VERSIONS

sysinfo() first appeared in Linux 0.98.pl6.

STANDARDS

This function is Linux-specific, and should not be used in programs intended to be portable.

NOTES

All of the information provided by this system call is also available via */proc/meminfo* and */proc/loadavg*.

SEE ALSO

proc(5)

NAME

systemctl – Control the systemd system and service manager

SYNOPSIS

systemctl [OPTIONS...] COMMAND [UNIT...]

DESCRIPTION

systemctl may be used to introspect and control the state of the "systemd" system and service manager.

Please refer to **systemd(1)** for an introduction into the basic concepts and functionality this tool manages.

COMMANDS

The following commands are understood:

Unit Commands (Introspection and Modification)

list-units [*PATTERN...*]

List units that **systemd** currently has in memory. This includes units that are either referenced directly or through a dependency, units that are pinned by applications programmatically, or units that were active in the past and have failed. By default only units which are active, have pending jobs, or have failed are shown; this can be changed with option **--all**. If one or more *PATTERNs* are specified, only units matching one of them are shown. The units that are shown are additionally filtered by **--type=** and **--state=** if those options are specified.

Note that this command does not show unit templates, but only instances of unit templates. Units templates that aren't instantiated are not runnable, and will thus never show up in the output of this command. Specifically this means that *foo@.service* will never be shown in this list — unless instantiated, e.g. as *foo@bar.service*. Use **list-unit-files** (see below) for listing installed unit template files.

Produces output similar to

UNIT	LOAD	ACTIVE	SUB	DESCRIPTION
sys-module-fuse.device	loaded	active	plugged	/sys/module/fuse
-.mount	loaded	active	mounted	Root Mount
boot-efi.mount	loaded	active	mounted	/boot/efi
systemd-journald.service	loaded	active	running	Journal Service
systemd-logind.service	loaded	active	running	Login Service
user@1000.service	loaded	failed	failed	User Manager for UID 1000
...				
systemd-tmpfiles-clean.timer	loaded	active	waiting	Daily Cleanup of Temporary Directories

LOAD = Reflects whether the unit definition was properly loaded.

ACTIVE = The high-level unit activation state, i.e. generalization of **SUB**.

SUB = The low-level unit activation state, values depend on unit type.

123 loaded units listed. Pass **--all** to see loaded but inactive units, too.

To show all installed unit files use '**systemctl list-unit-files**'.

The header and the last unit of a given type are underlined if the terminal supports that. A colored dot is shown next to services which were masked, not found, or otherwise failed.

The LOAD column shows the load state, one of **loaded**, **not-found**, **bad-setting**, **error**, **masked**. The ACTIVE columns shows the general unit state, one of **active**, **reloading**, **inactive**, **failed**, **activating**, **deactivating**. The SUB column shows the unit-type-specific detailed state of the unit, possible values vary by unit type. The list of possible LOAD, ACTIVE, and SUB states is not constant and new systemd releases may both add and remove values.

systemctl --state=help

command maybe be used to display the current set of possible values.

This is the default command.

list-sockets [PATTERN...]

List socket units currently in memory, ordered by listening address. If one or more *PATTERNs* are specified, only socket units matching one of them are shown. Produces output similar to

LISTEN	UNIT	ACTIVATES
/dev/initctl	systemd-initctl.socket	systemd-initctl.service
...		
[::]:22	sshd.socket	sshd.service
kobject-uevent 1	systemd-udevd-kernel.socket	systemd-udevd.service

5 sockets listed.

Note: because the addresses might contains spaces, this output is not suitable for programmatic consumption.

Also see **--show-types**, **--all**, and **--state=**.

list-timers [PATTERN...]

List timer units currently in memory, ordered by the time they elapse next. If one or more *PATTERNs* are specified, only units matching one of them are shown. Produces output similar to

NEXT	LEFT	LAST	PASSED	UNIT	ACTIVATES
n/a	n/a	Thu 2017-02-23 13:40:29 EST	3 days ago	ureadahead-stop.timer	ureadahead-stop.
Sun 2017-02-26 18:55:42 EST	1min 14s left	Thu 2017-02-23 13:54:44 EST	3 days ago	systemd-tmpfiles-clean.	
Sun 2017-02-26 20:37:16 EST	1h 42min left	Sun 2017-02-26 11:56:36 EST	6h ago	apt-daily.timer	ap
Sun 2017-02-26 20:57:49 EST	2h 3min left	Sun 2017-02-26 11:56:36 EST	6h ago	snapd.refresh.timer	sr

NEXT shows the next time the timer will run.

LEFT shows how long till the next time the timer runs.

LAST shows the last time the timer ran.

PASSED shows how long has passed since the timer last ran.

UNIT shows the name of the timer

ACTIVATES shows the name the service the timer activates when it runs.

Also see **--all** and **--state=**.

is-active PATTERN...

Check whether any of the specified units are active (i.e. running). Returns an exit code **0** if at least one is active, or non-zero otherwise. Unless **--quiet** is specified, this will also print the current unit state to standard output.

is-failed PATTERN...

Check whether any of the specified units are in a "failed" state. Returns an exit code **0** if at least one has failed, non-zero otherwise. Unless **--quiet** is specified, this will also print the current unit state to standard output.

status [PATTERN...|PID...]]

Show terse runtime status information about one or more units, followed by most recent log data from the journal. If no units are specified, show system status. If combined with **--all**, also show the status of all units (subject to limitations specified with **-t**). If a PID is passed, show information about the unit the process belongs to.

This function is intended to generate human-readable output. If you are looking for computer-parsable output, use **show** instead. By default, this function only shows 10 lines of output and ellipsizes lines to fit in the terminal window. This can be changed with **--lines** and **--full**, see above. In addition, **journalctl --unit=NAME** or **journalctl --user-unit=NAME** use a similar filter for messages and might be more convenient.

systemd implicitly loads units as necessary, so just running the **status** will attempt to load a file. The command is thus not useful for determining if something was already loaded or not. The units may possibly also be quickly unloaded after the operation is completed if there's no reason to keep it in memory thereafter.

Example 1. Example output from systemctl status

```
$ systemctl status bluetooth
bluetooth.service - Bluetooth service
   Loaded: loaded (/lib/systemd/system/bluetooth.service; enabled; vendor preset: enabled)
     Active: active (running) since Wed 2017-01-04 13:54:04 EST; 1 weeks 0 days ago
       Docs: man:bluetoothd(8)
    Main PID: 930 (bluetoothd)
      Status: "Running"
        Tasks: 1
     Memory: 648.0K
        CPU: 435ms
      CGroup: /system.slice/bluetooth.service
              930 /usr/lib/bluetooth/bluetoothd
```

```
Jan 12 10:46:45 example.com bluetoothd[8900]: Not enough free handles to register service
Jan 12 10:46:45 example.com bluetoothd[8900]: Current Time Service could not be registered
Jan 12 10:46:45 example.com bluetoothd[8900]: gatt-time-server: Input/output error (5)
```

The dot ("") uses color on supported terminals to summarize the unit state at a glance. Along with its color, its shape varies according to its state: "inactive" or "maintenance" is a white circle ("○"), "active" is a green dot ("."), "deactivating" is a white dot, "failed" or "error" is a red cross ("×"), and "reloading" is a green clockwise circle arrow ("").

The "Loaded:" line in the output will show "loaded" if the unit has been loaded into memory. Other possible values for "Loaded:" include: "error" if there was a problem loading it, "not-found" if no unit file was found for this unit, "bad-setting" if an essential unit file setting could not be parsed and "masked" if the unit file has been masked. Along with showing the path to the unit file, this line will also show the enablement state. Enabled commands start at boot. See the full table of possible enablement states — including the definition of "masked" — in the documentation for the **is-enabled** command.

The "Active:" line shows active state. The value is usually "active" or "inactive". Active could mean started, bound, plugged in, etc depending on the unit type. The unit could also be in process of changing states, reporting a state of "activating" or "deactivating". A special "failed" state is entered when the service failed in some way, such as a crash, exiting with an error code or timing out. If the failed state is entered the cause will be logged for later reference.

show [PATTERN...|JOB...]

Show properties of one or more units, jobs, or the manager itself. If no argument is specified,

properties of the manager will be shown. If a unit name is specified, properties of the unit are shown, and if a job ID is specified, properties of the job are shown. By default, empty properties are suppressed. Use **--all** to show those too. To select specific properties to show, use **--property=**. This command is intended to be used whenever computer-parsable output is required. Use **status** if you are looking for formatted human-readable output.

Many properties shown by **systemctl show** map directly to configuration settings of the system and service manager and its unit files. Note that the properties shown by the command are generally more low-level, normalized versions of the original configuration settings and expose runtime state in addition to configuration. For example, properties shown for service units include the service's current main process identifier as "MainPID" (which is runtime state), and time settings are always exposed as properties ending in the "...USec" suffix even if a matching configuration options end in "...Sec", because microseconds is the normalized time unit used internally by the system and service manager.

For details about many of these properties, see the documentation of the D-Bus interface backing these properties, see [org.freedesktop.systemd1\(5\)](#).

cat *PATTERN...*

Show backing files of one or more units. Prints the "fragment" and "drop-ins" (source files) of units. Each file is preceded by a comment which includes the file name. Note that this shows the contents of the backing files on disk, which may not match the system manager's understanding of these units if any unit files were updated on disk and the **daemon-reload** command wasn't issued since.

help *PATTERN...|PID...*

Show manual pages for one or more units, if available. If a PID is given, the manual pages for the unit the process belongs to are shown.

list-dependencies [*UNIT...*]

Shows units required and wanted by the specified units. This recursively lists units following the *Requires=*, *Requisite=*, *ConsistsOf=*, *Wants=*, *BindsTo=* dependencies. If no units are specified, *default.target* is implied.

By default, only target units are recursively expanded. When **--all** is passed, all other units are recursively expanded as well.

Options **--reverse**, **--after**, **--before** may be used to change what types of dependencies are shown.

Note that this command only lists units currently loaded into memory by the service manager. In particular, this command is not suitable to get a comprehensive list at all reverse dependencies on a specific unit, as it won't list the dependencies declared by units currently not loaded.

start *PATTERN...*

Start (activate) one or more units specified on the command line.

Note that unit glob patterns expand to names of units currently in memory. Units which are not active and are not in a failed state usually are not in memory, and will not be matched by any pattern. In addition, in case of instantiated units, systemd is often unaware of the instance name until the instance has been started. Therefore, using glob patterns with **start** has limited usefulness. Also, secondary alias names of units are not considered.

Option **--all** may be used to also operate on inactive units which are referenced by other loaded units. Note that this is not the same as operating on "all" possible units, because as the previous paragraph describes, such a list is ill-defined. Nevertheless, **systemctl start --all GLOB** may be useful if all the units that should match the pattern are pulled in by some target which is known to be loaded.

stop *PATTERN...*

Stop (deactivate) one or more units specified on the command line.

This command will fail if the unit does not exist or if stopping of the unit is prohibited (see `RefuseManualStop=` in [systemd.unit\(5\)](#)). It will *not* fail if any of the commands configured to stop the unit (`ExecStop=`, etc.) fail, because the manager will still forcibly terminate the unit.

reload PATTERN...

Asks all units listed on the command line to reload their configuration. Note that this will reload the service-specific configuration, not the unit configuration file of systemd. If you want systemd to reload the configuration file of a unit, use the **daemon-reload** command. In other words: for the example case of Apache, this will reload Apache's httpd.conf in the web server, not the apache.service systemd unit file.

This command should not be confused with the **daemon-reload** command.

restart PATTERN...

Stop and then start one or more units specified on the command line. If the units are not running yet, they will be started.

Note that restarting a unit with this command does not necessarily flush out all of the unit's resources before it is started again. For example, the per-service file descriptor storage facility (see `FileDescriptorStoreMax=` in [systemd.service\(5\)](#)) will remain intact as long as the unit has a job pending, and is only cleared when the unit is fully stopped and no jobs are pending anymore. If it is intended that the file descriptor store is flushed out, too, during a restart operation an explicit **systemctl stop** command followed by **systemctl start** should be issued.

try-restart PATTERN...

Stop and then start one or more units specified on the command line if the units are running. This does nothing if units are not running.

reload-or-restart PATTERN...

Reload one or more units if they support it. If not, stop and then start them instead. If the units are not running yet, they will be started.

try-reload-or-restart PATTERN...

Reload one or more units if they support it. If not, stop and then start them instead. This does nothing if the units are not running.

isolate UNIT

Start the unit specified on the command line and its dependencies and stop all others, unless they have `IgnoreOnIsolate=yes` (see [systemd.unit\(5\)](#)). If a unit name with no extension is given, an extension of ".target" will be assumed.

This command is dangerous, since it will immediately stop processes that are not enabled in the new target, possibly including the graphical environment or terminal you are currently using.

Note that this is allowed only on units where `AllowIsolate=` is enabled. See [systemd.unit\(5\)](#) for details.

kill PATTERN...

Send a signal to one or more processes of the unit. Use `--kill-who=` to select which process to kill. Use `--signal=` to select the signal to send.

clean PATTERN...

Remove the configuration, state, cache, logs or runtime data of the specified units. Use `--what=` to select which kind of resource to remove. For service units this may be used to remove the directories configured with `ConfigurationDirectory=`, `StateDirectory=`, `CacheDirectory=`, `LogsDirectory=` and `RuntimeDirectory=`, see [systemd.exec\(5\)](#) for details. For timer units this may be used to clear out the persistent timestamp data if `Persistent=` is used and `--what=state` is selected, see [systemd.timer\(5\)](#). This command only applies to units that use either of these settings. If `--what=` is not specified, both the cache and runtime data are removed (as these two types of data are generally redundant and

reproducible on the next invocation of the unit).

freeze PATTERN...

Freeze one or more units specified on the command line using cgroup freezer

Freezing the unit will cause all processes contained within the cgroup corresponding to the unit to be suspended. Being suspended means that unit's processes won't be scheduled to run on CPU until thawed. Note that this command is supported only on systems that use unified cgroup hierarchy. Unit is automatically thawed just before we execute a job against the unit, e.g. before the unit is stopped.

thaw PATTERN...

Thaw (unfreeze) one or more units specified on the command line.

This is the inverse operation to the **freeze** command and resumes the execution of processes in the unit's cgroup.

set–property UNIT PROPERTY=VALUE...

Set the specified unit properties at runtime where this is supported. This allows changing configuration parameter properties such as resource control settings at runtime. Not all properties may be changed at runtime, but many resource control settings (primarily those in **systemd.resource-control(5)**) may. The changes are applied immediately, and stored on disk for future boots, unless **--runtime** is passed, in which case the settings only apply until the next reboot. The syntax of the property assignment follows closely the syntax of assignments in unit files.

Example: **systemctl set–property foobar.service CPUWeight=200**

If the specified unit appears to be inactive, the changes will be only stored on disk as described previously hence they will be effective when the unit will be started.

Note that this command allows changing multiple properties at the same time, which is preferable over setting them individually.

Example: **systemctl set–property foobar.service CPUWeight=200 MemoryMax=2G IPAccounting=yes**

Like with unit file configuration settings, assigning an empty setting usually resets a property to its defaults.

Example: **systemctl set–property avahi–daemon.service IPAddressDeny=**

bind UNIT PATH [PATH]

Bind-mounts a file or directory from the host into the specified unit's mount namespace. The first path argument is the source file or directory on the host, the second path argument is the destination file or directory in the unit's mount namespace. When the latter is omitted, the destination path in the unit's mount namespace is the same as the source path on the host. When combined with the **--read-only** switch, a ready-only bind mount is created. When combined with the **--mkdir** switch, the destination path is first created before the mount is applied.

Note that this option is currently only supported for units that run within a mount namespace (e.g.: with **RootImage=**, **PrivateMounts=**, etc.). This command supports bind-mounting directories, regular files, device nodes, **AF_UNIX** socket nodes, as well as FIFOs. The bind mount is ephemeral, and it is undone as soon as the current unit process exists. Note that the namespace mentioned here, where the bind mount will be added to, is the one where the main service process runs. Other processes (those executed by **ExecReload=**, **ExecStartPre=**, etc.) run in distinct namespaces.

mount–image UNIT IMAGE [PATH [PARTITION_NAME:MOUNT_OPTIONS]]

Mounts an image from the host into the specified unit's mount namespace. The first path argument is

the source image on the host, the second path argument is the destination directory in the unit's mount namespace (i.e. inside **RootImage=/RootDirectory=**). The following argument, if any, is interpreted as a colon-separated tuple of partition name and comma-separated list of mount options for that partition. The format is the same as the service **MountImages=** setting. When combined with the **--read-only** switch, a ready-only mount is created. When combined with the **--mkdir** switch, the destination path is first created before the mount is applied.

Note that this option is currently only supported for units that run within a mount namespace (i.e. with **RootImage=**, **PrivateMounts=**, etc.). Note that the namespace mentioned here where the image mount will be added to, is the one where the main service process runs. Note that the namespace mentioned here, where the bind mount will be added to, is the one where the main service process runs. Other processes (those executed by **ExecReload=**, **ExecStartPre=**, etc.) run in distinct namespaces.

Example:

```
systemctl mount-image foo.service /tmp/img.raw /var/lib/image root:ro,nosuid
```

```
systemctl mount-image --mkdir bar.service /tmp/img.raw /var/lib/baz/img
```

service-log-level *SERVICE [LEVEL]*

If the *LEVEL* argument is not given, print the current log level as reported by service *SERVICE*.

If the optional argument *LEVEL* is provided, then change the current log level of the service to *LEVEL*. The log level should be a typical syslog log level, i.e. a value in the range 0...7 or one of the strings **emerg**, **alert**, **crit**, **err**, **warning**, **notice**, **info**, **debug**; see **syslog(3)** for details.

The service must have the appropriate *BusName=destination* property and also implement the generic **org.freedesktop.LogControl1(5)** interface. (systemctl will use the generic D-Bus protocol to access the **org.freedesktop.LogControl1.LogLevel** interface for the D-Bus name *destination*.)

service-log-target *SERVICE [TARGET]*

If the *TARGET* argument is not given, print the current log target as reported by service *SERVICE*.

If the optional argument *TARGET* is provided, then change the current log target of the service to *TARGET*. The log target should be one of the strings **console** (for log output to the service's standard error stream), **kmsg** (for log output to the kernel log buffer), **journal** (for log output to **systemd-journald.service(8)** using the native journal protocol), **syslog** (for log output to the classic syslog socket /dev/log), **null** (for no log output whatsoever) or **auto** (for an automatically determined choice, typically equivalent to **console** if the service is invoked interactively, and **journal** or **syslog** otherwise).

For most services, only a small subset of log targets make sense. In particular, most "normal" services should only implement **console**, **journal**, and **null**. Anything else is only appropriate for low-level services that are active in very early boot before proper logging is established.

The service must have the appropriate *BusName=destination* property and also implement the generic **org.freedesktop.LogControl1(5)** interface. (systemctl will use the generic D-Bus protocol to access the **org.freedesktop.LogControl1.LogLevel** interface for the D-Bus name *destination*.)

reset-failed [*PATTERN...*]

Reset the "failed" state of the specified units, or if no unit name is passed, reset the state of all units. When a unit fails in some way (i.e. process exiting with non-zero error code, terminating abnormally or timing out), it will automatically enter the "failed" state and its exit code and status is recorded for

introspection by the administrator until the service is stopped/re-started or reset with this command.

In addition to resetting the "failed" state of a unit it also resets various other per-unit properties: the start rate limit counter of all unit types is reset to zero, as is the restart counter of service units. Thus, if a unit's start limit (as configured with *StartLimitIntervalSec=/StartLimitBurst=*) is hit and the unit refuses to be started again, use this command to make it startable again.

Unit File Commands

list-unit-files [*PATTERN...*]

List unit files installed on the system, in combination with their enablement state (as reported by **is-enabled**). If one or more *PATTERNs* are specified, only unit files whose name matches one of them are shown (patterns matching unit file system paths are not supported).

Unlike **list-units** this command will list template units in addition to explicitly instantiated units.

enable *UNIT...*, **enable** *PATH...*

Enable one or more units or unit instances. This will create a set of symlinks, as encoded in the [Install] sections of the indicated unit files. After the symlinks have been created, the system manager configuration is reloaded (in a way equivalent to **daemon-reload**), in order to ensure the changes are taken into account immediately. Note that this does *not* have the effect of also starting any of the units being enabled. If this is desired, combine this command with the **--now** switch, or invoke **start** with appropriate arguments later. Note that in case of unit instance enablement (i.e. enablement of units of the form *foo@bar.service*), symlinks named the same as instances are created in the unit configuration directory, however they point to the single template unit file they are instantiated from.

This command expects either valid unit names (in which case various unit file directories are automatically searched for unit files with appropriate names), or absolute paths to unit files (in which case these files are read directly). If a specified unit file is located outside of the usual unit file directories, an additional symlink is created, linking it into the unit configuration path, thus ensuring it is found when requested by commands such as **start**. The file system where the linked unit files are located must be accessible when systemd is started (e.g. anything underneath /home/ or /var/ is not allowed, unless those directories are located on the root file system).

This command will print the file system operations executed. This output may be suppressed by passing **--quiet**.

Note that this operation creates only the symlinks suggested in the [Install] section of the unit files. While this command is the recommended way to manipulate the unit configuration directory, the administrator is free to make additional changes manually by placing or removing symlinks below this directory. This is particularly useful to create configurations that deviate from the suggested default installation. In this case, the administrator must make sure to invoke **daemon-reload** manually as necessary, in order to ensure the changes are taken into account.

Enabling units should not be confused with starting (activating) units, as done by the **start** command. Enabling and starting units is orthogonal: units may be enabled without being started and started without being enabled. Enabling simply hooks the unit into various suggested places (for example, so that the unit is automatically started on boot or when a particular kind of hardware is plugged in). Starting actually spawns the daemon process (in case of service units), or binds the socket (in case of socket units), and so on.

Depending on whether **--system**, **--user**, **--runtime**, or **--global** is specified, this enables the unit for the system, for the calling user only, for only this boot of the system, or for all future logins of all users. Note that in the last case, no systemd daemon configuration is reloaded.

Using **enable** on masked units is not supported and results in an error.

disable *UNIT...*

Disables one or more units. This removes all symlinks to the unit files backing the specified units from the unit configuration directory, and hence undoes any changes made by **enable** or **link**. Note that this removes *all* symlinks to matching unit files, including manually created symlinks, and not just those actually created by **enable** or **link**. Note that while **disable** undoes the effect of **enable**, the two commands are otherwise not symmetric, as **disable** may remove more symlinks than a prior **enable** invocation of the same unit created.

This command expects valid unit names only, it does not accept paths to unit files.

In addition to the units specified as arguments, all units are disabled that are listed in the *Also=* setting contained in the [Install] section of any of the unit files being operated on.

This command implicitly reloads the system manager configuration after completing the operation. Note that this command does not implicitly stop the units that are being disabled. If this is desired, either combine this command with the **--now** switch, or invoke the **stop** command with appropriate arguments later.

This command will print information about the file system operations (symlink removals) executed. This output may be suppressed by passing **--quiet**.

This command honors **--system**, **--user**, **--runtime** and **--global** in a similar way as **enable**.

reenable *UNIT...*

Reenable one or more units, as specified on the command line. This is a combination of **disable** and **enable** and is useful to reset the symlinks a unit file is enabled with to the defaults configured in its [Install] section. This command expects a unit name only, it does not accept paths to unit files.

preset *UNIT...*

Reset the enable/disable status one or more unit files, as specified on the command line, to the defaults configured in the preset policy files. This has the same effect as **disable** or **enable**, depending how the unit is listed in the preset files.

Use **--preset-mode=** to control whether units shall be enabled and disabled, or only enabled, or only disabled.

If the unit carries no install information, it will be silently ignored by this command. *UNIT* must be the real unit name, any alias names are ignored silently.

For more information on the preset policy format, see **systemd.preset(5)**.

preset-all

Resets all installed unit files to the defaults configured in the preset policy file (see above).

Use **--preset-mode=** to control whether units shall be enabled and disabled, or only enabled, or only disabled.

is-enabled *UNIT...*

Checks whether any of the specified unit files are enabled (as with **enable**). Returns an exit code of 0 if at least one is enabled, non-zero otherwise. Prints the current enable status (see table). To suppress this output, use **--quiet**. To show installation targets, use **--full**.

Table 1. is-enabled output

mask *UNIT...*

Mask one or more units, as specified on the command line. This will link these unit files to /dev/null, making it impossible to start them. This is a stronger version of **disable**, since it prohibits all kinds of activation of the unit, including enablement and manual activation. Use this option with care. This honors the **--runtime** option to only mask temporarily until the next reboot of the system. The **--now** option may be used to ensure that the units are also stopped. This command expects valid unit names only, it does not accept unit file paths.

unmask *UNIT...*

Unmask one or more unit files, as specified on the command line. This will undo the effect of **mask**. This command expects valid unit names only, it does not accept unit file paths.

link *PATH...*

Link a unit file that is not in the unit file search paths into the unit file search path. This command expects an absolute path to a unit file. The effect of this may be undone with **disable**. The effect of this command is that a unit file is made available for commands such as **start**, even though it is not installed directly in the unit search path. The file system where the linked unit files are located must be accessible when systemd is started (e.g. anything underneath /home/ or /var/ is not allowed, unless those directories are located on the root file system).

revert *UNIT...*

Revert one or more unit files to their vendor versions. This command removes drop-in configuration files that modify the specified units, as well as any user-configured unit file that overrides a matching vendor supplied unit file. Specifically, for a unit "foo.service" the matching directories "foo.service.d/" with all their contained files are removed, both below the persistent and runtime configuration directories (i.e. below /etc/systemd/system and /run/systemd/system); if the unit file has a vendor-supplied version (i.e. a unit file located below /usr/) any matching persistent or runtime unit file that overrides it is removed, too. Note that if a unit file has no vendor-supplied version (i.e. is only defined below /etc/systemd/system or /run/systemd/system, but not in a unit file stored below /usr/), then it is not removed. Also, if a unit is masked, it is unmasked.

Effectively, this command may be used to undo all changes made with **systemctl edit**, **systemctl set-property** and **systemctl mask** and puts the original unit file with its settings back in effect.

add-wants *TARGET UNIT...*, **add-requires** *TARGET UNIT...*

Adds "Wants=" or "Requires=" dependencies, respectively, to the specified *TARGET* for one or more units.

This command honors **--system**, **--user**, **--runtime** and **--global** in a way similar to **enable**.

edit *UNIT...*

Edit a drop-in snippet or a whole replacement file if **--full** is specified, to extend or override the specified unit.

Depending on whether **--system** (the default), **--user**, or **--global** is specified, this command creates a drop-in file for each unit either for the system, for the calling user, or for all future logins of all users. Then, the editor (see the "Environment" section below) is invoked on temporary files which will be written to the real location if the editor exits successfully.

If **--full** is specified, this will copy the original units instead of creating drop-in files.

If **--force** is specified and any units do not already exist, new unit files will be opened for editing.

If **--runtime** is specified, the changes will be made temporarily in /run/ and they will be lost on the next reboot.

If the temporary file is empty upon exit, the modification of the related unit is canceled.

After the units have been edited, systemd configuration is reloaded (in a way that is equivalent to **daemon-reload**).

Note that this command cannot be used to remotely edit units and that you cannot temporarily edit units which are in /etc/, since they take precedence over /run/.

get-default

Return the default target to boot into. This returns the target unit name default.target is aliased (symlinked) to.

set-default TARGET

Set the default target to boot into. This sets (symlinks) the default.target alias to the given target unit.

Machine Commands

list-machines [PATTERN...]

List the host and all running local containers with their state. If one or more *PATTERNs* are specified, only containers matching one of them are shown.

Job Commands

list-jobs [PATTERN...]

List jobs that are in progress. If one or more *PATTERNs* are specified, only jobs for units matching one of them are shown.

When combined with **--after** or **--before** the list is augmented with information on which other job each job is waiting for, and which other jobs are waiting for it, see above.

cancel JOB...

Cancel one or more jobs specified on the command line by their numeric job IDs. If no job ID is specified, cancel all pending jobs.

Environment Commands

systemd supports an environment block that is passed to processes the manager spawns. The names of the variables can contain ASCII letters, digits, and the underscore character. Variable names cannot be empty or start with a digit. In variable values, most characters are allowed, but the whole sequence must be valid UTF-8. (Note that control characters like newline (**NL**), tab (**TAB**), or the escape character (**ESC**), are valid ASCII and thus valid UTF-8). The total length of the environment block is limited to **_SC_ARG_MAX** value defined by **sysconf(3)**.

show-environment

Dump the systemd manager environment block. This is the environment block that is passed to all processes the manager spawns. The environment block will be dumped in straight-forward form suitable for sourcing into most shells. If no special characters or whitespace is present in the variable values, no escaping is performed, and the assignments have the form "VARIABLE=value". If whitespace or characters which have special meaning to the shell are present, dollar-single-quote escaping is used, and assignments have the form "VARIABLE=\$'value'". This syntax is known to be supported by **bash(1)**, **zsh(1)**, **ksh(1)**, and **busybox(1)**'s **ash(1)**, but not **dash(1)** or **fish(1)**.

set-environment VARIABLE=VALUE...

Set one or more systemd manager environment variables, as specified on the command line. This command will fail if variable names and values do not conform to the rules listed above.

unset-environment VARIABLE...

Unset one or more systemd manager environment variables. If only a variable name is specified, it will be removed regardless of its value. If a variable and a value are specified, the variable is only removed if it has the specified value.

import-environment VARIABLE...

Import all, one or more environment variables set on the client into the systemd manager environment block. If a list of environment variable names is passed, client-side values are then imported into the manager's environment block. If any names are not valid environment variable names or have invalid

values according to the rules described above, an error is raised. If no arguments are passed, the entire environment block inherited by the **systemctl** process is imported. In this mode, any inherited invalid environment variables are quietly ignored.

Importing of the full inherited environment block (calling this command without any arguments) is deprecated. A shell will set dozens of variables which only make sense locally and are only meant for processes which are descendants of the shell. Such variables in the global environment block are confusing to other processes.

Manager State Commands

daemon-reload

Reload the systemd manager configuration. This will rerun all generators (see **systemd.generator(7)**), reload all unit files, and recreate the entire dependency tree. While the daemon is being reloaded, all sockets systemd listens on behalf of user configuration will stay accessible.

This command should not be confused with the **reload** command.

daemon-reeexec

Reexecute the systemd manager. This will serialize the manager state, reexecute the process and deserialize the state again. This command is of little use except for debugging and package upgrades. Sometimes, it might be helpful as a heavy-weight **daemon-reload**. While the daemon is being reexecuted, all sockets systemd listening on behalf of user configuration will stay accessible.

log-level [LEVEL]

If no argument is given, print the current log level of the manager. If an optional argument *LEVEL* is provided, then the command changes the current log level of the manager to *LEVEL* (accepts the same values as **--log-level=** described in **systemd(1)**).

log-target [TARGET]

If no argument is given, print the current log target of the manager. If an optional argument *TARGET* is provided, then the command changes the current log target of the manager to *TARGET* (accepts the same values as **--log-target=**, described in **systemd(1)**).

service-watchdogs [yes|no]

If no argument is given, print the current state of service runtime watchdogs of the manager. If an optional boolean argument is provided, then globally enables or disables the service runtime watchdogs (**WatchdogSec=**) and emergency actions (e.g. **OnFailure=** or **StartLimitAction=**); see **systemd.service(5)**. The hardware watchdog is not affected by this setting.

System Commands

is-system-running

Checks whether the system is operational. This returns success (exit code 0) when the system is fully up and running, specifically not in startup, shutdown or maintenance mode, and with no failed services. Failure is returned otherwise (exit code non-zero). In addition, the current state is printed in a short string to standard output, see the table below. Use **--quiet** to suppress this output.

Use **--wait** to wait until the boot process is completed before printing the current state and returning the appropriate error status. If **--wait** is in use, states *initializing* or *starting* will not be reported, instead the command will block until a later state (such as *running* or *degraded*) is reached.

Table 2. is-system-running output

Name	Description	Exit Code
<i>initializing</i>	Early bootup, before basic.target is reached or the <i>maintenance</i> state entered.	> 0
<i>starting</i>	Late bootup, before the job queue becomes idle for the first time, or one of the rescue targets are reached.	> 0
<i>running</i>	The system is fully operational.	0
<i>degraded</i>	The system is operational but one or more units failed.	> 0
<i>maintenance</i>	The rescue or emergency target is active.	> 0
<i>stopping</i>	The manager is shutting down.	> 0
<i>offline</i>	The manager is not running. Specifically, this is the operational state if an incompatible program is running as system manager (PID 1).	> 0
<i>unknown</i>	The operational state could not be determined, due to lack of resources or another error cause.	> 0

default

Enter default mode. This is equivalent to **systemctl isolate default.target**. This operation is blocking by default, use **--no-block** to request asynchronous behavior.

rescue

Enter rescue mode. This is equivalent to **systemctl isolate rescue.target**. This operation is blocking by default, use **--no-block** to request asynchronous behavior.

emergency

Enter emergency mode. This is equivalent to **systemctl isolate emergency.target**. This operation is blocking by default, use **--no-block** to request asynchronous behavior.

halt

Shut down and halt the system. This is mostly equivalent to **systemctl start halt.target --job-mode=replace-irreversibly --no-block**, but also prints a wall message to all users. This command is asynchronous; it will return after the halt operation is enqueued, without waiting for it to complete. Note that this operation will simply halt the OS kernel after shutting down, leaving the hardware powered on. Use **systemctl poweroff** for powering off the system (see below).

If combined with **--force**, shutdown of all running services is skipped, however all processes are killed and all file systems are unmounted or mounted read-only, immediately followed by the system halt. If **--force** is specified twice, the operation is immediately executed without terminating any processes or unmounting any file systems. This may result in data loss. Note that when **--force** is specified twice the halt operation is executed by **systemctl** itself, and the system manager is not contacted. This means the command should succeed even when the system manager has crashed.

poweroff

Shut down and power-off the system. This is mostly equivalent to **systemctl start poweroff.target**

--job-mode=replace-irreversibly --no-block, but also prints a wall message to all users. This command is asynchronous; it will return after the power-off operation is enqueued, without waiting for it to complete.

If combined with **--force**, shutdown of all running services is skipped, however all processes are killed and all file systems are unmounted or mounted read-only, immediately followed by the powering off. If **--force** is specified twice, the operation is immediately executed without terminating any processes or unmounting any file systems. This may result in data loss. Note that when **--force** is specified twice the power-off operation is executed by **systemctl** itself, and the system manager is not contacted. This means the command should succeed even when the system manager has crashed.

reboot

Shut down and reboot the system. This is mostly equivalent to **systemctl start reboot.target** **--job-mode=replace-irreversibly --no-block**, but also prints a wall message to all users. This command is asynchronous; it will return after the reboot operation is enqueued, without waiting for it to complete.

If combined with **--force**, shutdown of all running services is skipped, however all processes are killed and all file systems are unmounted or mounted read-only, immediately followed by the reboot. If **--force** is specified twice, the operation is immediately executed without terminating any processes or unmounting any file systems. This may result in data loss. Note that when **--force** is specified twice the reboot operation is executed by **systemctl** itself, and the system manager is not contacted. This means the command should succeed even when the system manager has crashed.

If the switch **--reboot-argument=** is given, it will be passed as the optional argument to the **reboot(2)** system call.

kexec

Shut down and reboot the system via **kexec**. This is equivalent to **systemctl start kexec.target** **--job-mode=replace-irreversibly --no-block**. This command is asynchronous; it will return after the reboot operation is enqueued, without waiting for it to complete.

If combined with **--force**, shutdown of all running services is skipped, however all processes are killed and all file systems are unmounted or mounted read-only, immediately followed by the reboot.

exit [*EXIT_CODE*]

Ask the service manager to quit. This is only supported for user service managers (i.e. in conjunction with the **--user** option) or in containers and is equivalent to **poweroff** otherwise. This command is asynchronous; it will return after the exit operation is enqueued, without waiting for it to complete.

The service manager will exit with the specified exit code, if *EXIT_CODE* is passed.

switch-root *ROOT* [*INIT*]

Switches to a different root directory and executes a new system manager process below it. This is intended for usage in initial RAM disks ("initrd"), and will transition from the initrd's system manager process (a.k.a. "init" process) to the main system manager process which is loaded from the actual host volume. This call takes two arguments: the directory that is to become the new root directory, and the path to the new system manager binary below it to execute as PID 1. If the latter is omitted or the empty string, a systemd binary will automatically be searched for and used as init. If the system manager path is omitted, equal to the empty string or identical to the path to the systemd binary, the state of the initrd's system manager process is passed to the main system manager, which allows later introspection of the state of the services involved in the initrd boot phase.

suspend

Suspend the system. This will trigger activation of the special target unit **suspend.target**. This command is asynchronous, and will return after the suspend operation is successfully enqueued. It will not wait for the suspend/resume cycle to complete.

hibernate

Hibernate the system. This will trigger activation of the special target unit hibernate.target. This command is asynchronous, and will return after the hibernation operation is successfully enqueued. It will not wait for the hibernate/thaw cycle to complete.

hybrid-sleep

Hibernate and suspend the system. This will trigger activation of the special target unit hybrid-sleep.target. This command is asynchronous, and will return after the hybrid sleep operation is successfully enqueued. It will not wait for the sleep/wake-up cycle to complete.

suspend-then-hibernate

Suspend the system and hibernate it after the delay specified in systemd-sleep.conf. This will trigger activation of the special target unit suspend-then-hibernate.target. This command is asynchronous, and will return after the hybrid sleep operation is successfully enqueued. It will not wait for the sleep/wake-up or hibernate/thaw cycle to complete.

Parameter Syntax

Unit commands listed above take either a single unit name (designated as *UNIT*), or multiple unit specifications (designated as *PATTERN...*). In the first case, the unit name with or without a suffix must be given. If the suffix is not specified (unit name is "abbreviated"), systemctl will append a suitable suffix, ".service" by default, and a type-specific suffix in case of commands which operate only on specific unit types. For example,

```
# systemctl start sshd
```

and

```
# systemctl start sshd.service
```

are equivalent, as are

```
# systemctl isolate default
```

and

```
# systemctl isolate default.target
```

Note that (absolute) paths to device nodes are automatically converted to device unit names, and other (absolute) paths to mount unit names.

```
# systemctl status /dev/sda
# systemctl status /home
```

are equivalent to:

```
# systemctl status dev-sda.device
# systemctl status home.mount
```

In the second case, shell-style globs will be matched against the primary names of all units currently in memory; literal unit names, with or without a suffix, will be treated as in the first case. This means that literal unit names always refer to exactly one unit, but globs may match zero units and this is not considered an error.

Glob patterns use **fnmatch(3)**, so normal shell-style globbing rules are used, and "*", "?", "[]" may be used. See **glob(7)** for more details. The patterns are matched against the primary names of units currently in memory, and patterns which do not match anything are silently skipped. For example:

```
# systemctl stop sshd@*.service
```

will stop all sshd@.service instances. Note that alias names of units, and units that aren't in memory are not considered for glob expansion.

For unit file commands, the specified *UNIT* should be the name of the unit file (possibly abbreviated, see above), or the absolute path to the unit file:

```
# systemctl enable foo.service
```

or

```
# systemctl link /path/to/foo.service
```

OPTIONS

The following options are understood:

-t, --type=

The argument should be a comma-separated list of unit types such as **service** and **socket**.

If one of the arguments is a unit type, when listing units, limit display to certain unit types. Otherwise, units of all types will be shown.

As a special case, if one of the arguments is **help**, a list of allowed values will be printed and the program will exit.

--state=

The argument should be a comma-separated list of unit LOAD, SUB, or ACTIVE states. When listing units, show only those in the specified states. Use **--state=failed** to show only failed units.

As a special case, if one of the arguments is **help**, a list of allowed values will be printed and the program will exit.

-p, --property=

When showing unit/job/manager properties with the **show** command, limit display to properties specified in the argument. The argument should be a comma-separated list of property names, such as "MainPID". Unless specified, all known properties are shown. If specified more than once, all properties with the specified names are shown. Shell completion is implemented for property names.

For the manager itself, **systemctl show** will show all available properties, most of which are derived or closely match the options described in **systemd-system.conf(5)**.

Properties for units vary by unit type, so showing any unit (even a non-existent one) is a way to list properties pertaining to this type. Similarly, showing any job will list properties pertaining to all jobs. Properties for units are documented in **systemd.unit(5)**, and the pages for individual unit types **systemd.service(5)**, **systemd.socket(5)**, etc.

-P

Equivalent to **--value --property=**, i.e. shows the value of the property without the property name or "**=**". Note that using **-P** once will also affect all properties listed with **-p/--property=**.

-a, --all

When listing units with **list-units**, also show inactive units and units which are following other units. When showing unit/job/manager properties, show all properties regardless whether they are set or not.

To list all units installed in the file system, use the **list-unit-files** command instead.

When listing units with **list-dependencies**, recursively show dependencies of all dependent units (by

default only dependencies of target units are shown).

When used with **status**, show journal messages in full, even if they include unprintable characters or are very long. By default, fields with unprintable characters are abbreviated as "blob data". (Note that the pager may escape unprintable characters again.)

-r, --recursive

When listing units, also show units of local containers. Units of local containers will be prefixed with the container name, separated by a single colon character ("!").

--reverse

Show reverse dependencies between units with **list-dependencies**, i.e. follow dependencies of type *WantedBy=*, *RequiredBy=*, *PartOf=*, *BoundBy=*, instead of *Wants=* and similar.

--after

With **list-dependencies**, show the units that are ordered before the specified unit. In other words, recursively list units following the *After=* dependency.

Note that any *After=* dependency is automatically mirrored to create a *Before=* dependency. Temporal dependencies may be specified explicitly, but are also created implicitly for units which are *WantedBy=* targets (see **systemd.target(5)**), and as a result of other directives (for example *RequiresMountsFor=*). Both explicitly and implicitly introduced dependencies are shown with **list-dependencies**.

When passed to the **list-jobs** command, for each printed job show which other jobs are waiting for it. May be combined with **--before** to show both the jobs waiting for each job as well as all jobs each job is waiting for.

--before

With **list-dependencies**, show the units that are ordered after the specified unit. In other words, recursively list units following the *Before=* dependency.

When passed to the **list-jobs** command, for each printed job show which other jobs it is waiting for. May be combined with **--after** to show both the jobs waiting for each job as well as all jobs each job is waiting for.

--with-dependencies

When used with **status**, **cat**, **list-units**, and **list-unit-files**, those commands print all specified units and the dependencies of those units.

Options **--reverse**, **--after**, **--before** may be used to change what types of dependencies are shown.

-l, --full

Do not ellipsize unit names, process tree entries, journal output, or truncate unit descriptions in the output of **status**, **list-units**, **list-jobs**, and **list-timers**.

Also, show installation targets in the output of **is-enabled**.

--value

When printing properties with **show**, only print the value, and skip the property name and "*=*". Also see option **-P** above.

--show-types

When showing sockets, show the type of the socket.

--job-mode

When queuing a new job, this option controls how to deal with already queued jobs. It takes one of "fail", "replace", "replace-irreversibly", "isolate", "ignore-dependencies", "ignore-requirements", "flush", or "triggering". Defaults to "replace", except when the **isolate** command is used which implies the "isolate" job mode.

If "fail" is specified and a requested operation conflicts with a pending job (more specifically: causes an already pending start job to be reversed into a stop job or vice versa), cause the operation to fail.

If "replace" (the default) is specified, any conflicting pending job will be replaced, as necessary.

If "replace-irreversibly" is specified, operate like "replace", but also mark the new jobs as irreversible. This prevents future conflicting transactions from replacing these jobs (or even being enqueued while the irreversible jobs are still pending). Irreversible jobs can still be cancelled using the **cancel** command. This job mode should be used on any transaction which pulls in shutdown.target.

"isolate" is only valid for start operations and causes all other units to be stopped when the specified unit is started. This mode is always used when the **isolate** command is used.

"flush" will cause all queued jobs to be canceled when the new job is enqueued.

If "ignore-dependencies" is specified, then all unit dependencies are ignored for this new job and the operation is executed immediately. If passed, no required units of the unit passed will be pulled in, and no ordering dependencies will be honored. This is mostly a debugging and rescue tool for the administrator and should not be used by applications.

"ignore-requirements" is similar to "ignore-dependencies", but only causes the requirement dependencies to be ignored, the ordering dependencies will still be honored.

"triggering" may only be used with **systemctl stop**. In this mode, the specified unit and any active units that trigger it are stopped. See the discussion of *Triggers=* in **systemd.unit(5)** for more information about triggering units.

-T, --show-transaction

When enqueueing a unit job (for example as effect of a **systemctl start** invocation or similar), show brief information about all jobs enqueued, covering both the requested job and any added because of unit dependencies. Note that the output will only include jobs immediately part of the transaction requested. It is possible that service start-up program code run as effect of the enqueued jobs might request further jobs to be pulled in. This means that completion of the listed jobs might ultimately entail more jobs than the listed ones.

--fail

Shorthand for **--job-mode=fail**.

When used with the **kill** command, if no units were killed, the operation results in an error.

--check-inhibitors=

When system shutdown or sleep state is request, this option controls how to deal with inhibitor locks. It takes one of "auto", "yes" or "no". Defaults to "auto", which will behave like "yes" for interactive invocations (i.e. from a TTY) and "no" for non-interactive invocations. "yes" will let the request respect inhibitor locks. "no" will let the request ignore inhibitor locks.

Applications can establish inhibitor locks to avoid that certain important operations (such as CD burning or suchlike) are interrupted by system shutdown or a sleep state. Any user may take these locks and privileged users may override these locks. If any locks are taken, shutdown and sleep state requests will normally fail (unless privileged) and a list of active locks is printed. However, if "no" is specified or "auto" is specified on a non-interactive requests, the established locks are ignored and not shown, and the operation attempted anyway, possibly requiring additional privileges. May be overridden by **--force**.

-i

Shortcut for **--check-inhibitors=no**.

--dry-run

Just print what would be done. Currently supported by verbs **halt**, **poweroff**, **reboot**, **kexec**, **suspend**, **hibernate**, **hybrid-sleep**, **suspend-then-hibernate**, **default**, **rescue**, **emergency**, and **exit**.

--q, --quiet

Suppress printing of the results of various commands and also the hints about truncated log lines. This does not suppress output of commands for which the printed output is the only result (like **show**). Errors are always printed.

--no-block

Do not synchronously wait for the requested operation to finish. If this is not specified, the job will be verified, enqueued and **systemctl** will wait until the unit's start-up is completed. By passing this argument, it is only verified and enqueued. This option may not be combined with **--wait**.

--wait

Synchronously wait for started units to terminate again. This option may not be combined with **--no-block**. Note that this will wait forever if any given unit never terminates (by itself or by getting stopped explicitly); particularly services which use "RemainAfterExit=yes".

When used with **is-system-running**, wait until the boot process is completed before returning.

--user

Talk to the service manager of the calling user, rather than the service manager of the system.

--system

Talk to the service manager of the system. This is the implied default.

--failed

List units in failed state. This is equivalent to **--state=failed**.

--no-wall

Do not send wall message before halt, power-off and reboot.

--global

When used with **enable** and **disable**, operate on the global user configuration directory, thus enabling or disabling a unit file globally for all future logins of all users.

--no-reload

When used with **enable** and **disable**, do not implicitly reload daemon configuration after executing the changes.

--no-ask-password

When used with **start** and related commands, disables asking for passwords. Background services may require input of a password or passphrase string, for example to unlock system hard disks or cryptographic certificates. Unless this option is specified and the command is invoked from a terminal, **systemctl** will query the user on the terminal for the necessary secrets. Use this option to switch this behavior off. In this case, the password must be supplied by some other means (for example graphical password agents) or the service might fail. This also disables querying the user for authentication for privileged operations.

--kill-who=

When used with **kill**, choose which processes to send a signal to. Must be one of **main**, **control** or **all** to select whether to kill only the main process, the control process or all processes of the unit. The main process of the unit is the one that defines the life-time of it. A control process of a unit is one that is invoked by the manager to induce state changes of it. For example, all processes started due to the *ExecStartPre=*, *ExecStop=* or *ExecReload=* settings of service units are control processes. Note that there is only one control process per unit at a time, as only one state change is executed at a time. For services of type *Type=forking*, the initial process started by the manager for *ExecStart=* is a control process, while the process ultimately forked off by that one is then considered the main process of the unit (if it can be determined). This is different for service units of other types, where the process forked off by the manager for *ExecStart=* is always the main process itself. A service unit consists of zero or one main process, zero or one control process plus any number of additional

processes. Not all unit types manage processes of these types however. For example, for mount units, control processes are defined (which are the invocations of `/bin/mount` and `/bin/umount`), but no main process is defined. If omitted, defaults to **all**.

-s, --signal=

When used with **kill**, choose which signal to send to selected processes. Must be one of the well-known signal specifiers such as **SIGTERM**, **SIGINT** or **SIGSTOP**. If omitted, defaults to **SIGTERM**.

The special value "help" will list the known values and the program will exit immediately, and the special value "list" will list known values along with the numerical signal numbers and the program will exit immediately.

--what=

Select what type of per-unit resources to remove when the **clean** command is invoked, see below. Takes one of **configuration**, **state**, **cache**, **logs**, **runtime** to select the type of resource. This option may be specified more than once, in which case all specified resource types are removed. Also accepts the special value **all** as a shortcut for specifying all five resource types. If this option is not specified defaults to the combination of **cache** and **runtime**, i.e. the two kinds of resources that are generally considered to be redundant and can be reconstructed on next invocation.

-f, --force

When used with **enable**, overwrite any existing conflicting symlinks.

When used with **edit**, create all of the specified units which do not already exist.

When used with **halt**, **poweroff**, **reboot** or **kexec**, execute the selected operation without shutting down all units. However, all processes will be killed forcibly and all file systems are unmounted or remounted read-only. This is hence a drastic but relatively safe option to request an immediate reboot. If **--force** is specified twice for these operations (with the exception of **kexec**), they will be executed immediately, without terminating any processes or unmounting any file systems. Warning: specifying **--force** twice with any of these operations might result in data loss. Note that when **--force** is specified twice the selected operation is executed by **systemctl** itself, and the system manager is not contacted. This means the command should succeed even when the system manager has crashed.

--message=

When used with **halt**, **poweroff** or **reboot**, set a short message explaining the reason for the operation. The message will be logged together with the default shutdown message.

--now

When used with **enable**, the units will also be started. When used with **disable** or **mask**, the units will also be stopped. The start or stop operation is only carried out when the respective enable or disable operation has been successful.

--root=

When used with **enable/disable/is-enabled** (and related commands), use the specified root path when looking for unit files. If this option is present, **systemctl** will operate on the file system directly, instead of communicating with the **systemd** daemon to carry out changes.

--runtime

When used with **enable**, **disable**, **edit**, (and related commands), make changes only temporarily, so that they are lost on the next reboot. This will have the effect that changes are not made in subdirectories of `/etc/` but in `/run/`, with identical immediate effects, however, since the latter is lost on reboot, the changes are lost too.

Similarly, when used with **set-property**, make changes only temporarily, so that they are lost on the next reboot.

--preset-mode=

Takes one of "full" (the default), "enable-only", "disable-only". When used with the **preset** or **preset-all** commands, controls whether units shall be disabled and enabled according to the preset rules, or only enabled, or only disabled.

-n, --lines=

When used with **status**, controls the number of journal lines to show, counting from the most recent ones. Takes a positive integer argument, or 0 to disable journal output. Defaults to 10.

-o, --output=

When used with **status**, controls the formatting of the journal entries that are shown. For the available choices, see **journalctl(1)**. Defaults to "short".

--firmware-setup

When used with the **reboot** command, indicate to the system's firmware to reboot into the firmware setup interface. Note that this functionality is not available on all systems.

--boot-loader-menu=

When used with the **reboot** command, indicate to the system's boot loader to show the boot loader menu on the following boot. Takes a time value as parameter — indicating the menu timeout. Pass zero in order to disable the menu timeout. Note that not all boot loaders support this functionality.

--boot-loader-entry=

When used with the **reboot** command, indicate to the system's boot loader to boot into a specific boot loader entry on the following boot. Takes a boot loader entry identifier as argument, or "help" in order to list available entries. Note that not all boot loaders support this functionality.

--reboot-argument=

This switch is used with **reboot**. The value is architecture and firmware specific. As an example, "recovery" might be used to trigger system recovery, and "fota" might be used to trigger a "firmware over the air" update.

--plain

When used with **list-dependencies**, **list-units** or **list-machines**, the output is printed as a list instead of a tree, and the bullet circles are omitted.

--timestamp=

Change the format of printed timestamps. The following values may be used:

pretty (this is the default)

"Day YYYY-MM-DD HH:MM:SS TZ"

us, us

"Day YYYY-MM-DD HH:MM:SS.UUUUUU TZ"

utc

"Day YYYY-MM-DD HH:MM:SS UTC"

us+utc, us+utc

"Day YYYY-MM-DD HH:MM:SS.UUUUUU UTC"

--mkdir

When used with **bind**, creates the destination file or directory before applying the bind mount. Note that even though the name of this option suggests that it is suitable only for directories, this option also creates the destination file node to mount over if the object to mount is not a directory, but a regular file, device node, socket or FIFO.

--marked

Only allowed with **reload-or-restart**. Enqueues restart jobs for all units that have the "needs-restart" mark, and reload jobs for units that have the "needs-reload" mark. When a unit marked for reload does not support reload, restart will be queued. Those properties can be set using **set-property Marks**.

Unless **--no-block** is used, **systemctl** will wait for the queued jobs to finish.

--read-only

When used with **bind**, creates a read-only bind mount.

-H, --host=

Execute the operation remotely. Specify a hostname, or a username and hostname separated by "@", to connect to. The hostname may optionally be suffixed by a port ssh is listening on, separated by ":"; and then a container name, separated by "/", which connects directly to a specific container on the specified host. This will use SSH to talk to the remote machine manager instance. Container names may be enumerated with **machinectl -H HOST**. Put IPv6 addresses in brackets.

-M, --machine=

Execute operation on a local container. Specify a container name to connect to, optionally prefixed by a user name to connect as and a separating "@" character. If the special string ".host" is used in place of the container name, a connection to the local system is made (which is useful to connect to a specific user's user bus: "--user --machine=lennart@.host"). If the "@" syntax is not used, the connection is made as root user. If the "@" syntax is used either the left hand side or the right hand side may be omitted (but not both) in which case the local user name and ".host" are implied.

--no-pager

Do not pipe output into a pager.

--legend=BOOL

Enable or disable printing of the legend, i.e. column headers and the footer with hints. The legend is printed by default, unless disabled with **--quiet** or similar.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

EXIT STATUS

On success, 0 is returned, a non-zero failure code otherwise.

systemctl uses the return codes defined by LSB, as defined in [LSB 3.0.0^{\[1\]}](#).

Table 3. LSB return codes

Value	Description in LSB	Use in systemd
0	"program is running or service is OK"	unit is active
1	"program is dead and /var/run pid file exists"	unit <i>not</i> failed (used by is-failed)
2	"program is dead and /var/lock lock file exists"	unused
3	"program is not running"	unit is not active
4	"program or service status is unknown"	no such unit

The mapping of LSB service states to systemd unit states is imperfect, so it is better to not rely on those return values but to look for specific unit states and substates instead.

ENVIRONMENT**\$SYSTEMD_EDITOR**

Editor to use when editing units; overrides **\$EDITOR** and **\$VISUAL**. If neither **\$SYSTEMD_EDITOR** nor **\$EDITOR** nor **\$VISUAL** are present or if it is set to an empty string or if their execution failed, **systemctl** will try to execute well known editors in this order: **editor(1)**, **nano(1)**, **vim(1)**, **vi(1)**.

\$SYSTEMD_LOG_LEVEL

The maximum log level of emitted messages (messages with a higher log level, i.e. less important

ones, will be suppressed). Either one of (in order of decreasing importance) **emerg**, **alert**, **crit**, **err**, **warning**, **notice**, **info**, **debug**, or an integer in the range 0...7. See **syslog(3)** for more information.

\$SYSTEMD_LOG_COLOR

A boolean. If true, messages written to the tty will be colored according to priority.

This setting is only useful when messages are written directly to the terminal, because **journctl(1)** and other tools that display logs will color messages based on the log level on their own.

\$SYSTEMD_LOG_TIME

A boolean. If true, console log messages will be prefixed with a timestamp.

This setting is only useful when messages are written directly to the terminal or a file, because **journctl(1)** and other tools that display logs will attach timestamps based on the entry metadata on their own.

\$SYSTEMD_LOG_LOCATION

A boolean. If true, messages will be prefixed with a filename and line number in the source code where the message originates.

Note that the log location is often attached as metadata to journal entries anyway. Including it directly in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TARGET

The destination for log messages. One of **console** (log to the attached tty), **console-prefixed** (log to the attached tty but with prefixes encoding the log level and "facility", see **syslog(3)**), **kmsg** (log to the kernel circular log buffer), **journal** (log to the journal), **journal-or-kmsg** (log to the journal if available, and to kmsg otherwise), **auto** (determine the appropriate log target automatically, the default), **null** (disable log output).

\$SYSTEMD_PAGER

Pager to use when **--no-pager** is not given; overrides **\$PAGER**. If neither **\$SYSTEMD_PAGER** nor **\$PAGER** are set, a set of well-known pager implementations are tried in turn, including **less(1)** and **more(1)**, until one is found. If no pager implementation is discovered no pager is invoked. Setting this environment variable to an empty string or the value "cat" is equivalent to passing **--no-pager**.

\$SYSTEMD_LESS

Override the options passed to **less** (by default "FRSXMK").

Users might want to change two options in particular:

K

This option instructs the pager to exit immediately when Ctrl+C is pressed. To allow **less** to handle Ctrl+C itself to switch back to the pager command prompt, unset this option.

If the value of **\$SYSTEMD_LESS** does not include "K", and the pager that is invoked is **less**, Ctrl+C will be ignored by the executable, and needs to be handled by the pager.

X

This option instructs the pager to not send termcap initialization and deinitialization strings to the terminal. It is set by default to allow command output to remain visible in the terminal even after the pager exits. Nevertheless, this prevents some pager functionality from working, in particular paged output cannot be scrolled with the mouse.

See **less(1)** for more discussion.

\$SYSTEMD_LESSCHARSET

Override the charset passed to **less** (by default "utf-8", if the invoking terminal is determined to be UTF-8 compatible).

\$SYSTEMD_PAGERSECURE

Takes a boolean argument. When true, the "secure" mode of the pager is enabled; if false, disabled. If **\$SYSTEMD_PAGERSECURE** is not set at all, secure mode is enabled if the effective UID is not the same as the owner of the login session, see **geteuid(2)** and **sd_pid_get_owner_uid(3)**. In secure mode, **LESSSECURE=1** will be set when invoking the pager, and the pager shall disable commands that open or create new files or start new subprocesses. When **\$SYSTEMD_PAGERSECURE** is not set at all, pagers which are not known to implement secure mode will not be used. (Currently only **less(1)** implements secure mode.)

Note: when commands are invoked with elevated privileges, for example under **sudo(8)** or **pkexec(1)**, care must be taken to ensure that unintended interactive features are not enabled. "Secure" mode for the pager may be enabled automatically as described above. Setting **SYSTEMD_PAGERSECURE=0** or not removing it from the inherited environment allows the user to invoke arbitrary commands. Note that if the **\$SYSTEMD_PAGER** or **\$PAGER** variables are to be honoured, **\$SYSTEMD_PAGERSECURE** must be set too. It might be reasonable to completely disable the pager using **--no-pager** instead.

\$SYSTEMD_COLORS

Takes a boolean argument. When true, **systemd** and related utilities will use colors in their output, otherwise the output will be monochrome. Additionally, the variable can take one of the following special values: "16", "256" to restrict the use of colors to the base 16 or 256 ANSI colors, respectively. This can be specified to override the automatic decision based on **\$TERM** and what the console is connected to.

\$SYSTEMD_URLIFY

The value must be a boolean. Controls whether clickable links should be generated in the output for terminal emulators supporting this. This can be specified to override the decision that **systemd** makes based on **\$TERM** and other conditions.

NAME

systemd-analyze – Analyze and debug system manager

SYNOPSIS

```
systemd-analyze [OPTIONS...] [time]
systemd-analyze [OPTIONS...] blame
systemd-analyze [OPTIONS...] critical-chain [UNIT...]
systemd-analyze [OPTIONS...] dump
systemd-analyze [OPTIONS...] plot [>file.svg]
systemd-analyze [OPTIONS...] dot [PATTERN...] [>file.dot]
systemd-analyze [OPTIONS...] unit-paths
systemd-analyze [OPTIONS...] exit-status [STATUS...]
systemd-analyze [OPTIONS...] capability [CAPABILITY...]
systemd-analyze [OPTIONS...] condition CONDITION...
systemd-analyze [OPTIONS...] syscall-filter [SET...]
systemd-analyze [OPTIONS...] calendar SPEC...
systemd-analyze [OPTIONS...] timestamp TIMESTAMP...
systemd-analyze [OPTIONS...] timespan SPAN...
systemd-analyze [OPTIONS...] cat-config NAME|PATH...
systemd-analyze [OPTIONS...] verify [FILE...]
systemd-analyze [OPTIONS...] security UNIT...
```

DESCRIPTION

systemd-analyze may be used to determine system boot-up performance statistics and retrieve other state and tracing information from the system and service manager, and to verify the correctness of unit files. It is also used to access special functions useful for advanced system manager debugging.

If no command is passed, **systemd-analyze time** is implied.

systemd-analyze time

This command prints the time spent in the kernel before userspace has been reached, the time spent in the initial RAM disk (initrd) before normal system userspace has been reached, and the time normal system userspace took to initialize. Note that these measurements simply measure the time passed up to the point where all system services have been spawned, but not necessarily until they fully finished initialization or the disk is idle.

Example 1. Show how long the boot took

```
# in a container
$ systemd-analyze time
Startup finished in 296ms (userspace)
multi-user.target reached after 275ms in userspace

# on a real machine
$ systemd-analyze time
Startup finished in 2.584s (kernel) + 19.176s (initrd) + 47.847s (userspace) = 1min 9.608s
multi-user.target reached after 47.820s in userspace
```

systemd-analyze blame

This command prints a list of all running units, ordered by the time they took to initialize. This information may be used to optimize boot-up times. Note that the output might be misleading as the initialization of one service might be slow simply because it waits for the initialization of another service to complete. Also

note: **systemd-analyze blame** doesn't display results for services with *Type=simple*, because systemd considers such services to be started immediately, hence no measurement of the initialization delays can be done. Also note that this command only shows the time units took for starting up, it does not show how long unit jobs spent in the execution queue. In particular it shows the time units spent in "activating" state, which is not defined for units such as device units that transition directly from "inactive" to "active". This command hence gives an impression of the performance of program code, but cannot accurately reflect latency introduced by waiting for hardware and similar events.

Example 2. Show which units took the most time during boot

```
$ systemd-analyze blame
 32.875s pmlogger.service
 20.905s systemd-networkd-wait-online.service
 13.299s dev-vda1.device
 ...
 23ms sysroot.mount
 11ms initrd-udevadm-cleanup-db.service
 3ms sys-kernel-config.mount
```

systemd-analyze critical-chain [UNIT...]

This command prints a tree of the time-critical chain of units (for each of the specified *UNITS* or for the default target otherwise). The time after the unit is active or started is printed after the "@" character. The time the unit takes to start is printed after the "+" character. Note that the output might be misleading as the initialization of services might depend on socket activation and because of the parallel execution of units. Also, similar to the **blame** command, this only takes into account the time units spent in "activating" state, and hence does not cover units that never went through an "activating" state (such as device units that transition directly from "inactive" to "active"). Moreover it does not show information on jobs (and in particular not jobs that timed out).

Example 3. systemd-analyze critical-chain

```
$ systemd-analyze critical-chain
multi-user.target @47.820s
pmie.service @35.968s +548ms
pmcd.service @33.715s +2.247s
network-online.target @33.712s
  systemd-networkd-wait-online.service @12.804s +20.905s
    systemd-networkd.service @11.109s +1.690s
      systemd-udevd.service @9.201s +1.904s
        systemd-tmpfiles-setup-dev.service @7.306s +1.776s
          kmod-static-nodes.service @6.976s +177ms
            systemd-journald.socket
              system.slice
                -.slice
```

systemd-analyze dump

This command outputs a (usually very long) human-readable serialization of the complete server state. Its format is subject to change without notice and should not be parsed by applications.

Example 4. Show the internal state of user manager

```
$ systemd-analyze --user dump
Timestamp userspace: Thu 2019-03-14 23:28:07 CET
Timestamp finish: Thu 2019-03-14 23:28:07 CET
Timestamp generators-start: Thu 2019-03-14 23:28:07 CET
Timestamp generators-finish: Thu 2019-03-14 23:28:07 CET
```

```

Timestamp units-load-start: Thu 2019-03-14 23:28:07 CET
Timestamp units-load-finish: Thu 2019-03-14 23:28:07 CET
-> Unit proc-timer_list.mount:
    Description: /proc/timer_list
    ...
-> Unit default.target:
    Description: Main user target
    ...

```

systemd-analyze plot

This command prints an SVG graphic detailing which system services have been started at what time, highlighting the time they spent on initialization.

Example 5. Plot a bootchart

```
$ systemd-analyze plot >bootup.svg
$ eog bootup.svg&
```

systemd-analyze dot [pattern...]

This command generates textual dependency graph description in dot format for further processing with the GraphViz **dot**(1) tool. Use a command line like **systemd-analyze dot | dot -Tsvg >systemd.svg** to generate a graphical dependency tree. Unless **--order** or **--require** is passed, the generated graph will show both ordering and requirement dependencies. Optional pattern globbing style specifications (e.g. `*.target`) may be given at the end. A unit dependency is included in the graph if any of these patterns match either the origin or destination node.

Example 6. Plot all dependencies of any unit whose name starts with "avahi-daemon"

```
$ systemd-analyze dot 'avahi-daemon.*' | dot -Tsvg >avahi.svg
$ eog avahi.svg
```

Example 7. Plot the dependencies between all known target units

```
$ systemd-analyze dot --to-pattern='*.target' --from-pattern='*.target' \
| dot -Tsvg >targets.svg
$ eog targets.svg
```

systemd-analyze unit-paths

This command outputs a list of all directories from which unit files, .d overrides, and .wants, .requires symlinks may be loaded. Combine with **--user** to retrieve the list for the user manager instance, and **--global** for the global configuration of user manager instances.

Example 8. Show all paths for generated units

```
$ systemd-analyze unit-paths | grep '^/run'
/run/systemd/system.control
/run/systemd/transient
/run/systemd/generator.early
/run/systemd/system
/run/systemd/system.attached
/run/systemd/generator
/run/systemd/generator.late
```

Note that this verb prints the list that is compiled into **systemd-analyze** itself, and does not communicate with the running manager. Use

```
systemctl [--user] [--global] show -p UnitPath --value
```

to retrieve the actual list that the manager uses, with any empty directories omitted.

systemd-analyze exit-status [STATUS...]

This command prints a list of exit statuses along with their "class", i.e. the source of the definition (one of "glibc", "systemd", "LSB", or "BSD"), see the Process Exit Codes section in **systemd.exec(5)**. If no additional arguments are specified, all known statuses are shown. Otherwise, only the definitions for the specified codes are shown.

Example 9. Show some example exit status names

```
$ systemd-analyze exit-status 0 1 {63..65}
NAME STATUS CLASS
SUCCESS 0 glibc
FAILURE 1 glibc
- 63 -
USAGE 64 BSD
DATAERR 65 BSD
```

systemd-analyze capability [CAPABILITY...]

This command prints a list of Linux capabilities along with their numeric IDs. See **capabilities(7)** for details. If no argument is specified the full list of capabilities known to the service manager and the kernel is shown. Capabilities defined by the kernel but not known to the service manager are shown as "cap_??". Optionally, if arguments are specified they may refer to specific capabilities by name or numeric ID, in which case only the indicated capabilities are shown in the table.

Example 10. Show some example capability names

```
$ systemd-analyze capability 0 1 {30..32}
NAME NUMBER
cap_chown 0
cap_dac_override 1
cap_audit_control 30
cap_setfcap 31
cap_mac_override 32
```

systemd-analyze condition CONDITION...

This command will evaluate *Condition*=...* and *Assert*=...* assignments, and print their values, and the resulting value of the combined condition set. See **systemd.unit(5)** for a list of available conditions and asserts.

Example 11. Evaluate conditions that check kernel versions

```
$ systemd-analyze condition 'ConditionKernelVersion = !<4.0' \
  'ConditionKernelVersion = >=5.1' \
  'ConditionACPower=false' \
  'ConditionArchitecture=!arm' \
  'AssertPathExists=/etc/os-release'
test.service: AssertPathExists=/etc/os-release succeeded.
Asserts succeeded.
test.service: ConditionArchitecture=!arm succeeded.
test.service: ConditionACPower=false failed.
test.service: ConditionKernelVersion=>=5.1 succeeded.
test.service: ConditionKernelVersion!=<4.0 succeeded.
Conditions succeeded.
```

systemd-analyze syscall-filter [SET...]

This command will list system calls contained in the specified system call set *SET*, or all known sets if no sets are specified. Argument *SET* must include the "@" prefix.

systemd-analyze calendar EXPRESSION...

This command will parse and normalize repetitive calendar time events, and will calculate when they elapse next. This takes the same input as the *OnCalendar=* setting in **systemd.timer(5)**, following the syntax described in **systemd.time(7)**. By default, only the next time the calendar expression will elapse is shown; use **--iterations=** to show the specified number of next times the expression elapses. Each time the expression elapses forms a timestamp, see the **timestamp** verb below.

Example 12. Show leap days in the near future

```
$ systemd-analyze calendar --iterations=5 '*-2-29 0:0:0'
Original form: *-2-29 0:0:0
Normalized form: *-02-29 00:00:00
Next elapse: Sat 2020-02-29 00:00:00 UTC
From now: 11 months 15 days left
Iter. #2: Thu 2024-02-29 00:00:00 UTC
From now: 4 years 11 months left
Iter. #3: Tue 2028-02-29 00:00:00 UTC
From now: 8 years 11 months left
Iter. #4: Sun 2032-02-29 00:00:00 UTC
From now: 12 years 11 months left
Iter. #5: Fri 2036-02-29 00:00:00 UTC
From now: 16 years 11 months left
```

systemd-analyze timestamp TIMESTAMP...

This command parses a timestamp (i.e. a single point in time) and outputs the normalized form and the difference between this timestamp and now. The timestamp should adhere to the syntax documented in **systemd.time(7)**, section "PARSING TIMESTAMPS".

Example 13. Show parsing of timestamps

```
$ systemd-analyze timestamp yesterday now tomorrow
Original form: yesterday
Normalized form: Mon 2019-05-20 00:00:00 CEST
(in UTC): Sun 2019-05-19 22:00:00 UTC
UNIX seconds: @15583032000
From now: 1 day 9h ago

Original form: now
Normalized form: Tue 2019-05-21 09:48:39 CEST
(in UTC): Tue 2019-05-21 07:48:39 UTC
UNIX seconds: @1558424919.659757
From now: 43us ago
```

```
Original form: tomorrow
Normalized form: Wed 2019-05-22 00:00:00 CEST
(in UTC): Tue 2019-05-21 22:00:00 UTC
UNIX seconds: @15584760000
From now: 14h left
```

systemd-analyze timespan EXPRESSION...

This command parses a time span (i.e. a difference between two timestamps) and outputs the normalized form and the equivalent value in microseconds. The time span should adhere to the syntax documented in **systemd.time(7)**, section "PARSING TIME SPANS". Values without units are parsed as seconds.

Example 14. Show parsing of timespans

```
$ systemd-analyze timespan 1s 300s '1year 0.000001s'
```

```
Original: 1s
  μs: 1000000
Human: 1s
```

```
Original: 300s
  μs: 300000000
Human: 5min
```

```
Original: 1year 0.000001s
  μs: 315576000000001
Human: 1y 1us
```

systemd-analyze cat–config NAME|PATH...

This command is similar to **systemctl cat**, but operates on config files. It will copy the contents of a config file and any drop-ins to standard output, using the usual systemd set of directories and rules for precedence. Each argument must be either an absolute path including the prefix (such as /etc/systemd/logind.conf or /usr/lib/systemd/logind.conf), or a name relative to the prefix (such as systemd/logind.conf).

Example 15. Showing logind configuration

```
$ systemd-analyze cat–config systemd/logind.conf
# /etc/systemd/logind.conf
...
[Login]
NAutoVTs=8
...
# /usr/lib/systemd/logind.conf.d/20–test.conf
... some override from another package
# /etc/systemd/logind.conf.d/50–override.conf
... some administrator override
```

systemd-analyze verify FILE...

This command will load unit files and print warnings if any errors are detected. Files specified on the command line will be loaded, but also any other units referenced by them. The full unit search path is formed by combining the directories for all command line arguments, and the usual unit load paths. The variable \$SYSTEMD_UNIT_PATH is supported, and may be used to replace or augment the compiled in set of unit load paths; see **systemd.unit(5)**. All units files present in the directories containing the command line arguments will be used in preference to the other paths.

The following errors are currently detected:

- unknown sections and directives,
- missing dependencies which are required to start the given unit,
- man pages listed in *Documentation=* which are not found in the system,
- commands listed in *ExecStart=* and similar which are not found in the system or not executable.

Example 16. Misspelt directives

```
$ cat ./user.slice
[Unit]
WhatIsThis=11
Documentation=man:nosuchfile(1)
Requires=different.service
```

```
[Service]
Description=x

$ systemd-analyze verify ./user.slice
[./user.slice:9] Unknown lvalue 'WhatIsThis' in section 'Unit'
[./user.slice:13] Unknown section 'Service'. Ignoring.
Error: org.freedesktop.systemd1.LoadFailed:
  Unit different.service failed to load:
    No such file or directory.
Failed to create user.slice/start: Invalid argument
user.slice: man nosuchfile(1) command failed with code 16
```

Example 17. Missing service units

```
$ tail ./a.socket ./b.socket
==> ./a.socket <==
[Socket]
ListenStream=100

==> ./b.socket <==
[Socket]
ListenStream=100
Accept=yes

$ systemd-analyze verify ./a.socket ./b.socket
Service a.service not loaded, a.socket cannot be started.
Service b@0.service not loaded, b.socket cannot be started.
```

systemd-analyze security [UNIT...]

This command analyzes the security and sandboxing settings of one or more specified service units. If at least one unit name is specified the security settings of the specified service units are inspected and a detailed analysis is shown. If no unit name is specified, all currently loaded, long-running service units are inspected and a terse table with results shown. The command checks for various security-related service settings, assigning each a numeric "exposure level" value, depending on how important a setting is. It then calculates an overall exposure level for the whole unit, which is an estimation in the range 0.0...10.0 indicating how exposed a service is security-wise. High exposure levels indicate very little applied sandboxing. Low exposure levels indicate tight sandboxing and strongest security restrictions. Note that this only analyzes the per-service security features systemd itself implements. This means that any additional security mechanisms applied by the service code itself are not accounted for. The exposure level determined this way should not be misunderstood: a high exposure level neither means that there is no effective sandboxing applied by the service code itself, nor that the service is actually vulnerable to remote or local attacks. High exposure levels do indicate however that most likely the service might benefit from additional settings applied to them.

Please note that many of the security and sandboxing settings individually can be circumvented — unless combined with others. For example, if a service retains the privilege to establish or undo mount points many of the sandboxing options can be undone by the service code itself. Due to that it is essential that each service uses the most comprehensive and strict sandboxing and security settings possible. The tool will take into account some of these combinations and relationships between the settings, but not all. Also note that the security and sandboxing settings analyzed here only apply to the operations executed by the service code itself. If a service has access to an IPC system (such as D-Bus) it might request operations from other services that are not subject to the same restrictions. Any comprehensive security and sandboxing analysis is hence incomplete if the IPC access policy is not validated too.

Example 18. Analyze systemd-logind.service

```
$ systemd-analyze security --no-pager systemd-logind.service
  NAME          DESCRIPTION          EXPOSURE
PrivateNetwork=  Service has access to the host's network  0.5
User=/DynamicUser= Service runs as root user            0.4
DeviceAllow=    Service has no device ACL                0.2
✓ IPAddressDeny= Service blocks all IP address ranges
...
→ Overall exposure level for systemd-logind.service: 4.1 OK
```

OPTIONS

The following options are understood:

--system

Operates on the system systemd instance. This is the implied default.

--user

Operates on the user systemd instance.

--global

Operates on the system-wide configuration for user systemd instance.

--order, --require

When used in conjunction with the **dot** command (see above), selects which dependencies are shown in the dependency graph. If **--order** is passed, only dependencies of type *After*= or *Before*= are shown. If **--require** is passed, only dependencies of type *Requires*=, *Requisite*=, *Wants*= and *Conflicts*= are shown. If neither is passed, this shows dependencies of all these types.

--from-pattern=, --to-pattern=

When used in conjunction with the **dot** command (see above), this selects which relationships are shown in the dependency graph. Both options require a **glob(7)** pattern as an argument, which will be matched against the left-hand and the right-hand, respectively, nodes of a relationship.

Each of these can be used more than once, in which case the unit name must match one of the values. When tests for both sides of the relation are present, a relation must pass both tests to be shown. When patterns are also specified as positional arguments, they must match at least one side of the relation. In other words, patterns specified with those two options will trim the list of edges matched by the positional arguments, if any are given, and fully determine the list of edges shown otherwise.

--fuzz=*timespan*

When used in conjunction with the **critical-chain** command (see above), also show units, which finished *timespan* earlier, than the latest unit in the same level. The unit of *timespan* is seconds unless specified with a different unit, e.g. "50ms".

--man=no

Do not invoke **man(1)** to verify the existence of man pages listed in *Documentation*=.

--generators

Invoke unit generators, see **systemd.generator(7)**. Some generators require root privileges. Under a normal user, running with generators enabled will generally result in some warnings.

--root=PATH

With **cat-files**, show config files underneath the specified root path *PATH*.

--iterations=NUMBER

When used with the **calendar** command, show the specified number of iterations the specified calendar expression will elapse next. Defaults to 1.

--base-time=TIMESTAMP

When used with the **calendar** command, show next iterations relative to the specified point in time. If not specified defaults to the current time.

-H, --host=

Execute the operation remotely. Specify a hostname, or a username and hostname separated by "@", to connect to. The hostname may optionally be suffixed by a port ssh is listening on, separated by ":"; and then a container name, separated by "/", which connects directly to a specific container on the specified host. This will use SSH to talk to the remote machine manager instance. Container names may be enumerated with **machinectl -H HOST**. Put IPv6 addresses in brackets.

-M, --machine=

Execute operation on a local container. Specify a container name to connect to, optionally prefixed by a user name to connect as and a separating "@" character. If the special string ".host" is used in place of the container name, a connection to the local system is made (which is useful to connect to a specific user's user bus: "--user --machine=lennart@.host"). If the "@" syntax is not used, the connection is made as root user. If the "@" syntax is used either the left hand side or the right hand side may be omitted (but not both) in which case the local user name and ".host" are implied.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

--no-pager

Do not pipe output into a pager.

EXIT STATUS

On success, 0 is returned, a non-zero failure code otherwise.

ENVIRONMENT***\$SYSTEMD_LOG_LEVEL***

The maximum log level of emitted messages (messages with a higher log level, i.e. less important ones, will be suppressed). Either one of (in order of decreasing importance) **emerg**, **alert**, **crit**, **err**, **warning**, **notice**, **info**, **debug**, or an integer in the range 0...7. See **syslog(3)** for more information.

\$SYSTEMD_LOG_COLOR

A boolean. If true, messages written to the tty will be colored according to priority.

This setting is only useful when messages are written directly to the terminal, because **journalctl(1)** and other tools that display logs will color messages based on the log level on their own.

\$SYSTEMD_LOG_TIME

A boolean. If true, console log messages will be prefixed with a timestamp.

This setting is only useful when messages are written directly to the terminal or a file, because **journalctl(1)** and other tools that display logs will attach timestamps based on the entry metadata on their own.

\$SYSTEMD_LOG_LOCATION

A boolean. If true, messages will be prefixed with a filename and line number in the source code where the message originates.

Note that the log location is often attached as metadata to journal entries anyway. Including it directly in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TID

A boolean. If true, messages will be prefixed with the current numerical thread ID (TID).

Note that the this information is attached as metadata to journal entries anyway. Including it directly in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TARGET

The destination for log messages. One of **console** (log to the attached tty), **console-prefixed** (log to the attached tty but with prefixes encoding the log level and "facility", see **syslog(3)**), **kmsg** (log to the

kernel circular log buffer), **journal** (log to the journal), **journal-or-kmsg** (log to the journal if available, and to kmsg otherwise), **auto** (determine the appropriate log target automatically, the default), **null** (disable log output).

\$SYSTEMD_PAGER

Pager to use when **--no-pager** is not given; overrides **\$PAGER**. If neither **\$SYSTEMD_PAGER** nor **\$PAGER** are set, a set of well-known pager implementations are tried in turn, including **less(1)** and **more(1)**, until one is found. If no pager implementation is discovered no pager is invoked. Setting this environment variable to an empty string or the value "cat" is equivalent to passing **--no-pager**.

\$SYSTEMD_LESS

Override the options passed to **less** (by default "FRSXMK").

Users might want to change two options in particular:

K

This option instructs the pager to exit immediately when Ctrl+C is pressed. To allow **less** to handle Ctrl+C itself to switch back to the pager command prompt, unset this option.

If the value of **\$SYSTEMD_LESS** does not include "K", and the pager that is invoked is **less**, Ctrl+C will be ignored by the executable, and needs to be handled by the pager.

X

This option instructs the pager to not send termcap initialization and deinitialization strings to the terminal. It is set by default to allow command output to remain visible in the terminal even after the pager exits. Nevertheless, this prevents some pager functionality from working, in particular paged output cannot be scrolled with the mouse.

See **less(1)** for more discussion.

\$SYSTEMD_LESSCHARSET

Override the charset passed to **less** (by default "utf-8", if the invoking terminal is determined to be UTF-8 compatible).

\$SYSTEMD_PAGERSECURE

Takes a boolean argument. When true, the "secure" mode of the pager is enabled; if false, disabled. If **\$SYSTEMD_PAGERSECURE** is not set at all, secure mode is enabled if the effective UID is not the same as the owner of the login session, see **geteuid(2)** and **sd_pid_get_owner_uid(3)**. In secure mode, **LESSSECURE=1** will be set when invoking the pager, and the pager shall disable commands that open or create new files or start new subprocesses. When **\$SYSTEMD_PAGERSECURE** is not set at all, pagers which are not known to implement secure mode will not be used. (Currently only **less(1)** implements secure mode.)

Note: when commands are invoked with elevated privileges, for example under **sudo(8)** or **pkexec(1)**, care must be taken to ensure that unintended interactive features are not enabled. "Secure" mode for the pager may be enabled automatically as described above. Setting **SYSTEMD_PAGERSECURE=0** or not removing it from the inherited environment allows the user to invoke arbitrary commands. Note that if the **\$SYSTEMD_PAGER** or **\$PAGER** variables are to be honoured,

\$SYSTEMD_PAGERSECURE must be set too. It might be reasonable to completely disable the pager using **--no-pager** instead.

\$SYSTEMD_COLORS

Takes a boolean argument. When true, **systemd** and related utilities will use colors in their output, otherwise the output will be monochrome. Additionally, the variable can take one of the following special values: "16", "256" to restrict the use of colors to the base 16 or 256 ANSI colors, respectively. This can be specified to override the automatic decision based on **\$TERM** and what the console is connected to.

\$SYSTEMD_URLIFY

The value must be a boolean. Controls whether clickable links should be generated in the output for terminal emulators supporting this. This can be specified to override the decision that **systemd** makes based on *\$TERM* and other conditions.

NAME

systemd-fsck@.service, systemd-fsck-root.service, systemd-fsck – File system checker logic

SYNOPSIS

```
systemd-fsck@.service
systemd-fsck-root.service
/lib/systemd/systemd-fsck
```

DESCRIPTION

systemd-fsck@.service and systemd-fsck-root.service are services responsible for file system checks. They are instantiated for each device that is configured for file system checking. systemd-fsck-root.service is responsible for file system checks on the root file system, but only if the root filesystem was not checked in the initramfs. systemd-fsck@.service is used for all other file systems and for the root file system in the initramfs.

These services are started at boot if **passno** in /etc/fstab for the file system is set to a value greater than zero. The file system check for root is performed before the other file systems. Other file systems may be checked in parallel, except when they are on the same rotating disk.

systemd-fsck does not know any details about specific filesystems, and simply executes file system checkers specific to each filesystem type (/sbin/fsck.type). These checkers will decide if the filesystem should actually be checked based on the time since last check, number of mounts, unclean unmount, etc.

If a file system check fails for a service without **nofail**, emergency mode is activated, by isolating to emergency.target.

KERNEL COMMAND LINE

systemd-fsck understands these kernel command line parameters:

fsck.mode=

One of "auto", "force", "skip". Controls the mode of operation. The default is "auto", and ensures that file system checks are done when the file system checker deems them necessary. "force" unconditionally results in full file system checks. "skip" skips any file system checks.

fsck.repair=

One of "preen", "yes", "no". Controls the mode of operation. The default is "preen", and will automatically repair problems that can be safely fixed. "yes" will answer yes to all questions by fsck and "no" will answer no to all questions.

NAME

systemd-hostnamed.service, systemd-hostnamed – Daemon to control system hostname from programs

SYNOPSIS

systemd-hostnamed.service

/lib/systemd/systemd-hostnamed

DESCRIPTION

systemd-hostnamed.service is a system service that may be used to change the system's hostname and related machine metadata from user programs. It is automatically activated on request and terminates itself when unused.

It currently offers access to five variables:

- The current hostname (Example: "dhcp-192-168-47-11")
- The static (configured) hostname (Example: "lennarts-computer")
- The pretty hostname (Example: "Lennart's Computer")
- A suitable icon name for the local host (Example: "computer-laptop")
- A chassis type (Example: "tablet")

The static hostname is stored in /etc/hostname, see **hostname(5)** for more information. The pretty hostname, chassis type, and icon name are stored in /etc/machine-info, see **machine-info(5)**.

The tool **hostnamectl(1)** is a command line client to this service.

See **org.freedesktop.hostname1(5)** and **org.freedesktop.LogControl1(5)** for a description of the D-Bus API.

NAME

systemd-journald.service, systemd-journald.socket, systemd-journald-dev-log.socket, systemd-journald-audit.socket, systemd-journald@.service, systemd-journald@.socket, systemd-journald-varlink@.socket, systemd-journald – Journal service

SYNOPSIS

```
systemd-journald.service
systemd-journald.socket
systemd-journald-dev-log.socket
systemd-journald-audit.socket
systemd-journald@.service
systemd-journald@.socket
systemd-journald-varlink@.socket
/lib/systemd/systemd-journald
```

DESCRIPTION

systemd-journald is a system service that collects and stores logging data. It creates and maintains structured, indexed journals based on logging information that is received from a variety of sources:

- Kernel log messages, via kmsg
- Simple system log messages, via the libc **syslog(3)** call
- Structured system log messages via the native Journal API, see **sd_journal_print(3)** and **Native Journal Protocol**^[1]
- Standard output and standard error of service units. For further details see below.
- Audit records, originating from the kernel audit subsystem

The daemon will implicitly collect numerous metadata fields for each log messages in a secure and unforgeable way. See **systemd.journal-fields(7)** for more information about the collected metadata.

Log data collected by the journal is primarily text-based but can also include binary data where necessary. Individual fields making up a log record stored in the journal may be up to $2^{64}-1$ bytes in size.

The journal service stores log data either persistently below `/var/log/journal` or in a volatile way below `/run/log/journal/` (in the latter case it is lost at reboot). By default, log data is stored persistently if `/var/log/journal/` exists during boot, with an implicit fallback to volatile storage otherwise. Use `Storage=` in **journald.conf(5)** to configure where log data is placed, independently of the existence of `/var/log/journal/`.

Note that journald will initially use volatile storage, until a call to **journalctl --flush** (or sending **SIGUSR1** to journald) will cause it to switch to persistent logging (under the conditions mentioned above). This is done automatically on boot via "systemd-journal-flush.service".

On systems where `/var/log/journal/` does not exist yet but where persistent logging is desired (and the default **journald.conf** is used), it is sufficient to create the directory, and ensure it has the correct access modes and ownership:

```
mkdir -p /var/log/journal
systemd-tmpfiles --create --prefix /var/log/journal
```

See **journald.conf(5)** for information about the configuration of this service.

STREAM LOGGING

The systemd service manager invokes all service processes with standard output and standard error connected to the journal by default. This behaviour may be altered via the `StandardOutput=/StandardError=` unit file settings, see **systemd.exec(5)** for details. The journal converts the log byte stream received this way into individual log records, splitting the stream at newline ("\\n", ASCII **10**) and **NUL** bytes.

If `systemd-journald.service` is stopped, the stream connections associated with all services are terminated. Further writes to those streams by the service will result in **EPIPE** errors. In order to react gracefully in this case it is recommended that programs logging to standard output/error ignore such errors. If the **SIGPIPE** UNIX signal handler is not blocked or turned off, such write attempts will also result in such process signals being generated, see `signal(7)`. To mitigate this issue, systemd service manager explicitly turns off the **SIGPIPE** signal for all invoked processes by default (this may be changed for each unit individually via the `IgnoreSIGPIPE=` option, see `systemd.exec(5)` for details). After the standard output/standard error streams have been terminated they may not be recovered until the services they are associated with are restarted. Note that during normal operation, `systemd-journald.service` stores copies of the file descriptors for those streams in the service manager. If `systemd-journald.service` is restarted using `systemctl restart` or equivalent operation instead of a pair of separate `systemctl stop` and `systemctl start` commands (or equivalent operations), these stream connections are not terminated and survive the restart. It is thus safe to restart `systemd-journald.service`, but stopping it is not recommended.

Note that the log record metadata for records transferred via such standard output/error streams reflect the metadata of the peer the stream was originally created for. If the stream connection is passed on to other processes (such as further child processes forked off the main service process), the log records will not reflect their metadata, but will continue to describe the original process. This is different from the other logging transports listed above, which are inherently record based and where the metadata is always associated with the individual record.

In addition to the implicit standard output/error logging of services, stream logging is also available via the `systemd-cat(1)` command line tool.

Currently, the number of parallel log streams `systemd-journald` will accept is limited to 4096. When this limit is reached further log streams may be established but will receive **EPIPE** right from the beginning.

JOURNAL NAMESPACES

Journal 'namespaces' are both a mechanism for logically isolating the log stream of projects consisting of one or more services from the rest of the system and a mechanism for improving performance. Multiple journal namespaces may exist simultaneously, each defining its own, independent log stream managed by its own instance of `systemd-journald`. Namespaces are independent of each other, both in the data store and in the IPC interface. By default only a single 'default' namespace exists, managed by `systemd-journald.service` (and its associated socket units). Additional namespaces are created by starting an instance of the `systemd-journald@.service` service template. The instance name is the namespace identifier, which is a short string used for referencing the journal namespace. Service units may be assigned to a specific journal namespace through the `LogNamespace=` unit file setting, see `systemd.exec(5)` for details. The `--namespace=` switch of `journalctl(1)` may be used to view the log stream of a specific namespace. If the switch is not used the log stream of the default namespace is shown, i.e. log data from other namespaces is not visible.

Services associated with a specific log namespace may log via syslog, the native logging protocol of the journal and via `stdout/stderr`; the logging from all three transports is associated with the namespace.

By default only the default namespace will collect kernel and audit log messages.

The `systemd-journald` instance of the default namespace is configured through `/etc/systemd/journald.conf` (see below), while the other instances are configured through `/etc/systemd/journald@NAMESPACE.conf`. The journal log data for the default namespace is placed in `/var/log/journal/MACHINE_ID` (see below) while the data for the other namespaces is located in `/var/log/journal/MACHINE_ID.NAMESPACE`.

SIGNALS

SIGUSR1

Request that journal data from `/run/` is flushed to `/var/` in order to make it persistent (if this is enabled). This must be used after `/var/` is mounted, as otherwise log data from `/run/` is never flushed to `/var/` regardless of the configuration. Use the `journalctl --flush` command to request flushing of the journal files, and wait for the operation to complete. See `journalctl(1)` for details.

SIGUSR2

Request immediate rotation of the journal files. Use the `journalctl --rotate` command to request

journal file rotation, and wait for the operation to complete.

SIGRTMIN+1

Request that all unwritten log data is written to disk. Use the **journaldctl --sync** command to trigger journal synchronization, and wait for the operation to complete.

KERNEL COMMAND LINE

A few configuration parameters from journald.conf may be overridden on the kernel command line:

systemd.journald.forward_to_syslog=, *systemd.journald.forward_to_kmsg=*,
systemd.journald.forward_to_console=, *systemd.journald.forward_to_wall=*

Enables/disables forwarding of collected log messages to syslog, the kernel log buffer, the system console or wall.

See **journald.conf(5)** for information about these settings.

Note that these kernel command line options are only honoured by the default namespace, see above.

ACCESS CONTROL

Journal files are, by default, owned and readable by the "systemd-journal" system group but are not writable. Adding a user to this group thus enables them to read the journal files.

By default, each user, with a UID outside the range of system users, dynamic service users, and the nobody user, will get their own set of journal files in /var/log/journal/. See **Users, Groups, UIDs and GIDs on systemd systems**^[2] for more details about UID ranges. These journal files will not be owned by the user, however, in order to avoid that the user can write to them directly. Instead, file system ACLs are used to ensure the user gets read access only.

Additional users and groups may be granted access to journal files via file system access control lists (ACL). Distributions and administrators may choose to grant read access to all members of the "wheel" and "adm" system groups with a command such as the following:

```
# setfacl -Rnm g:wheel:rx,d:g:wheel:rx,g:adm:rx,d:g:adm:rx /var/log/journal/
```

Note that this command will update the ACLs both for existing journal files and for future journal files created in the /var/log/journal/ directory.

FILES

/etc/systemd/journald.conf

Configure **systemd-journald** behavior. See **journald.conf(5)**.

/run/log/journal/*machine-id*/*.journal, /run/log/journal/*machine-id*/*.journal~,
/var/log/journal/*machine-id*/*.journal, /var/log/journal/*machine-id*/*.journal~

systemd-journald writes entries to files in /run/log/journal/*machine-id*/ or
/var/log/journal/*machine-id*/ with the ".journal" suffix. If the daemon is stopped uncleanly, or if the files are found to be corrupted, they are renamed using the ".journal~" suffix, and **systemd-journald** starts writing to a new file. /run/ is used when /var/log/journal is not available, or when **Storage=volatile** is set in the **journald.conf(5)** configuration file.

When **systemd-journald** ceases writing to a journal file, it will be renamed to "*original-name@suffix.journal*" (or "*original-name@suffix.journal~*"). Such files are "archived" and will not be written to any more.

In general, it is safe to read or copy any journal file (active or archived). **journaldctl(1)** and the functions in the **sd-journal(3)** library should be able to read all entries that have been fully written.

systemd-journald will automatically remove the oldest archived journal files to limit disk use. See **SystemMaxUse=** and related settings in **journald.conf(5)**.

/dev/kmsg, /dev/log, /run/systemd/journal/dev-log, /run/systemd/journal/socket,
/run/systemd/journal/stdout

Sockets and other file node paths that **systemd-journald** will listen on and are visible in the file system. In addition to these, **systemd-journald** can listen for audit events using **netlink(7)**.

If journal namespacing is used these paths are slightly altered to include a namespace identifier, see above.

NAME

`systemd-machined.service`, `systemd-machined` – Virtual machine and container registration manager

SYNOPSIS

```
systemd-machined.service
/lib/systemd/systemd-machined
```

DESCRIPTION

systemd-machined is a system service that keeps track of locally running virtual machines and containers.

systemd-machined is useful for registering and keeping track of both OS containers (containers that share the host kernel but run a full init system of their own and behave in most regards like a full virtual operating system rather than just one virtualized app) and full virtual machines (virtualized hardware running normal operating systems and possibly different kernels).

systemd-machined should *not* be used for registering/keeping track of application sandbox containers. A *machine* in the context of **systemd-machined** is supposed to be an abstract term covering both OS containers and full virtual machines, but not application sandboxes.

Machines registered with machined are exposed in various ways in the system. For example:

- Tools like **ps**(1) will show to which machine a specific process belongs in a column of its own, and so will **gnome-system-monitor**^[1] or **systemd-cgls**(1).
- `systemctl`'s various tools (**systemctl**(1), **journalctl**(1), **logindctl**(1), **hostnamectl**(1), **timedatectl**(1), **localectl**(1), **machinectl**(1), ...) support the **-M** switch to operate on local containers instead of the host system.
- **systemctl list-machines** will show the system state of all local containers, connecting to the container's init system for that.
- `systemctl`'s **--recursive** switch has the effect of not only showing the locally running services, but recursively showing the services of all registered containers.
- The **machinectl** command provides access to a number of useful operations on registered containers, such as introspecting them, rebooting, shutting them down, and getting a login prompt on them.
- The **sd-bus**(3) library exposes the **sd_bus_open_system_machine**(3) call to connect to the system bus of any registered container.
- The **nss-myrmachines**(8) module makes sure all registered containers can be resolved via normal glibc **gethostbyname**(3) or **getaddrinfo**(3) calls.

See **systemd-nspawn**(1) for some examples on how to run containers with OS tools.

If you are interested in writing a VM or container manager that makes use of machined, please have look at [Writing Virtual Machine or Container Managers](#)^[2]. Also see the [New Control Group Interfaces](#)^[3].

The daemon provides both a C library interface (which is shared with **systemd-logind.service**(8)) as well as a D-Bus interface. The library interface may be used to introspect and watch the state of virtual machines/containers. The bus interface provides the same but in addition may also be used to register or terminate machines. For more information please consult **sd-login**(3) and **org.freedesktop.machine1**(5) and **org.freedesktop.LogControl1**(5).

A small companion daemon **systemd-importd.service**(8) is also available, which implements importing, exporting, and downloading of container and VM images.

For each container registered with `systemd-machined.service` that employs user namespacing, users/groups are synthesized for the used UIDs/GIDs. These are made available to the system using the [User/Group Record Lookup API via Varlink](#)^[4], and thus may be resolved with **userdbctl**(1) or the usual glibc NSS calls.

NAME

systemd-mount, **systemd-umount** – Establish and destroy transient mount or auto-mount points

SYNOPSIS

```
systemd-mount [OPTIONS...] WHAT [WHERE]
systemd-mount [OPTIONS...] --list
systemd-mount [OPTIONS...] --umount WHAT/WHERE...
```

DESCRIPTION

systemd-mount may be used to create and start a transient .mount or .automount unit of the file system *WHAT* on the mount point *WHERE*.

In many ways, **systemd-mount** is similar to the lower-level **mount**(8) command, however instead of executing the mount operation directly and immediately, **systemd-mount** schedules it through the service manager job queue, so that it may pull in further dependencies (such as parent mounts, or a file system checker to execute a priori), and may make use of the auto-mounting logic.

The command takes either one or two arguments. If only one argument is specified it should refer to a block device or regular file containing a file system (e.g. "/dev/sdb1" or "/path/to/disk.img"). The block device or image file is then probed for a file system label and other metadata, and is mounted to a directory below /run/media/system/ whose name is generated from the file system label. In this mode the block device or image file must exist at the time of invocation of the command, so that it may be probed. If the device is found to be a removable block device (e.g. a USB stick), an automount point is created instead of a regular mount point (i.e. the **--automount**= option is implied, see below).

If two arguments are specified, the first indicates the mount source (the *WHAT*) and the second indicates the path to mount it on (the *WHERE*). In this mode no probing of the source is attempted, and a backing device node doesn't have to exist. However, if this mode is combined with **--discover**, device node probing for additional metadata is enabled, and – much like in the single-argument case discussed above – the specified device has to exist at the time of invocation of the command.

Use the **--list** command to show a terse table of all local, known block devices with file systems that may be mounted with this command.

systemd-umount can be used to unmount a mount or automount point. It is the same as **systemd-mount** **--umount**.

OPTIONS

The following options are understood:

--no-block

Do not synchronously wait for the requested operation to finish. If this is not specified, the job will be verified, enqueued and **systemd-mount** will wait until the mount or automount unit's start-up is completed. By passing this argument, it is only verified and enqueued.

-l, --full

Do not ellipsize the output when **--list** is specified.

--no-pager

Do not pipe output into a pager.

--no-legend

Do not print the legend, i.e. column headers and the footer with hints.

--no-ask-password

Do not query the user for authentication for privileged operations.

--quiet, -q

Suppresses additional informational output while running.

--discover

Enable probing of the mount source. This switch is implied if a single argument is specified on the command line. If passed, additional metadata is read from the device to enhance the unit to create. For

example, a descriptive string for the transient units is generated from the file system label and device model. Moreover if a removable block device (e.g. USB stick) is detected an automount unit instead of a regular mount unit is created, with a short idle timeout, in order to ensure the file-system is placed in a clean state quickly after each access.

--type=, -t

Specifies the file system type to mount (e.g. "vfat" or "ext4"). If omitted or set to "auto", the file system type is determined automatically.

--options=, -o

Additional mount options for the mount point.

--owner=USER

Let the specified user *USER* own the mounted file system. This is done by appending **uid=** and **gid=** options to the list of mount options. Only certain file systems support this option.

--fsck=

Takes a boolean argument, defaults to on. Controls whether to run a file system check immediately before the mount operation. In the automount case (see **--automount** below) the check will be run the moment the first access to the device is made, which might slightly delay the access.

--description=

Provide a description for the mount or automount unit. See *Description=* in **systemd.unit(5)**.

--property=, -p

Sets a unit property for the mount unit that is created. This takes an assignment in the same format as **systemctl(1)**'s **set-property** command.

--automount=

Takes a boolean argument. Controls whether to create an automount point or a regular mount point. If true an automount point is created that is backed by the actual file system at the time of first access. If false a plain mount point is created that is backed by the actual file system immediately. Automount points have the benefit that the file system stays unmounted and hence in clean state until it is first accessed. In automount mode the **--timeout-idle-sec=** switch (see below) may be used to ensure the mount point is unmounted automatically after the last access and an idle period passed.

If this switch is not specified it defaults to false. If not specified and **--discover** is used (or only a single argument passed, which implies **--discover**, see above), and the file system block device is detected to be removable, it is set to true, in order to increase the chance that the file system is in a fully clean state if the device is unplugged abruptly.

-A

Equivalent to **--automount=yes**.

--timeout-idle-sec=

Takes a time value that controls the idle timeout in automount mode. If set to "infinity" (the default) no automatic unmounts are done. Otherwise the file system backing the automount point is detached after the last access and the idle timeout passed. See **systemd.time(7)** for details on the time syntax supported. This option has no effect if only a regular mount is established, and automounting is not used.

Note that if **--discover** is used (or only a single argument passed, which implies **--discover**, see above), and the file system block device is detected to be removable, **--timeout-idle-sec=1s** is implied.

--automount-property=

Similar to **--property=**, but applies additional properties to the automount unit created, instead of the mount unit.

--bind-device

This option only has an effect in automount mode, and controls whether the automount unit shall be

bound to the backing device's lifetime. If set, the automount point will be removed automatically when the backing device vanishes. By default the automount point stays around, and subsequent accesses will block until backing device is replugged. This option has no effect in case of non-device mounts, such as network or virtual file system mounts.

Note that if **--discover** is used (or only a single argument passed, which implies **--discover**, see above), and the file system block device is detected to be removable, this option is implied.

--list

Instead of establishing a mount or automount point, print a terse list of block devices containing file systems that may be mounted with "systemd-mount", along with useful metadata such as labels, etc.

-u, --umount

Stop the mount and automount units corresponding to the specified mount points *WHERE* or the devices *WHAT*. **systemd-mount** with this option or **systemd-umount** can take multiple arguments which can be mount points, devices, /etc/fstab style node names, or backing files corresponding to loop devices, like **systemd-mount --umount /path/to/umount /dev/sda1 UUID=xxxxxx-xxxx LABEL=xxxxx /path/to/disk.img**. Note that when **-H** or **-M** is specified, only absolute paths to mount points are supported.

-G, --collect

Unload the transient unit after it completed, even if it failed. Normally, without this option, all mount units that mount and failed are kept in memory until the user explicitly resets their failure state with **systemctl reset-failed** or an equivalent command. On the other hand, units that stopped successfully are unloaded immediately. If this option is turned on the "garbage collection" of units is more aggressive, and unloads units regardless if they exited successfully or failed. This option is a shortcut for **--property=CollectMode=inactive-or-failed**, see the explanation for *CollectMode*= in **systemd.unit(5)** for further information.

--user

Talk to the service manager of the calling user, rather than the service manager of the system.

--system

Talk to the service manager of the system. This is the implied default.

-H, --host=

Execute the operation remotely. Specify a hostname, or a username and hostname separated by "@", to connect to. The hostname may optionally be suffixed by a port ssh is listening on, separated by ":"; and then a container name, separated by "/", which connects directly to a specific container on the specified host. This will use SSH to talk to the remote machine manager instance. Container names may be enumerated with **machinectl -H HOST**. Put IPv6 addresses in brackets.

-M, --machine=

Execute operation on a local container. Specify a container name to connect to, optionally prefixed by a user name to connect as and a separating "@" character. If the special string ".host" is used in place of the container name, a connection to the local system is made (which is useful to connect to a specific user's user bus: "--user --machine=lennart@.host"). If the "@" syntax is not used, the connection is made as root user. If the "@" syntax is used either the left hand side or the right hand side may be omitted (but not both) in which case the local user name and ".host" are implied.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

EXIT STATUS

On success, 0 is returned, a non-zero failure code otherwise.

THE UDEV DATABASE

If **--discover** is used, **systemd-mount** honors a couple of additional udev properties of block devices:

SYSTEMD_MOUNT_OPTIONS=

The mount options to use, if **--options=** is not used.

SYSTEMD_MOUNT_WHERE=

The file system path to place the mount point at, instead of the automatically generated one.

EXAMPLE

Use a udev rule like the following to automatically mount all USB storage plugged in:

```
ACTION=="add", SUBSYSTEMS=="usb", SUBSYSTEM=="block", ENV{ID_FS_USAGE}=="filesystem", \
    RUN{program}+="/usr/bin/systemd-mount --no-block --automount=yes --collect $devnode"
```

systemd-run(1)

NAME

systemd-networkd.service, systemd-networkd – Network manager

SYNOPSIS

systemd–networkd.service

/lib/systemd/systemd–networkd

DESCRIPTION

systemd–networkd is a system service that manages networks. It detects and configures network devices as they appear, as well as creating virtual network devices.

To configure low-level link settings independently of networks, see **systemd.link(5)**.

systemd–networkd will create network devices based on the configuration in **systemd.netdev(5)** files, respecting the [Match] sections in those files.

systemd–networkd will manage network addresses and routes for any link for which it finds a .network file with an appropriate [Match] section, see **systemd.network(5)**. For those links, it will flush existing network addresses and routes when bringing up the device. Any links not matched by one of the .network files will be ignored. It is also possible to explicitly tell systemd–networkd to ignore a link by using *Unmanaged=yes* option, see **systemd.network(5)**.

When systemd–networkd exits, it generally leaves existing network devices and configuration intact. This makes it possible to transition from the initramfs and to restart the service without breaking connectivity. This also means that when configuration is updated and systemd–networkd is restarted, netdev interfaces for which configuration was removed will not be dropped, and may need to be cleaned up manually.

systemd–networkd may be introspected and controlled at runtime using **networkctl(1)**.

CONFIGURATION FILES

The configuration files are read from the files located in the system network directory /lib/systemd/network, the volatile runtime network directory /run/systemd/network and the local administration network directory /etc/systemd/network.

Networks are configured in .network files, see **systemd.network(5)**, and virtual network devices are configured in .netdev files, see **systemd.netdev(5)**.

SEE ALSO

networkctl(1), **systemd(1)**, **systemd.link(5)**, **systemd.network(5)**, **systemd.netdev(5)**, **systemd-networkd-wait-online.service(8)**, **systemd-network-generator.service(8)**

NAME

systemd-resolved.service, systemd-resolved – Network Name Resolution manager

SYNOPSIS

systemd-resolved.service

/lib/systemd/systemd-resolved

DESCRIPTION

systemd-resolved is a system service that provides network name resolution to local applications. It implements a caching and validating DNS/DNSSEC stub resolver, as well as an LLMNR and MulticastDNS resolver and responder. Local applications may submit network name resolution requests via three interfaces:

- The native, fully-featured API **systemd-resolved** exposes on the bus, see **org.freedesktop.resolve1(5)** and **org.freedesktop.LogControl1(5)** for details. Usage of this API is generally recommended to clients as it is asynchronous and fully featured (for example, properly returns DNSSEC validation status and interface scope for addresses as necessary for supporting link-local networking).
- The glibc **getaddrinfo(3)** API as defined by [RFC3493^{\[1\]}](#) and its related resolver functions, including **gethostbyname(3)**. This API is widely supported, including beyond the Linux platform. In its current form it does not expose DNSSEC validation status information however, and is synchronous only. This API is backed by the glibc Name Service Switch (**nss(5)**). Usage of the glibc NSS module **nss-resolve(8)** is required in order to allow glibc's NSS resolver functions to resolve hostnames via **systemd-resolved**.
- Additionally, **systemd-resolved** provides a local DNS stub listener on IP address 127.0.0.53 on the local loopback interface. Programs issuing DNS requests directly, bypassing any local API may be directed to this stub, in order to connect them to **systemd-resolved**. Note however that it is strongly recommended that local programs use the glibc NSS or bus APIs instead (as described above), as various network resolution concepts (such as link-local addressing, or LLMNR Unicode domains) cannot be mapped to the unicast DNS protocol.

The DNS servers contacted are determined from the global settings in /etc/systemd/resolved.conf, the per-link static settings in /etc/systemd/network/*.network files (in case **systemd-networkd.service(8)** is used), the per-link dynamic settings received over DHCP, information provided via **resolvectl(1)**, and any DNS server information made available by other system services. See **resolved.conf(5)** and **systemd.network(5)** for details about systemd's own configuration files for DNS servers. To improve compatibility, /etc/resolv.conf is read in order to discover configured system DNS servers, but only if it is not a symlink to /run/systemd/resolve/stub-resolv.conf, /usr/lib/systemd/resolv.conf or /run/systemd/resolve/resolv.conf (see below).

SYNTHETIC RECORDS

systemd-resolved synthesizes DNS resource records (RRs) for the following cases:

- The local, configured hostname is resolved to all locally configured IP addresses ordered by their scope, or — if none are configured — the IPv4 address 127.0.0.2 (which is on the local loopback interface) and the IPv6 address ::1 (which is the local host).
- The hostnames "localhost" and "localhost.localdomain" as well as any hostname ending in ".localhost" or ".localhost.localdomain" are resolved to the IP addresses 127.0.0.1 and ::1.
- The hostname "_gateway" is resolved to all current default routing gateway addresses, ordered by their metric. This assigns a stable hostname to the current gateway, useful for referencing it independently of the current network configuration state.
- The hostname "_outbound" is resolved to the local IPv4 and IPv6 addresses that are most likely used for communication with other hosts. This is determined by requesting a routing decision to the configured default gateways from the kernel and then using the local IP addresses selected by this decision. This hostname is only available if there is at least one local default gateway configured. This assigns a stable hostname to the local outbound IP addresses, useful for referencing them

independently of the current network configuration state.

- The mappings defined in /etc/hosts are resolved to their configured addresses and back, but they will not affect lookups for non-address types (like MX). Support for /etc/hosts may be disabled with *ReadEtcHosts=no*, see **resolved.conf(5)**.

PROTOCOLS AND ROUTING

The lookup requests that systemd-resolved.service receives are routed to the available DNS servers, LLMNR, and MulticastDNS interfaces according to the following rules:

- Names for which synthetic records are generated (the local hostname, "localhost" and "localdomain", local gateway, as listed in the previous section) and addresses configured in /etc/hosts are never routed to the network and a reply is sent immediately.
- Single-label names are resolved using LLMNR on all local interfaces where LLMNR is enabled. Lookups for IPv4 addresses are only sent via LLMNR on IPv4, and lookups for IPv6 addresses are only sent via LLMNR on IPv6. Note that lookups for single-label synthesized names are not routed to LLMNR, MulticastDNS or unicast DNS.
- Queries for the address records (A and AAAA) of single-label non-synthesized names are resolved via unicast DNS using search domains. For any interface which defines search domains, such look-ups are routed to the servers defined for that interface, suffixed with each of those search domains. When global search domains are defined, such look-ups are routed to the global servers. For each search domain, queries are performed by suffixing the name with each of the search domains in turn. Additionally, lookup of single-label names via unicast DNS may be enabled with the *ResolveUnicastSingleLabel=yes* setting. The details of which servers are queried and how the final reply is chosen are described below. Note that this means that address queries for single-label names are never sent out to remote DNS servers by default, and resolution is only possible if search domains are defined.
- Multi-label names with the domain suffix ".local" are resolved using MulticastDNS on all local interfaces where MulticastDNS is enabled. As with LLMNR, IPv4 address lookups are sent via IPv4 and IPv6 address lookups are sent via IPv6.
- Queries for multi-label names are routed via unicast DNS on local interfaces that have a DNS server configured, plus the globally configured DNS servers if there are any. Which interfaces are used is determined by the routing logic based on search and route-only domains, described below. Note that by default, lookups for domains with the ".local" suffix are not routed to DNS servers, unless the domain is specified explicitly as routing or search domain for the DNS server and interface. This means that on networks where the ".local" domain is defined in a site-specific DNS server, explicit search or routing domains need to be configured to make lookups work within this DNS domain. Note that these days, it's generally recommended to avoid defining ".local" in a DNS server, as [RFC6762^{\[2\]}](#) reserves this domain for exclusive MulticastDNS use.
- Address lookups (reverse lookups) are routed similarly to multi-label names, with the exception that addresses from the link-local address range are never routed to unicast DNS and are only resolved using LLMNR and MulticastDNS (when enabled).

If lookups are routed to multiple interfaces, the first successful response is returned (thus effectively merging the lookup zones on all matching interfaces). If the lookup failed on all interfaces, the last failing response is returned.

Routing of lookups is determined by the per-interface routing domains (search and route-only) and global search domains. See **systemd.network(5)** and **resolvectl(1)** for a description how those settings are set dynamically and the discussion of *Domains=* in **resolved.conf(5)** for a description of globally configured DNS settings.

The following query routing logic applies for unicast DNS lookups initiated by systemd-resolved.service:

- If a name to look up matches (that is: is equal to or has as suffix) any of the configured routing domains (search or route-only) of any link, or the globally configured DNS settings, "best matching" routing domain is determined: the matching one with the most labels. The query is then

sent to all DNS servers of any links or the globally configured DNS servers associated with this "best matching" routing domain. (Note that more than one link might have this same "best matching" routing domain configured, in which case the query is sent to all of them in parallel).

In case of single-label names, when search domains are defined, the same logic applies, except that the name is first suffixed by each of the search domains in turn. Note that this search logic doesn't apply to any names with at least one dot. Also see the discussion about compatibility with the traditional glibc resolver below.

- If a query does not match any configured routing domain (either per-link or global), it is sent to all DNS servers that are configured on links with the *DefaultRoute*= option set, as well as the globally configured DNS server.
- If there is no link configured as *DefaultRoute*= and no global DNS server configured, one of the compiled-in fallback DNS servers is used.
- Otherwise the unicast DNS query fails, as no suitable DNS servers can be determined.

The *DefaultRoute*= option is a boolean setting configurable with **resolvectl** or in .network files. If not set, it is implicitly determined based on the configured DNS domains for a link: if there's a route-only domain other than ".~.", it defaults to false, otherwise to true.

Effectively this means: in order to support single-label non-synthesized names, define appropriate search domains. In order to preferably route all DNS queries not explicitly matched by routing domain configuration to a specific link, configure a ".~." route-only domain on it. This will ensure that other links will not be considered for these queries (unless they too carry such a routing domain). In order to route all such DNS queries to a specific link only if no other link is preferred, set the *DefaultRoute*= option for the link to true and do not configure a ".~." route-only domain on it. Finally, in order to ensure that a specific link never receives any DNS traffic not matching any of its configured routing domains, set the *DefaultRoute*= option for it to false.

See **org.freedesktop.resolve1(5)** for information about the D-Bus APIs `systemd-resolved` provides.

COMPATIBILITY WITH THE TRADITIONAL GLIBC STUB RESOLVER

This section provides a short summary of differences in the stub resolver implemented by **nss-resolve(8)** together with **systemd-resolved** and the traditional stub resolver implemented in `nss-dns`.

- Some names are always resolved internally (see Synthetic Records above). Traditionally they would be resolved by `nss-files` if provided in /etc/hosts. But note that the details of how a query is constructed are under the control of the client library. `nss-dns` will first try to resolve names using search domains and even if those queries are routed to `systemd-resolved`, it will send them out over the network using the usual rules for multi-label name routing^[3].
- Single-label names are not resolved for A and AAAA records using unicast DNS (unless overridden with *ResolveUnicastSingleLabel*=, see **resolved.conf(5)**). This is similar to the **no-tld-query** option being set in **resolv.conf(5)**.
- Search domains are not used for *sufficing* of multi-label names. (Search domains are nevertheless used for lookup *routing*, for names that were originally specified as single-label or multi-label.) Any name with at least one dot is always interpreted as a FQDN. `nss-dns` would resolve names both as relative (using search domains) and absolute FQDN names. Some names would be resolved as relative first, and after that query has failed, as absolute, while other names would be resolved in opposite order. The *ndots* option in /etc/resolv.conf was used to control how many dots the name needs to have to be resolved as relative first. This stub resolver does not implement this at all: multi-label names are only resolved as FQDNs.^[4]
- This resolver has a notion of the special ".local" domain used for MulticastDNS, and will not route queries with that suffix to unicast DNS servers unless explicitly configured, see above. Also, reverse lookups for link-local addresses are not sent to unicast DNS servers.
- This resolver reads and caches /etc/hosts internally. (In other words, `nss-resolve` replaces `nss-files` in addition to `nss-dns`). Entries in /etc/hosts have highest priority.

- This resolver also implements LLMNR and MulticastDNS in addition to the classic unicast DNS protocol, and will resolve single-label names using LLMNR (when enabled) and names ending in ".local" using MulticastDNS (when enabled).
- Environment variables `$LOCALDOMAIN` and `$RES_OPTIONS` described in **resolv.conf(5)** are not supported currently.

/ETC/RESOLV.CONF

Four modes of handling `/etc/resolv.conf` (see **resolv.conf(5)**) are supported:

- **systemd-resolved** maintains the `/run/systemd/resolve/stub-resolv.conf` file for compatibility with traditional Linux programs. This file may be symlinked from `/etc/resolv.conf`. This file lists the 127.0.0.53 DNS stub (see above) as the only DNS server. It also contains a list of search domains that are in use by `systemd-resolved`. The list of search domains is always kept up-to-date. Note that `/run/systemd/resolve/stub-resolv.conf` should not be used directly by applications, but only through a symlink from `/etc/resolv.conf`. This file may be symlinked from `/etc/resolv.conf` in order to connect all local clients that bypass local DNS APIs to **systemd-resolved** with correct search domains settings. This mode of operation is recommended.
- A static file `/usr/lib/systemd/resolv.conf` is provided that lists the 127.0.0.53 DNS stub (see above) as only DNS server. This file may be symlinked from `/etc/resolv.conf` in order to connect all local clients that bypass local DNS APIs to **systemd-resolved**. This file does not contain any search domains.
- **systemd-resolved** maintains the `/run/systemd/resolve/resolv.conf` file for compatibility with traditional Linux programs. This file may be symlinked from `/etc/resolv.conf` and is always kept up-to-date, containing information about all known DNS servers. Note the file format's limitations: it does not know a concept of per-interface DNS servers and hence only contains system-wide DNS server definitions. Note that `/run/systemd/resolve/resolv.conf` should not be used directly by applications, but only through a symlink from `/etc/resolv.conf`. If this mode of operation is used local clients that bypass any local DNS API will also bypass **systemd-resolved** and will talk directly to the known DNS servers.
- Alternatively, `/etc/resolv.conf` may be managed by other packages, in which case **systemd-resolved** will read it for DNS configuration data. In this mode of operation **systemd-resolved** is consumer rather than provider of this configuration file.

Note that the selected mode of operation for this file is detected fully automatically, depending on whether `/etc/resolv.conf` is a symlink to `/run/systemd/resolve/resolv.conf` or lists 127.0.0.53 as DNS server.

SIGNALS

SIGUSR1

Upon reception of the **SIGUSR1** process signal **systemd-resolved** will dump the contents of all DNS resource record caches it maintains, as well as all feature level information it learnt about configured DNS servers into the system logs.

SIGUSR2

Upon reception of the **SIGUSR2** process signal **systemd-resolved** will flush all caches it maintains. Note that it should normally not be necessary to request this explicitly – except for debugging purposes – as **systemd-resolved** flushes the caches automatically anyway any time the host's network configuration changes. Sending this signal to **systemd-resolved** is equivalent to the **resolvectl flush-caches** command, however the latter is recommended since it operates in a synchronous way.

SIGRTMIN+1

Upon reception of the **SIGRTMIN+1** process signal **systemd-resolved** will forget everything it learnt about the configured DNS servers. Specifically any information about server feature support is flushed out, and the server feature probing logic is restarted on the next request, starting with the most fully featured level. Note that it should normally not be necessary to request this explicitly – except for debugging purposes – as **systemd-resolved** automatically forgets learnt information any time the DNS server configuration changes. Sending this signal to **systemd-resolved** is equivalent to the

resolvectl reset-server-features command, however the latter is recommended since it operates in a synchronous way.

SEE ALSO

systemd(1), resolved.conf(5), dnssec-trust-anchors.d(5), nss-resolve(8), resolvectl(1), resolv.conf(5), hosts(5), systemd.network(5), systemd-networkd.service(8)

NOTES

1. RFC3493
<https://tools.ietf.org/html/rfc3493>
2. RFC6762
<https://tools.ietf.org/html/rfc6762>
3. For example, if /etc/resolv.conf has

```
nameserver 127.0.0.53
search foobar.com barbar.com
```

and we look up "localhost", nss-dns will send the following queries to systemd-resolved listening on 127.0.0.53:53: first "localhost.foobar.com", then "localhost.barbar.com", and finally "localhost". If (hopefully) the first two queries fail, systemd-resolved will synthesize an answer for the third query.

When using nss-dns with any search domains, it is thus crucial to always configure nss-files with higher priority and provide mappings for names that should not be resolved using search domains.

4. There are currently more than 1500 top-level domain names defined, and new ones are added regularly, often using "attractive" names that are also likely to be used locally. Not looking up multi-label names in this fashion avoids fragility in both directions: a valid global name could be obscured by a local name, and resolution of a relative local name could suddenly break when a new top-level domain is created, or when a new subdomain of a top-level domain is registered. Resolving any given name as either relative or absolute avoids this ambiguity.

NAME

systemd-sysctl.service, systemd-sysctl – Configure kernel parameters at boot

SYNOPSIS

/lib/systemd/systemd-sysctl [OPTIONS...] [CONFIGFILE...]

systemd-sysctl.service

DESCRIPTION

systemd-sysctl.service is an early boot service that configures **sysctl(8)** kernel parameters by invoking **/lib/systemd/systemd-sysctl**.

When invoked with no arguments, **/lib/systemd/systemd-sysctl** applies all directives from configuration files listed in **sysctl.d(5)**. If one or more filenames are passed on the command line, only the directives in these files are applied.

In addition, **--prefix=** option may be used to limit which sysctl settings are applied.

See **sysctl.d(5)** for information about the configuration of sysctl settings. After sysctl configuration is changed on disk, it must be written to the files in **/proc/sys/** before it takes effect. It is possible to update specific settings, or simply to reload all configuration, see Examples below.

OPTIONS

--prefix=

Only apply rules with the specified prefix.

--cat-config

Copy the contents of config files to standard output. Before each file, the filename is printed as a comment.

--no-pager

Do not pipe output into a pager.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

EXAMPLES

Example 1. Reset all sysctl settings

```
systemctl restart systemd-sysctl
```

Example 2. View coredump handler configuration

```
# sysctl kernel.core_pattern  
kernel.core_pattern = |/libexec/abrt-hook-ccpp %s %c %p %u %g %t %P %I
```

Example 3. Update coredump handler configuration

```
# /lib/systemd/systemd-sysctl --prefix kernel.core_pattern
```

This searches all the directories listed in **sysctl.d(5)** for configuration files and writes **/proc/sys/kernel/core_pattern**.

Example 4. Update coredump handler configuration according to a specific file

```
# /lib/systemd/systemd-sysctl 50-coredump.conf
```

This applies all the settings found in **50-coredump.conf**. Either **/etc/sysctl.d/50-coredump.conf**, or **/run/sysctl.d/50-coredump.conf**, or **/usr/lib/sysctl.d/50-coredump.conf** will be used, in the order of preference.

See **sysctl(8)** for various ways to directly apply sysctl settings.

SEE ALSO

systemd(1), sysctl.d(5), sysctl(8),

NAME

`systemd-system.conf`, `system.conf.d`, `systemd-user.conf`, `user.conf.d` – System and session service manager configuration files

SYNOPSIS

```
/etc/systemd/system.conf, /etc/systemd/system.conf.d/*.conf, /run/systemd/system.conf.d/*.conf,
/lib/systemd/system.conf.d/*.conf
~/.config/systemd/user.conf, /etc/systemd/user.conf, /etc/systemd/user.conf.d/*.conf,
/run/systemd/user.conf.d/*.conf, /usr/lib/systemd/user.conf.d/*.conf
```

DESCRIPTION

When run as a system instance, **systemd** interprets the configuration file `system.conf` and the files in `system.conf.d` directories; when run as a user instance, it interprets the configuration file `user.conf` (either in the home directory of the user, or if not found, under `/etc/systemd/`) and the files in `user.conf.d` directories. These configuration files contain a few settings controlling basic manager operations.

See **systemd.syntax(7)** for a general description of the syntax.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in `/etc/systemd/` contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from `/usr/lib/systemd/*.conf.d/`, `/usr/local/lib/systemd/*.conf.d/`, and `/etc/systemd/*.conf.d/`. Those drop-ins have higher precedence and override the main configuration file. Files in the `*.conf.d/` configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under `/usr/`. Files in `/etc/` are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to `/dev/null` in the configuration directory in `/etc/`, with the same filename as the vendor configuration file.

OPTIONS

All options are configured in the [Manager] section:

LogColor=, *LogLevel=*, *LogLocation=*, *LogTarget=*, *LogTime=*, *DumpCore=yes*, *CrashChangeVT=no*,
CrashShell=no, *CrashReboot=no*, *ShowStatus=yes*, *DefaultStandardOutput=journal*,
DefaultStandardError=inherit

Configures various parameters of basic manager operation. These options may be overridden by the respective process and kernel command line arguments. See **systemd(1)** for details.

CtrlAltDelBurstAction=

Defines what action will be performed if user presses Ctrl–Alt–Delete more than 7 times in 2s. Can be set to "reboot–force", "poweroff–force", "reboot–immediate", "poweroff–immediate" or disabled with "none". Defaults to "reboot–force".

CPUAffinity=

Configures the CPU affinity for the service manager as well as the default CPU affinity for all forked off processes. Takes a list of CPU indices or ranges separated by either whitespace or commas. CPU ranges are specified by the lower and upper CPU indices separated by a dash. This option may be specified more than once, in which case the specified CPU affinity masks are merged. If the empty

string is assigned, the mask is reset, all assignments prior to this will have no effect. Individual services may override the CPU affinity for their processes with the *CPUAffinity*= setting in unit files, see **systemd.exec(5)**.

***NUMAPolicy*=**

Configures the NUMA memory policy for the service manager and the default NUMA memory policy for all forked off processes. Individual services may override the default policy with the *NUMAPolicy*= setting in unit files, see **systemd.exec(5)**.

***NUMAMask*=**

Configures the NUMA node mask that will be associated with the selected NUMA policy. Note that **default** and **local** NUMA policies don't require explicit NUMA node mask and value of the option can be empty. Similarly to *NUMAPolicy*=, value can be overridden by individual services in unit files, see **systemd.exec(5)**.

***RuntimeWatchdogSec*=, *RebootWatchdogSec*=, *KExecWatchdogSec*=**

Configure the hardware watchdog at runtime and at reboot. Takes a timeout value in seconds (or in other time units if suffixed with "ms", "min", "h", "d", "w"). If *RuntimeWatchdogSec*= is set to a non-zero value, the watchdog hardware (/dev/watchdog or the path specified with *WatchdogDevice*= or the kernel option *systemd.watchdog-device*) will be programmed to automatically reboot the system if it is not contacted within the specified timeout interval. The system manager will ensure to contact it at least once in half the specified timeout interval. This feature requires a hardware watchdog device to be present, as it is commonly the case in embedded and server systems. Not all hardware watchdogs allow configuration of all possible reboot timeout values, in which case the closest available timeout is picked. *RebootWatchdogSec*= may be used to configure the hardware watchdog when the system is asked to reboot. It works as a safety net to ensure that the reboot takes place even if a clean reboot attempt times out. Note that the *RebootWatchdogSec*= timeout applies only to the second phase of the reboot, i.e. after all regular services are already terminated, and after the system and service manager process (PID 1) got replaced by the **systemd-shutdown** binary, see **system bootup(7)** for details. During the first phase of the shutdown operation the system and service manager remains running and hence *RuntimeWatchdogSec*= is still honoured. In order to define a timeout on this first phase of system shutdown, configure *JobTimeoutSec*= and *JobTimeoutAction*= in the [Unit] section of the shutdown.target unit. By default *RuntimeWatchdogSec*= defaults to 0 (off), and *RebootWatchdogSec*= to 10min. *KExecWatchdogSec*= may be used to additionally enable the watchdog when kexec is being executed rather than when rebooting. Note that if the kernel does not reset the watchdog on kexec (depending on the specific hardware and/or driver), in this case the watchdog might not get disabled after kexec succeeds and thus the system might get rebooted, unless *RuntimeWatchdogSec*= is also enabled at the same time. For this reason it is recommended to enable *KExecWatchdogSec*= only if *RuntimeWatchdogSec*= is also enabled. These settings have no effect if a hardware watchdog is not available.

***WatchdogDevice*=**

Configure the hardware watchdog device that the runtime and shutdown watchdog timers will open and use. Defaults to /dev/watchdog. This setting has no effect if a hardware watchdog is not available.

***CapabilityBoundingSet*=**

Controls which capabilities to include in the capability bounding set for PID 1 and its children. See **capabilities(7)** for details. Takes a whitespace-separated list of capability names as read by **cap_from_name(3)**. Capabilities listed will be included in the bounding set, all others are removed. If the list of capabilities is prefixed with ~, all but the listed capabilities will be included, the effect of the assignment inverted. Note that this option also affects the respective capabilities in the effective, permitted and inheritable capability sets. The capability bounding set may also be individually configured for units using the *CapabilityBoundingSet*= directive for units, but note that capabilities dropped for PID 1 cannot be regained in individual units, they are lost for good.

***NoNewPrivileges*=**

Takes a boolean argument. If true, ensures that PID 1 and all its children can never gain new privileges through **execve(2)** (e.g. via setuid or setgid bits, or filesystem capabilities). Defaults to false. General

purpose distributions commonly rely on executables with setuid or setgid bits and will thus not function properly with this option enabled. Individual units cannot disable this option. Also see **No New Privileges Flag**^[1].

SystemCallArchitectures=

Takes a space-separated list of architecture identifiers. Selects from which architectures system calls may be invoked on this system. This may be used as an effective way to disable invocation of non-native binaries system-wide, for example to prohibit execution of 32-bit x86 binaries on 64-bit x86-64 systems. This option operates system-wide, and acts similar to the *SystemCallArchitectures*= setting of unit files, see **systemd.exec(5)** for details. This setting defaults to the empty list, in which case no filtering of system calls based on architecture is applied. Known architecture identifiers are "x86", "x86-64", "x32", "arm" and the special identifier "native". The latter implicitly maps to the native architecture of the system (or more specifically, the architecture the system manager was compiled for). Set this setting to "native" to prohibit execution of any non-native binaries. When a binary executes a system call of an architecture that is not listed in this setting, it will be immediately terminated with the SIGSYS signal.

TimerSlackNSec=

Sets the timer slack in nanoseconds for PID 1, which is inherited by all executed processes, unless overridden individually, for example with the *TimerSlackNSec*= setting in service units (for details see **systemd.exec(5)**). The timer slack controls the accuracy of wake-ups triggered by system timers. See **prctl(2)** for more information. Note that in contrast to most other time span definitions this parameter takes an integer value in nano-seconds if no unit is specified. The usual time units are understood too.

StatusUnitFormat=

Takes **name**, **description** or **combined** as the value. If **name**, the system manager will use unit names in status messages (e.g. "systemd-journald.service"), instead of the longer and more informative descriptions set with *Description*= (e.g. "Journal Logging Service"). If **combined**, the system manager will use both unit names and descriptions in status messages (e.g. "systemd-journald.service – Journal Logging Service").

See **systemd.unit(5)** for details about unit names and *Description*=.

DefaultTimerAccuracySec=

Sets the default accuracy of timer units. This controls the global default for the *AccuracySec*= setting of timer units, see **systemd.timer(5)** for details. *AccuracySec*= set in individual units override the global default for the specific unit. Defaults to 1min. Note that the accuracy of timer units is also affected by the configured timer slack for PID 1, see *TimerSlackNSec*= above.

DefaultTimeoutStartSec=, *DefaultTimeoutStopSec*=, *DefaultTimeoutAbortSec*=, *DefaultRestartSec*=

Configures the default timeouts for starting, stopping and aborting of units, as well as the default time to sleep between automatic restarts of units, as configured per-unit in *TimeoutStartSec*=, *TimeoutStopSec*=, *TimeoutAbortSec*= and *RestartSec*= (for services, see **systemd.service(5)** for details on the per-unit settings). Disabled by default, when service with *Type=oneshot* is used. For non-service units, *DefaultTimeoutStartSec*= sets the default *TimeoutSec*= value. *DefaultTimeoutStartSec*= and *DefaultTimeoutStopSec*= default to 90s. *DefaultTimeoutAbortSec*= is not set by default so that all units fall back to *TimeoutStopSec*=. *DefaultRestartSec*= defaults to 100ms.

DefaultStartLimitIntervalSec=, *DefaultStartLimitBurst*=

Configure the default unit start rate limiting, as configured per-service by *StartLimitIntervalSec*= and *StartLimitBurst*=. See **systemd.service(5)** for details on the per-service settings.

DefaultStartLimitIntervalSec= defaults to 10s. *DefaultStartLimitBurst*= defaults to 5.

DefaultEnvironment=

Configures environment variables passed to all executed processes. Takes a space-separated list of variable assignments. See **environ(7)** for details about environment variables.

Simple "%"–specifier expansion is supported, see below for a list of supported specifiers.

Example:

```
DefaultEnvironment="VAR1=word1 word2" VAR2=word3 "VAR3=word 5 6"
```

Sets three variables "VAR1", "VAR2", "VAR3".

ManagerEnvironment=

Takes the same arguments as *DefaultEnvironment*=, see above. Sets environment variables just for the manager process itself. In contrast to user managers, these variables are not inherited by processes spawned by the system manager, use *DefaultEnvironment*= for that. Note that these variables are merged into the existing environment block. In particular, in case of the system manager, this includes variables set by the kernel based on the kernel command line.

Setting environment variables for the manager process may be useful to modify its behaviour. See [ENVIRONMENT](#)^[2] for a descriptions of some variables understood by **systemd**.

Simple "%"–specifier expansion is supported, see below for a list of supported specifiers.

DefaultCPUAccounting=, *DefaultBlockIOAccounting*=, *DefaultMemoryAccounting*=,
DefaultTasksAccounting=, *DefaultIOAccounting*=, *DefaultIPAccounting*=

Configure the default resource accounting settings, as configured per–unit by *CPUAccounting*=, *BlockIOAccounting*=, *MemoryAccounting*=, *TasksAccounting*=, *IOAccounting*= and *IPAccounting*=. See [systemd.resource-control\(5\)](#) for details on the per–unit settings. *DefaultTasksAccounting*= defaults to yes, *DefaultMemoryAccounting*= to yes. *DefaultCPUAccounting*= defaults to yes if enabling CPU accounting doesn't require the CPU controller to be enabled (Linux 4.15+ using the unified hierarchy for resource control), otherwise it defaults to no. The other three settings default to no.

DefaultTasksMax=

Configure the default value for the per–unit *TasksMax*= setting. See [systemd.resource-control\(5\)](#) for details. This setting applies to all unit types that support resource control settings, with the exception of slice units. Defaults to 15% of the minimum of *kernel.pid_max*=, *kernel.threads_max*= and root cgroup *pids.max*. Kernel has a default value for *kernel.pid_max*= and an algorithm of counting in case of more than 32 cores. For example with the default *kernel.pid_max*=, *DefaultTasksMax*= defaults to 4915, but might be greater in other systems or smaller in OS containers.

DefaultLimitCPU=, *DefaultLimitFSIZE*=, *DefaultLimitDATA*=, *DefaultLimitSTACK*=,
DefaultLimitCORE=, *DefaultLimitRSS*=, *DefaultLimitNOFILE*=, *DefaultLimitAS*=,
DefaultLimitNPROC=, *DefaultLimitMEMLOCK*=, *DefaultLimitLOCKS*=, *DefaultLimitSIGPENDING*=,
DefaultLimitMSGQUEUE=, *DefaultLimitNICE*=, *DefaultLimitRTPRIO*=, *DefaultLimitRTTIME*=

These settings control various default resource limits for processes executed by units. See [setrlimit\(2\)](#) for details. These settings may be overridden in individual units using the corresponding *LimitXXX*= directives and they accept the same parameter syntax, see [systemd.exec\(5\)](#) for details. Note that these resource limits are only defaults for units, they are not applied to the service manager process (i.e. PID 1) itself.

Most of these settings are unset, which means the resource limits are inherited from the kernel or, if invoked in a container, from the container manager. However, the following have defaults:

- *DefaultLimitNOFILE*= defaults to "1024:524288".
- *DefaultLimitCORE*= does not have a default but it is worth mentioning that *RLIMIT_CORE* is set to "infinity" by PID 1 which is inherited by its children.
- Note that the service manager internally increases *RLIMIT_MEMLOCK* for itself, however the limit is reverted to the original value for child processes forked off.

DefaultOOMPolicy=

Configure the default policy for reacting to processes being killed by the Linux Out–Of–Memory

(OOM) killer. This may be used to pick a global default for the per-unit *OOMPpolicy=* setting. See **systemd.service(5)** for details. Note that this default is not used for services that have *Delegate=* turned on.

SPECIFIERS

Specifiers may be used in the *DefaultEnvironment=* and *ManagerEnvironment=* settings. The following expansions are understood:

NAME

systemd-mount, **systemd-umount** – Establish and destroy transient mount or auto-mount points

SYNOPSIS

```
systemd-mount [OPTIONS...] WHAT [WHERE]
systemd-mount [OPTIONS...] --list
systemd-mount [OPTIONS...] --umount WHAT/WHERE...
```

DESCRIPTION

systemd-mount may be used to create and start a transient .mount or .automount unit of the file system *WHAT* on the mount point *WHERE*.

In many ways, **systemd-mount** is similar to the lower-level **mount**(8) command, however instead of executing the mount operation directly and immediately, **systemd-mount** schedules it through the service manager job queue, so that it may pull in further dependencies (such as parent mounts, or a file system checker to execute a priori), and may make use of the auto-mounting logic.

The command takes either one or two arguments. If only one argument is specified it should refer to a block device or regular file containing a file system (e.g. "/dev/sdb1" or "/path/to/disk.img"). The block device or image file is then probed for a file system label and other metadata, and is mounted to a directory below /run/media/system/ whose name is generated from the file system label. In this mode the block device or image file must exist at the time of invocation of the command, so that it may be probed. If the device is found to be a removable block device (e.g. a USB stick), an automount point is created instead of a regular mount point (i.e. the **--automount**= option is implied, see below).

If two arguments are specified, the first indicates the mount source (the *WHAT*) and the second indicates the path to mount it on (the *WHERE*). In this mode no probing of the source is attempted, and a backing device node doesn't have to exist. However, if this mode is combined with **--discover**, device node probing for additional metadata is enabled, and – much like in the single-argument case discussed above – the specified device has to exist at the time of invocation of the command.

Use the **--list** command to show a terse table of all local, known block devices with file systems that may be mounted with this command.

systemd-umount can be used to unmount a mount or automount point. It is the same as **systemd-mount** **--umount**.

OPTIONS

The following options are understood:

--no-block

Do not synchronously wait for the requested operation to finish. If this is not specified, the job will be verified, enqueued and **systemd-mount** will wait until the mount or automount unit's start-up is completed. By passing this argument, it is only verified and enqueued.

-l, --full

Do not ellipsize the output when **--list** is specified.

--no-pager

Do not pipe output into a pager.

--no-legend

Do not print the legend, i.e. column headers and the footer with hints.

--no-ask-password

Do not query the user for authentication for privileged operations.

--quiet, -q

Suppresses additional informational output while running.

--discover

Enable probing of the mount source. This switch is implied if a single argument is specified on the command line. If passed, additional metadata is read from the device to enhance the unit to create. For

example, a descriptive string for the transient units is generated from the file system label and device model. Moreover if a removable block device (e.g. USB stick) is detected an automount unit instead of a regular mount unit is created, with a short idle timeout, in order to ensure the file-system is placed in a clean state quickly after each access.

--type=, -t

Specifies the file system type to mount (e.g. "vfat" or "ext4"). If omitted or set to "auto", the file system type is determined automatically.

--options=, -o

Additional mount options for the mount point.

--owner=USER

Let the specified user *USER* own the mounted file system. This is done by appending **uid=** and **gid=** options to the list of mount options. Only certain file systems support this option.

--fsck=

Takes a boolean argument, defaults to on. Controls whether to run a file system check immediately before the mount operation. In the automount case (see **--automount=** below) the check will be run the moment the first access to the device is made, which might slightly delay the access.

--description=

Provide a description for the mount or automount unit. See *Description=* in **systemd.unit(5)**.

--property=, -p

Sets a unit property for the mount unit that is created. This takes an assignment in the same format as **systemctl(1)**'s **set-property** command.

--automount=

Takes a boolean argument. Controls whether to create an automount point or a regular mount point. If true an automount point is created that is backed by the actual file system at the time of first access. If false a plain mount point is created that is backed by the actual file system immediately. Automount points have the benefit that the file system stays unmounted and hence in clean state until it is first accessed. In automount mode the **--timeout-idle-sec=** switch (see below) may be used to ensure the mount point is unmounted automatically after the last access and an idle period passed.

If this switch is not specified it defaults to false. If not specified and **--discover** is used (or only a single argument passed, which implies **--discover**, see above), and the file system block device is detected to be removable, it is set to true, in order to increase the chance that the file system is in a fully clean state if the device is unplugged abruptly.

-A

Equivalent to **--automount=yes**.

--timeout-idle-sec=

Takes a time value that controls the idle timeout in automount mode. If set to "infinity" (the default) no automatic unmounts are done. Otherwise the file system backing the automount point is detached after the last access and the idle timeout passed. See **systemd.time(7)** for details on the time syntax supported. This option has no effect if only a regular mount is established, and automounting is not used.

Note that if **--discover** is used (or only a single argument passed, which implies **--discover**, see above), and the file system block device is detected to be removable, **--timeout-idle-sec=1s** is implied.

--automount-property=

Similar to **--property=**, but applies additional properties to the automount unit created, instead of the mount unit.

--bind-device

This option only has an effect in automount mode, and controls whether the automount unit shall be

bound to the backing device's lifetime. If set, the automount point will be removed automatically when the backing device vanishes. By default the automount point stays around, and subsequent accesses will block until backing device is replugged. This option has no effect in case of non-device mounts, such as network or virtual file system mounts.

Note that if **--discover** is used (or only a single argument passed, which implies **--discover**, see above), and the file system block device is detected to be removable, this option is implied.

--list

Instead of establishing a mount or automount point, print a terse list of block devices containing file systems that may be mounted with "systemd-mount", along with useful metadata such as labels, etc.

-u, --umount

Stop the mount and automount units corresponding to the specified mount points *WHERE* or the devices *WHAT*. **systemd-mount** with this option or **systemd-umount** can take multiple arguments which can be mount points, devices, /etc/fstab style node names, or backing files corresponding to loop devices, like **systemd-mount --umount /path/to/umount /dev/sda1 UUID=xxxxxx-xxxx LABEL=xxxxx /path/to/disk.img**. Note that when **-H** or **-M** is specified, only absolute paths to mount points are supported.

-G, --collect

Unload the transient unit after it completed, even if it failed. Normally, without this option, all mount units that mount and failed are kept in memory until the user explicitly resets their failure state with **systemctl reset-failed** or an equivalent command. On the other hand, units that stopped successfully are unloaded immediately. If this option is turned on the "garbage collection" of units is more aggressive, and unloads units regardless if they exited successfully or failed. This option is a shortcut for **--property=CollectMode=inactive-or-failed**, see the explanation for *CollectMode*= in **systemd.unit(5)** for further information.

--user

Talk to the service manager of the calling user, rather than the service manager of the system.

--system

Talk to the service manager of the system. This is the implied default.

-H, --host=

Execute the operation remotely. Specify a hostname, or a username and hostname separated by "@", to connect to. The hostname may optionally be suffixed by a port ssh is listening on, separated by ":"; and then a container name, separated by "/", which connects directly to a specific container on the specified host. This will use SSH to talk to the remote machine manager instance. Container names may be enumerated with **machinectl -H HOST**. Put IPv6 addresses in brackets.

-M, --machine=

Execute operation on a local container. Specify a container name to connect to, optionally prefixed by a user name to connect as and a separating "@" character. If the special string ".host" is used in place of the container name, a connection to the local system is made (which is useful to connect to a specific user's user bus: "--user --machine=lennart@.host"). If the "@" syntax is not used, the connection is made as root user. If the "@" syntax is used either the left hand side or the right hand side may be omitted (but not both) in which case the local user name and ".host" are implied.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

EXIT STATUS

On success, 0 is returned, a non-zero failure code otherwise.

THE UDEV DATABASE

If **--discover** is used, **systemd-mount** honors a couple of additional udev properties of block devices:

SYSTEMD_MOUNT_OPTIONS=

The mount options to use, if **--options=** is not used.

SYSTEMD_MOUNT_WHERE=

The file system path to place the mount point at, instead of the automatically generated one.

EXAMPLE

Use a udev rule like the following to automatically mount all USB storage plugged in:

```
ACTION=="add", SUBSYSTEMS=="usb", SUBSYSTEM=="block", ENV{ID_FS_USAGE}=="filesystem", \
    RUN{program}+="/usr/bin/systemd-mount --no-block --automount=yes --collect $devnode"
```

systemd-run(1)

NAME

`systemd-system.conf`, `system.conf.d`, `systemd-user.conf`, `user.conf.d` – System and session service manager configuration files

SYNOPSIS

```
/etc/systemd/system.conf, /etc/systemd/system.conf.d/*.conf, /run/systemd/system.conf.d/*.conf,
/lib/systemd/system.conf.d/*.conf
~/.config/systemd/user.conf, /etc/systemd/user.conf, /etc/systemd/user.conf.d/*.conf,
/run/systemd/user.conf.d/*.conf, /usr/lib/systemd/user.conf.d/*.conf
```

DESCRIPTION

When run as a system instance, **systemd** interprets the configuration file `system.conf` and the files in `system.conf.d` directories; when run as a user instance, it interprets the configuration file `user.conf` (either in the home directory of the user, or if not found, under `/etc/systemd/`) and the files in `user.conf.d` directories. These configuration files contain a few settings controlling basic manager operations.

See **systemd.syntax(7)** for a general description of the syntax.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in `/etc/systemd/` contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from `/usr/lib/systemd/*.conf.d/`, `/usr/local/lib/systemd/*.conf.d/`, and `/etc/systemd/*.conf.d/`. Those drop-ins have higher precedence and override the main configuration file. Files in the `*.conf.d/` configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under `/usr/`. Files in `/etc/` are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to `/dev/null` in the configuration directory in `/etc/`, with the same filename as the vendor configuration file.

OPTIONS

All options are configured in the [Manager] section:

LogColor=, *LogLevel=*, *LogLocation=*, *LogTarget=*, *LogTime=*, *DumpCore=yes*, *CrashChangeVT=no*,
CrashShell=no, *CrashReboot=no*, *ShowStatus=yes*, *DefaultStandardOutput=journal*,
DefaultStandardError=inherit

Configures various parameters of basic manager operation. These options may be overridden by the respective process and kernel command line arguments. See **systemd(1)** for details.

CtrlAltDelBurstAction=

Defines what action will be performed if user presses Ctrl–Alt–Delete more than 7 times in 2s. Can be set to "reboot–force", "poweroff–force", "reboot–immediate", "poweroff–immediate" or disabled with "none". Defaults to "reboot–force".

CPUAffinity=

Configures the CPU affinity for the service manager as well as the default CPU affinity for all forked off processes. Takes a list of CPU indices or ranges separated by either whitespace or commas. CPU ranges are specified by the lower and upper CPU indices separated by a dash. This option may be specified more than once, in which case the specified CPU affinity masks are merged. If the empty

string is assigned, the mask is reset, all assignments prior to this will have no effect. Individual services may override the CPU affinity for their processes with the *CPUAffinity*= setting in unit files, see **systemd.exec(5)**.

***NUMAPolicy*=**

Configures the NUMA memory policy for the service manager and the default NUMA memory policy for all forked off processes. Individual services may override the default policy with the *NUMAPolicy*= setting in unit files, see **systemd.exec(5)**.

***NUMAMask*=**

Configures the NUMA node mask that will be associated with the selected NUMA policy. Note that **default** and **local** NUMA policies don't require explicit NUMA node mask and value of the option can be empty. Similarly to *NUMAPolicy*=, value can be overridden by individual services in unit files, see **systemd.exec(5)**.

***RuntimeWatchdogSec*=, *RebootWatchdogSec*=, *KExecWatchdogSec*=**

Configure the hardware watchdog at runtime and at reboot. Takes a timeout value in seconds (or in other time units if suffixed with "ms", "min", "h", "d", "w"). If *RuntimeWatchdogSec*= is set to a non-zero value, the watchdog hardware (/dev/watchdog or the path specified with *WatchdogDevice*= or the kernel option *systemd.watchdog-device*) will be programmed to automatically reboot the system if it is not contacted within the specified timeout interval. The system manager will ensure to contact it at least once in half the specified timeout interval. This feature requires a hardware watchdog device to be present, as it is commonly the case in embedded and server systems. Not all hardware watchdogs allow configuration of all possible reboot timeout values, in which case the closest available timeout is picked. *RebootWatchdogSec*= may be used to configure the hardware watchdog when the system is asked to reboot. It works as a safety net to ensure that the reboot takes place even if a clean reboot attempt times out. Note that the *RebootWatchdogSec*= timeout applies only to the second phase of the reboot, i.e. after all regular services are already terminated, and after the system and service manager process (PID 1) got replaced by the **systemd-shutdown** binary, see **system bootup(7)** for details. During the first phase of the shutdown operation the system and service manager remains running and hence *RuntimeWatchdogSec*= is still honoured. In order to define a timeout on this first phase of system shutdown, configure *JobTimeoutSec*= and *JobTimeoutAction*= in the [Unit] section of the shutdown.target unit. By default *RuntimeWatchdogSec*= defaults to 0 (off), and *RebootWatchdogSec*= to 10min. *KExecWatchdogSec*= may be used to additionally enable the watchdog when kexec is being executed rather than when rebooting. Note that if the kernel does not reset the watchdog on kexec (depending on the specific hardware and/or driver), in this case the watchdog might not get disabled after kexec succeeds and thus the system might get rebooted, unless *RuntimeWatchdogSec*= is also enabled at the same time. For this reason it is recommended to enable *KExecWatchdogSec*= only if *RuntimeWatchdogSec*= is also enabled. These settings have no effect if a hardware watchdog is not available.

***WatchdogDevice*=**

Configure the hardware watchdog device that the runtime and shutdown watchdog timers will open and use. Defaults to /dev/watchdog. This setting has no effect if a hardware watchdog is not available.

***CapabilityBoundingSet*=**

Controls which capabilities to include in the capability bounding set for PID 1 and its children. See **capabilities(7)** for details. Takes a whitespace-separated list of capability names as read by **cap_from_name(3)**. Capabilities listed will be included in the bounding set, all others are removed. If the list of capabilities is prefixed with ~, all but the listed capabilities will be included, the effect of the assignment inverted. Note that this option also affects the respective capabilities in the effective, permitted and inheritable capability sets. The capability bounding set may also be individually configured for units using the *CapabilityBoundingSet*= directive for units, but note that capabilities dropped for PID 1 cannot be regained in individual units, they are lost for good.

***NoNewPrivileges*=**

Takes a boolean argument. If true, ensures that PID 1 and all its children can never gain new privileges through **execve(2)** (e.g. via setuid or setgid bits, or filesystem capabilities). Defaults to false. General

purpose distributions commonly rely on executables with setuid or setgid bits and will thus not function properly with this option enabled. Individual units cannot disable this option. Also see **No New Privileges Flag**^[1].

SystemCallArchitectures=

Takes a space-separated list of architecture identifiers. Selects from which architectures system calls may be invoked on this system. This may be used as an effective way to disable invocation of non-native binaries system-wide, for example to prohibit execution of 32-bit x86 binaries on 64-bit x86-64 systems. This option operates system-wide, and acts similar to the *SystemCallArchitectures*= setting of unit files, see **systemd.exec(5)** for details. This setting defaults to the empty list, in which case no filtering of system calls based on architecture is applied. Known architecture identifiers are "x86", "x86-64", "x32", "arm" and the special identifier "native". The latter implicitly maps to the native architecture of the system (or more specifically, the architecture the system manager was compiled for). Set this setting to "native" to prohibit execution of any non-native binaries. When a binary executes a system call of an architecture that is not listed in this setting, it will be immediately terminated with the SIGSYS signal.

TimerSlackNSec=

Sets the timer slack in nanoseconds for PID 1, which is inherited by all executed processes, unless overridden individually, for example with the *TimerSlackNSec*= setting in service units (for details see **systemd.exec(5)**). The timer slack controls the accuracy of wake-ups triggered by system timers. See **prctl(2)** for more information. Note that in contrast to most other time span definitions this parameter takes an integer value in nano-seconds if no unit is specified. The usual time units are understood too.

StatusUnitFormat=

Takes **name**, **description** or **combined** as the value. If **name**, the system manager will use unit names in status messages (e.g. "systemd-journald.service"), instead of the longer and more informative descriptions set with *Description*= (e.g. "Journal Logging Service"). If **combined**, the system manager will use both unit names and descriptions in status messages (e.g. "systemd-journald.service – Journal Logging Service").

See **systemd.unit(5)** for details about unit names and *Description*=.

DefaultTimerAccuracySec=

Sets the default accuracy of timer units. This controls the global default for the *AccuracySec*= setting of timer units, see **systemd.timer(5)** for details. *AccuracySec*= set in individual units override the global default for the specific unit. Defaults to 1min. Note that the accuracy of timer units is also affected by the configured timer slack for PID 1, see *TimerSlackNSec*= above.

DefaultTimeoutStartSec=, *DefaultTimeoutStopSec*=, *DefaultTimeoutAbortSec*=, *DefaultRestartSec*=

Configures the default timeouts for starting, stopping and aborting of units, as well as the default time to sleep between automatic restarts of units, as configured per-unit in *TimeoutStartSec*=, *TimeoutStopSec*=, *TimeoutAbortSec*= and *RestartSec*= (for services, see **systemd.service(5)** for details on the per-unit settings). Disabled by default, when service with *Type=oneshot* is used. For non-service units, *DefaultTimeoutStartSec*= sets the default *TimeoutSec*= value. *DefaultTimeoutStartSec*= and *DefaultTimeoutStopSec*= default to 90s. *DefaultTimeoutAbortSec*= is not set by default so that all units fall back to *TimeoutStopSec*=. *DefaultRestartSec*= defaults to 100ms.

DefaultStartLimitIntervalSec=, *DefaultStartLimitBurst*=

Configure the default unit start rate limiting, as configured per-service by *StartLimitIntervalSec*= and *StartLimitBurst*=. See **systemd.service(5)** for details on the per-service settings.

DefaultStartLimitIntervalSec= defaults to 10s. *DefaultStartLimitBurst*= defaults to 5.

DefaultEnvironment=

Configures environment variables passed to all executed processes. Takes a space-separated list of variable assignments. See **environ(7)** for details about environment variables.

Simple "%"–specifier expansion is supported, see below for a list of supported specifiers.

Example:

```
DefaultEnvironment="VAR1=word1 word2" VAR2=word3 "VAR3=word 5 6"
```

Sets three variables "VAR1", "VAR2", "VAR3".

ManagerEnvironment=

Takes the same arguments as *DefaultEnvironment*=, see above. Sets environment variables just for the manager process itself. In contrast to user managers, these variables are not inherited by processes spawned by the system manager, use *DefaultEnvironment*= for that. Note that these variables are merged into the existing environment block. In particular, in case of the system manager, this includes variables set by the kernel based on the kernel command line.

Setting environment variables for the manager process may be useful to modify its behaviour. See [ENVIRONMENT](#)^[2] for a descriptions of some variables understood by **systemd**.

Simple "%"–specifier expansion is supported, see below for a list of supported specifiers.

DefaultCPUAccounting=, *DefaultBlockIOAccounting*=, *DefaultMemoryAccounting*=,
DefaultTasksAccounting=, *DefaultIOAccounting*=, *DefaultIPAccounting*=

Configure the default resource accounting settings, as configured per–unit by *CPUAccounting*=, *BlockIOAccounting*=, *MemoryAccounting*=, *TasksAccounting*=, *IOAccounting*= and *IPAccounting*=. See [systemd.resource-control\(5\)](#) for details on the per–unit settings. *DefaultTasksAccounting*= defaults to yes, *DefaultMemoryAccounting*= to yes. *DefaultCPUAccounting*= defaults to yes if enabling CPU accounting doesn't require the CPU controller to be enabled (Linux 4.15+ using the unified hierarchy for resource control), otherwise it defaults to no. The other three settings default to no.

DefaultTasksMax=

Configure the default value for the per–unit *TasksMax*= setting. See [systemd.resource-control\(5\)](#) for details. This setting applies to all unit types that support resource control settings, with the exception of slice units. Defaults to 15% of the minimum of *kernel.pid_max*=, *kernel.threads_max*= and root cgroup *pids.max*. Kernel has a default value for *kernel.pid_max*= and an algorithm of counting in case of more than 32 cores. For example with the default *kernel.pid_max*=, *DefaultTasksMax*= defaults to 4915, but might be greater in other systems or smaller in OS containers.

DefaultLimitCPU=, *DefaultLimitFSIZE*=, *DefaultLimitDATA*=, *DefaultLimitSTACK*=,
DefaultLimitCORE=, *DefaultLimitRSS*=, *DefaultLimitNOFILE*=, *DefaultLimitAS*=,
DefaultLimitNPROC=, *DefaultLimitMEMLOCK*=, *DefaultLimitLOCKS*=, *DefaultLimitSIGPENDING*=,
DefaultLimitMSGQUEUE=, *DefaultLimitNICE*=, *DefaultLimitRTPRIO*=, *DefaultLimitRTTIME*=

These settings control various default resource limits for processes executed by units. See [setrlimit\(2\)](#) for details. These settings may be overridden in individual units using the corresponding *LimitXXX*= directives and they accept the same parameter syntax, see [systemd.exec\(5\)](#) for details. Note that these resource limits are only defaults for units, they are not applied to the service manager process (i.e. PID 1) itself.

Most of these settings are unset, which means the resource limits are inherited from the kernel or, if invoked in a container, from the container manager. However, the following have defaults:

- *DefaultLimitNOFILE*= defaults to "1024:524288".
- *DefaultLimitCORE*= does not have a default but it is worth mentioning that *RLIMIT_CORE* is set to "infinity" by PID 1 which is inherited by its children.
- Note that the service manager internally increases *RLIMIT_MEMLOCK* for itself, however the limit is reverted to the original value for child processes forked off.

DefaultOOMPolicy=

Configure the default policy for reacting to processes being killed by the Linux Out–Of–Memory

(OOM) killer. This may be used to pick a global default for the per-unit *OOMPpolicy=* setting. See **systemd.service(5)** for details. Note that this default is not used for services that have *Delegate=* turned on.

SPECIFIERS

Specifiers may be used in the *DefaultEnvironment=* and *ManagerEnvironment=* settings. The following expansions are understood:

Table 1. Specifiers available

NAME

systemd, init – systemd system and service manager

SYNOPSIS

/lib/systemd/systemd [OPTIONS...]

init [OPTIONS...] {COMMAND}

DESCRIPTION

systemd is a system and service manager for Linux operating systems. When run as first process on boot (as PID 1), it acts as init system that brings up and maintains userspace services. Separate instances are started for logged-in users to start their services.

systemd is usually not invoked directly by the user, but is installed as the `/sbin/init` symlink and started during early boot. The user manager instances are started automatically through the **user@.service(5)** service.

For compatibility with SysV, if the binary is called as **init** and is not the first process on the machine (PID is not 1), it will execute **telinit** and pass all command line arguments unmodified. That means **init** and **telinit** are mostly equivalent when invoked from normal login sessions. See **telinit(8)** for more information.

When run as a system instance, systemd interprets the configuration file `system.conf` and the files in `system.conf.d` directories; when run as a user instance, systemd interprets the configuration file `user.conf` and the files in `user.conf.d` directories. See **systemd-system.conf(5)** for more information.

CONCEPTS

systemd provides a dependency system between various entities called "units" of 11 different types. Units encapsulate various objects that are relevant for system boot-up and maintenance. The majority of units are configured in unit configuration files, whose syntax and basic set of options is described in **systemd.unit(5)**, however some are created automatically from other configuration files, dynamically from system state or programmatically at runtime. Units may be "active" (meaning started, bound, plugged in, ..., depending on the unit type, see below), or "inactive" (meaning stopped, unbound, unplugged, ...), as well as in the process of being activated or deactivated, i.e. between the two states (these states are called "activating", "deactivating"). A special "failed" state is available as well, which is very similar to "inactive" and is entered when the service failed in some way (process returned error code on exit, or crashed, an operation timed out, or after too many restarts). If this state is entered, the cause will be logged, for later reference. Note that the various unit types may have a number of additional substates, which are mapped to the five generalized unit states described here.

The following unit types are available:

1. Service units, which start and control daemons and the processes they consist of. For details, see **systemd.service(5)**.
2. Socket units, which encapsulate local IPC or network sockets in the system, useful for socket-based activation. For details about socket units, see **systemd.socket(5)**, for details on socket-based activation and other forms of activation, see **daemon(7)**.
3. Target units are useful to group units, or provide well-known synchronization points during boot-up, see **systemd.target(5)**.
4. Device units expose kernel devices in systemd and may be used to implement device-based activation. For details, see **systemd.device(5)**.
5. Mount units control mount points in the file system, for details see **systemd.mount(5)**.
6. Automount units provide automount capabilities, for on-demand mounting of file systems as well as parallelized boot-up. See **systemd.automount(5)**.
7. Timer units are useful for triggering activation of other units based on timers. You may find details in **systemd.timer(5)**.
8. Swap units are very similar to mount units and encapsulate memory swap partitions or files of the operating system. They are described in **systemd.swap(5)**.

9. Path units may be used to activate other services when file system objects change or are modified. See **systemd.path(5)**.
10. Slice units may be used to group units which manage system processes (such as service and scope units) in a hierarchical tree for resource management purposes. See **systemd.slice(5)**.
11. Scope units are similar to service units, but manage foreign processes instead of starting them as well. See **systemd.scope(5)**.

Units are named as their configuration files. Some units have special semantics. A detailed list is available in **systemd.special(7)**.

systemd knows various kinds of dependencies, including positive and negative requirement dependencies (i.e. *Requires=* and *Conflicts=*) as well as ordering dependencies (*After=* and *Before=*). NB: ordering and requirement dependencies are orthogonal. If only a requirement dependency exists between two units (e.g. `foo.service` requires `bar.service`), but no ordering dependency (e.g. `foo.service` after `bar.service`) and both are requested to start, they will be started in parallel. It is a common pattern that both requirement and ordering dependencies are placed between two units. Also note that the majority of dependencies are implicitly created and maintained by systemd. In most cases, it should be unnecessary to declare additional dependencies manually, however it is possible to do this.

Application programs and units (via dependencies) may request state changes of units. In systemd, these requests are encapsulated as 'jobs' and maintained in a job queue. Jobs may succeed or can fail, their execution is ordered based on the ordering dependencies of the units they have been scheduled for.

On boot systemd activates the target unit `default.target` whose job is to activate on-boot services and other on-boot units by pulling them in via dependencies. Usually, the unit name is just an alias (symlink) for either `graphical.target` (for fully-featured boots into the UI) or `multi-user.target` (for limited console-only boots for use in embedded or server environments, or similar; a subset of `graphical.target`). However, it is at the discretion of the administrator to configure it as an alias to any other target unit. See **systemd.special(7)** for details about these target units.

systemd only keeps a minimal set of units loaded into memory. Specifically, the only units that are kept loaded into memory are those for which at least one of the following conditions is true:

1. It is in an active, activating, deactivating or failed state (i.e. in any unit state except for "inactive")
2. It has a job queued for it
3. It is a dependency of at least one other unit that is loaded into memory
4. It has some form of resource still allocated (e.g. a service unit that is inactive but for which a process is still lingering that ignored the request to be terminated)
5. It has been pinned into memory programmatically by a D-Bus call

systemd will automatically and implicitly load units from disk — if they are not loaded yet — as soon as operations are requested for them. Thus, in many respects, the fact whether a unit is loaded or not is invisible to clients. Use **systemctl list-units --all** to comprehensively list all units currently loaded. Any unit for which none of the conditions above applies is promptly unloaded. Note that when a unit is unloaded from memory its accounting data is flushed out too. However, this data is generally not lost, as a journal log record is generated declaring the consumed resources whenever a unit shuts down.

Processes systemd spawns are placed in individual Linux control groups named after the unit which they belong to in the private systemd hierarchy. (see **cgroups.txt**^[1] for more information about control groups, or short "cgroups"). systemd uses this to effectively keep track of processes. Control group information is maintained in the kernel, and is accessible via the file system hierarchy (beneath `/sys/fs/cgroup/systemd/`), or in tools such as **systemd-cgls(1)** or **ps(1)** (**ps xawf -eo pid,user,cgroup,args** is particularly useful to list all processes and the systemd units they belong to.).

systemd is compatible with the SysV init system to a large degree: SysV init scripts are supported and simply read as an alternative (though limited) configuration file format. The SysV `/dev/initctl` interface is provided, and compatibility implementations of the various SysV client tools are available. In addition to

that, various established Unix functionality such as /etc/fstab or the utmp database are supported.

systemd has a minimal transaction system: if a unit is requested to start up or shut down it will add it and all its dependencies to a temporary transaction. Then, it will verify if the transaction is consistent (i.e. whether the ordering of all units is cycle-free). If it is not, systemd will try to fix it up, and removes non-essential jobs from the transaction that might remove the loop. Also, systemd tries to suppress non-essential jobs in the transaction that would stop a running service. Finally it is checked whether the jobs of the transaction contradict jobs that have already been queued, and optionally the transaction is aborted then. If all worked out and the transaction is consistent and minimized in its impact it is merged with all already outstanding jobs and added to the run queue. Effectively this means that before executing a requested operation, systemd will verify that it makes sense, fixing it if possible, and only failing if it really cannot work.

Note that transactions are generated independently of a unit's state at runtime, hence, for example, if a start job is requested on an already started unit, it will still generate a transaction and wake up any inactive dependencies (and cause propagation of other jobs as per the defined relationships). This is because the enqueued job is at the time of execution compared to the target unit's state and is marked successful and complete when both satisfy. However, this job also pulls in other dependencies due to the defined relationships and thus leads to, in our example, start jobs for any of those inactive units getting queued as well.

systemd contains native implementations of various tasks that need to be executed as part of the boot process. For example, it sets the hostname or configures the loopback network device. It also sets up and mounts various API file systems, such as /sys/ or /proc/.

For more information about the concepts and ideas behind systemd, please refer to the [Original Design Document](#)^[2].

Note that some but not all interfaces provided by systemd are covered by the [Interface Portability and Stability Promise](#)^[3].

Units may be generated dynamically at boot and system manager reload time, for example based on other configuration files or parameters passed on the kernel command line. For details, see [systemd.generator\(7\)](#).

The D-Bus API of [systemd](#) is described in [org.freedesktop.systemd1\(5\)](#) and [org.freedesktop.LogControl1\(5\)](#).

Systems which invoke systemd in a container or initrd environment should implement the [Container Interface](#)^[4] or [initrd Interface](#)^[5] specifications, respectively.

DIRECTORIES

System unit directories

The systemd system manager reads unit configuration from various directories. Packages that want to install unit files shall place them in the directory returned by [pkg-config systemd](#)

[--variable=systemdsystemunitdir](#). Other directories checked are /usr/local/lib/systemd/system and /lib/systemd/system. User configuration always takes precedence. [pkg-config systemd](#)

[--variable=systemdsystemconfdir](#) returns the path of the system configuration directory. Packages should alter the content of these directories only with the [enable](#) and [disable](#) commands of the [systemctl\(1\)](#) tool. Full list of directories is provided in [systemd.unit\(5\)](#).

User unit directories

Similar rules apply for the user unit directories. However, here the [XDG Base Directory specification](#)^[6] is followed to find units. Applications should place their unit files in the directory returned by [pkg-config systemd](#) [--variable=systemduserunitdir](#). Global configuration is done in the directory reported by [pkg-config systemd](#) [--variable=systemduserconfdir](#). The [enable](#) and [disable](#) commands of the [systemctl\(1\)](#) tool can handle both global (i.e. for all users) and private (for one user) enabling/disabling of units. Full list of directories is provided in [systemd.unit\(5\)](#).

SysV init scripts directory

The location of the SysV init script directory varies between distributions. If systemd cannot find a native unit file for a requested service, it will look for a SysV init script of the same name (with the

.service suffix removed).

SysV runlevel link farm directory

The location of the SysV runlevel link farm directory varies between distributions. systemd will take the link farm into account when figuring out whether a service shall be enabled. Note that a service unit with a native unit configuration file cannot be started by activating it in the SysV runlevel link farm.

SIGNALS

SIGTERM

Upon receiving this signal the systemd system manager serializes its state, reexecutes itself and deserializes the saved state again. This is mostly equivalent to **systemctl daemon-reexec**.

systemd user managers will start the exit.target unit when this signal is received. This is mostly equivalent to **systemctl --user start exit.target --job-mode=replace-irreversibly**.

SIGINT

Upon receiving this signal the systemd system manager will start the ctrl-alt-del.target unit. This is mostly equivalent to **systemctl start ctrl-alt-del.target --job-mode=replace-irreversibly**. If this signal is received more than 7 times per 2s, an immediate reboot is triggered. Note that pressing Ctrl+Alt+Del on the console will trigger this signal. Hence, if a reboot is hanging, pressing Ctrl+Alt+Del more than 7 times in 2 seconds is a relatively safe way to trigger an immediate reboot.

systemd user managers treat this signal the same way as **SIGTERM**.

SIGWINCH

When this signal is received the systemd system manager will start the kbrequest.target unit. This is mostly equivalent to **systemctl start kbrequest.target**.

This signal is ignored by systemd user managers.

SIGPWR

When this signal is received the systemd manager will start the sigpwr.target unit. This is mostly equivalent to **systemctl start sigpwr.target**.

SIGUSR1

When this signal is received the systemd manager will try to reconnect to the D-Bus bus.

SIGUSR2

When this signal is received the systemd manager will log its complete state in human-readable form. The data logged is the same as printed by **systemd-analyze dump**.

SIGHUP

Reloads the complete daemon configuration. This is mostly equivalent to **systemctl daemon-reload**.

SIGRTMIN+0

Enters default mode, starts the default.target unit. This is mostly equivalent to **systemctl isolate default.target**.

SIGRTMIN+1

Enters rescue mode, starts the rescue.target unit. This is mostly equivalent to **systemctl isolate rescue.target**.

SIGRTMIN+2

Enters emergency mode, starts the emergency.service unit. This is mostly equivalent to **systemctl isolate emergency.service**.

SIGRTMIN+3

Halts the machine, starts the halt.target unit. This is mostly equivalent to **systemctl start halt.target --job-mode=replace-irreversibly**.

SIGRTMIN+4

Powers off the machine, starts the poweroff.target unit. This is mostly equivalent to **systemctl start poweroff.target --job-mode=replace-irreversibly**.

SIGRTMIN+5

Reboots the machine, starts the reboot.target unit. This is mostly equivalent to **systemctl start reboot.target --job-mode=replace-irreversibly**.

SIGRTMIN+6

Reboots the machine via kexec, starts the kexec.target unit. This is mostly equivalent to **systemctl start kexec.target --job-mode=replace-irreversibly**.

SIGRTMIN+13

Immediately halts the machine.

SIGRTMIN+14

Immediately powers off the machine.

SIGRTMIN+15

Immediately reboots the machine.

SIGRTMIN+16

Immediately reboots the machine with kexec.

SIGRTMIN+20

Enables display of status messages on the console, as controlled via *systemd.show_status=1* on the kernel command line.

SIGRTMIN+21

Disables display of status messages on the console, as controlled via *systemd.show_status=0* on the kernel command line.

SIGRTMIN+22

Sets the service manager's log level to "debug", in a fashion equivalent to *systemd.log_level=debug* on the kernel command line.

SIGRTMIN+23

Restores the log level to its configured value. The configured value is derived from – in order of priority – the value specified with *systemd.log_level=* on the kernel command line, or the value specified with **LogLevel=** in the configuration file, or the built-in default of "info".

SIGRTMIN+24

Immediately exits the manager (only available for --user instances).

SIGRTMIN+26

Restores the log target to its configured value. The configured value is derived from – in order of priority – the value specified with *systemd.log_target=* on the kernel command line, or the value specified with **LogTarget=** in the configuration file, or the built-in default.

SIGRTMIN+27, SIGRTMIN+28

Sets the log target to "console" on **SIGRTMIN+27** (or "kmsg" on **SIGRTMIN+28**), in a fashion equivalent to *systemd.log_target=console* (or *systemd.log_target=kmsg* on **SIGRTMIN+28**) on the kernel command line.

ENVIRONMENT

The environment block for the system manager is initially set by the kernel. (In particular, "key=value" assignments on the kernel command line are returned into environment variables for PID 1). For the user manager, the system manager sets the environment as described in the "Environment Variables in Spawning Processes" section of **systemd.exec(5)**. The *DefaultEnvironment=* setting in the system manager applies to all services including *user@.service*. Additional entries may be configured (as for any other service) through the *Environment=* and *EnvironmentFile=* settings for *user@.service* (see **systemd.exec(5)**). Also, additional environment variables may be set through the *ManagerEnvironment=* setting in **systemd-system.conf(5)** and **systemd-user.conf(5)**.

Some of the variables understood by **systemd**:

\$SYSTEMD_LOG_LEVEL

The maximum log level of emitted messages (messages with a higher log level, i.e. less important ones, will be suppressed). Either one of (in order of decreasing importance) **emerg**, **alert**, **crit**, **err**, **warning**, **notice**, **info**, **debug**, or an integer in the range 0...7. See **syslog(3)** for more information.

This can be overridden with **--log-level=**.

\$SYSTEMD_LOG_COLOR

A boolean. If true, messages written to the tty will be colored according to priority.

This can be overridden with **--log-color=**.

\$SYSTEMD_LOG_TIME

A boolean. If true, console log messages will be prefixed with a timestamp.

This can be overridden with **--log-time=**.

\$SYSTEMD_LOG_LOCATION

A boolean. If true, messages will be prefixed with a filename and line number in the source code where the message originates.

This can be overridden with **--log-location=**.

\$SYSTEMD_LOG_TID

A boolean. If true, messages will be prefixed with the current numerical thread ID (TID).

\$SYSTEMD_LOG_TARGET

The destination for log messages. One of **console** (log to the attached tty), **console-prefixed** (log to the attached tty but with prefixes encoding the log level and "facility", see **syslog(3)**), **kmsg** (log to the kernel circular log buffer), **journal** (log to the journal), **journal-or-kmsg** (log to the journal if available, and to kmsg otherwise), **auto** (determine the appropriate log target automatically, the default), **null** (disable log output).

This can be overridden with **--log-target=**.

\$XDG_CONFIG_HOME*, *\$XDG_CONFIG_DIRS*, *\$XDG_DATA_HOME*, *\$XDG_DATA_DIRS

The systemd user manager uses these variables in accordance to the [XDG Base Directory specification](#)^[6] to find its configuration.

***\$SYSTEMD_UNIT_PATH*, *\$SYSTEMD_GENERATOR_PATH*,**

\$SYSTEMD_ENVIRONMENT_GENERATOR_PATH

Controls where systemd looks for unit files and generators.

These variables may contain a list of paths, separated by colons (:). When set, if the list ends with an empty component ("::"), this list is prepended to the usual set of paths. Otherwise, the specified list replaces the usual set of paths.

\$SYSTEMD_PAGER

Pager to use when **--no-pager** is not given; overrides **\$PAGER**. If neither **\$SYSTEMD_PAGER** nor **\$PAGER** are set, a set of well-known pager implementations are tried in turn, including **less(1)** and **more(1)**, until one is found. If no pager implementation is discovered no pager is invoked. Setting this environment variable to an empty string or the value "cat" is equivalent to passing **--no-pager**.

\$SYSTEMD_LESS

Override the options passed to **less** (by default "FRSXMK").

Users might want to change two options in particular:

K

This option instructs the pager to exit immediately when Ctrl+C is pressed. To allow **less** to handle Ctrl+C itself to switch back to the pager command prompt, unset this option.

If the value of `$SYSTEMD_LESS` does not include "K", and the pager that is invoked is **less**, Ctrl+C will be ignored by the executable, and needs to be handled by the pager.

X

This option instructs the pager to not send termcap initialization and deinitialization strings to the terminal. It is set by default to allow command output to remain visible in the terminal even after the pager exits. Nevertheless, this prevents some pager functionality from working, in particular paged output cannot be scrolled with the mouse.

See **less(1)** for more discussion.

`$SYSTEMD_LESSCHARSET`

Override the charset passed to **less** (by default "utf-8", if the invoking terminal is determined to be UTF-8 compatible).

`$SYSTEMD_PAGERSECURE`

Takes a boolean argument. When true, the "secure" mode of the pager is enabled; if false, disabled. If `$SYSTEMD_PAGERSECURE` is not set at all, secure mode is enabled if the effective UID is not the same as the owner of the login session, see `geteuid(2)` and `sd_pid_get_owner_uid(3)`. In secure mode, `LESSSECURE=1` will be set when invoking the pager, and the pager shall disable commands that open or create new files or start new subprocesses. When `$SYSTEMD_PAGERSECURE` is not set at all, pagers which are not known to implement secure mode will not be used. (Currently only **less(1)** implements secure mode.)

Note: when commands are invoked with elevated privileges, for example under **sudo(8)** or **pkexec(1)**, care must be taken to ensure that unintended interactive features are not enabled. "Secure" mode for the pager may be enabled automatically as described above. Setting `SYSTEMD_PAGERSECURE=0` or not removing it from the inherited environment allows the user to invoke arbitrary commands. Note that if the `$SYSTEMD_PAGER` or `$PAGER` variables are to be honoured, `$SYSTEMD_PAGERSECURE` must be set too. It might be reasonable to completely disable the pager using `--no-pager` instead.

`$SYSTEMD_COLORS`

Takes a boolean argument. When true, **systemd** and related utilities will use colors in their output, otherwise the output will be monochrome. Additionally, the variable can take one of the following special values: "16", "256" to restrict the use of colors to the base 16 or 256 ANSI colors, respectively. This can be specified to override the automatic decision based on `$TERM` and what the console is connected to.

`$SYSTEMD_URLIFY`

The value must be a boolean. Controls whether clickable links should be generated in the output for terminal emulators supporting this. This can be specified to override the decision that **systemd** makes based on `$TERM` and other conditions.

`$LISTEN_PID`, `$LISTEN_FDS`, `$LISTEN_FDNAME`

Set by **systemd** for supervised processes during socket-based activation. See `sd_listen_fds(3)` for more information.

`$NOTIFY_SOCKET`

Set by **systemd** for supervised processes for status and start-up completion notification. See `sd_notify(3)` for more information.

For further environment variables understood by **systemd** and its various components, see [Known Environment Variables](#)^[7].

KERNEL COMMAND LINE

When run as the system instance systemd parses a number of options listed below. They can be specified as kernel command line arguments^[8], or through the "SystemdOptions" EFI variable (on EFI systems). The kernel command line has higher priority. Following variables are understood:

systemd.unit=, *rd.systemd.unit=*

Overrides the unit to activate on boot. Defaults to default.target. This may be used to temporarily boot into a different boot unit, for example rescue.target or emergency.service. See **systemd.special(7)** for details about these units. The option prefixed with "rd." is honored only in the initial RAM disk (initrd), while the one that is not prefixed only in the main system.

systemd.dump_core

Takes a boolean argument or enables the option if specified without an argument. If enabled, the systemd manager (PID 1) dumps core when it crashes. Otherwise, no core dump is created. Defaults to enabled.

systemd.crash_chvt

Takes a positive integer, or a boolean argument. Can be also specified without an argument, with the same effect as a positive boolean. If a positive integer (in the range 1–63) is specified, the system manager (PID 1) will activate the specified virtual terminal when it crashes. Defaults to disabled, meaning that no such switch is attempted. If set to enabled, the virtual terminal the kernel messages are written to is used instead.

systemd.crash_shell

Takes a boolean argument or enables the option if specified without an argument. If enabled, the system manager (PID 1) spawns a shell when it crashes, after a 10s delay. Otherwise, no shell is spawned. Defaults to disabled, for security reasons, as the shell is not protected by password authentication.

systemd.crash_reboot

Takes a boolean argument or enables the option if specified without an argument. If enabled, the system manager (PID 1) will reboot the machine automatically when it crashes, after a 10s delay. Otherwise, the system will hang indefinitely. Defaults to disabled, in order to avoid a reboot loop. If combined with *systemd.crash_shell*, the system is rebooted after the shell exits.

systemd.confirm_spawn

Takes a boolean argument or a path to the virtual console where the confirmation messages should be emitted. Can be also specified without an argument, with the same effect as a positive boolean. If enabled, the system manager (PID 1) asks for confirmation when spawning processes using **/dev/console**. If a path or a console name (such as "ttyS0") is provided, the virtual console pointed to by this path or described by the give name will be used instead. Defaults to disabled.

systemd.service_watchdogs=

Takes a boolean argument. If disabled, all service runtime watchdogs (**WatchdogSec=**) and emergency actions (e.g. **OnFailure=** or **StartLimitAction=**) are ignored by the system manager (PID 1); see **systemd.service(5)**. Defaults to enabled, i.e. watchdogs and failure actions are processed normally. The hardware watchdog is not affected by this option.

systemd.show_status

Takes a boolean argument or the constants **error** and **auto**. Can be also specified without an argument, with the same effect as a positive boolean. If enabled, the system manager (PID 1) shows terse service status updates on the console during bootup. With **error**, only messages about failures are shown, but boot is otherwise quiet. **auto** behaves like **false** until there is a significant delay in boot. Defaults to enabled, unless **quiet** is passed as kernel command line option, in which case it defaults to **error**. If specified overrides the system manager configuration file option **ShowStatus=**, see **systemd-system.conf(5)**.

systemd.status_unit_format=

Takes **name**, **description** or **combined** as the value. If **name**, the system manager will use unit names in status messages. If **combined**, the system manager will use unit names and description in status

messages. When specified, overrides the system manager configuration file option `StatusUnitFormat=`, see [systemd-system.conf\(5\)](#).

`systemd.log_color`, `systemd.log_level=`, `systemd.log_location`, `systemd.log_target=`, `systemd.log_time`, `systemd.log_tid`

Controls log output, with the same effect as the `$SYSTEMD_LOG_COLOR`, `$SYSTEMD_LOG_LEVEL`, `$SYSTEMD_LOG_LOCATION`, `$SYSTEMD_LOG_TARGET`, `$SYSTEMD_LOG_TIME`, and `$SYSTEMD_LOG_TID` environment variables described above. `systemd.log_color`, `systemd.log_location`, `systemd.log_time`, and `systemd.log_tid=` can be specified without an argument, with the same effect as a positive boolean.

`systemd.default_standard_output=`, `systemd.default_standard_error=`

Controls default standard output and error output for services and sockets. That is, controls the default for `StandardOutput=` and `StandardError=` (see [systemd.exec\(5\)](#) for details). Takes one of `inherit`, `null`, `tty`, `journal`, `journal+console`, `kmsg`, `kmsg+console`. If the argument is omitted `systemd.default-standard-output=` defaults to `journal` and `systemd.default-standard-error=` to `inherit`.

`systemd.setenv=`

Takes a string argument in the form `VARIABLE=VALUE`. May be used to set default environment variables to add to forked child processes. May be used more than once to set multiple variables.

`systemd.machine_id=`

Takes a 32 character hex value to be used for setting the machine-id. Intended mostly for network booting where the same machine-id is desired for every boot.

`systemd.unified_cgroup_hierarchy`

When specified without an argument or with a true argument, enables the usage of [unified cgroup hierarchy](#)^[9] (a.k.a. cgroups-v2). When specified with a false argument, fall back to hybrid or full legacy cgroup hierarchy.

If this option is not specified, the default behaviour is determined during compilation (the `-Ddefault-hierarchy=` meson option). If the kernel does not support unified cgroup hierarchy, the legacy hierarchy will be used even if this option is specified.

`systemd.legacy_systemd_cgroup_controller`

Takes effect if the full unified cgroup hierarchy is not used (see previous option). When specified without an argument or with a true argument, disables the use of "hybrid" cgroup hierarchy (i.e. a cgroups-v2 tree used for systemd, and [legacy cgroup hierarchy](#)^[10], a.k.a. cgroups-v1, for other controllers), and forces a full "legacy" mode. When specified with a false argument, enables the use of "hybrid" hierarchy.

If this option is not specified, the default behaviour is determined during compilation (the `-Ddefault-hierarchy=` meson option). If the kernel does not support unified cgroup hierarchy, the legacy hierarchy will be used even if this option is specified.

`quiet`

Turn off status output at boot, much like `systemd.show_status=no` would. Note that this option is also read by the kernel itself and disables kernel log output. Passing this option hence turns off the usual output from both the system manager and the kernel.

`debug`

Turn on debugging output. This is equivalent to `systemd.log_level=debug`. Note that this option is also read by the kernel itself and enables kernel debug output. Passing this option hence turns on the debug output from both the system manager and the kernel.

`emergency, rd.emergency, -b`

Boot into emergency mode. This is equivalent to `systemd.unit=emergency.target` or `rd.systemd.unit=emergency.target`, respectively, and provided for compatibility reasons and to be easier to type.

rescue, rd.rescue, single, s, S, 1

Boot into rescue mode. This is equivalent to `systemd.unit=rescue.target` or `rd.systemd.unit=rescue.target`, respectively, and provided for compatibility reasons and to be easier to type.

2, 3, 4, 5

Boot into the specified legacy SysV runlevel. These are equivalent to `systemd.unit=runlevel2.target`, `systemd.unit=runlevel3.target`, `systemd.unit=runlevel4.target`, and `systemd.unit=runlevel5.target`, respectively, and provided for compatibility reasons and to be easier to type.

locale.LANG=, locale.LANGUAGE=, locale.LC_CTYPE=, locale.LC_NUMERIC=, locale.LC_TIME=, locale.LC_COLLATE=, locale.LC_MONETARY=, locale.LC_MESSAGES=, locale.LC_PAPER=, locale.LC_NAME=, locale.LC_ADDRESS=, locale.LC_TELEPHONE=, locale.LC_MEASUREMENT=, locale.LC_IDENTIFICATION=

Set the system locale to use. This overrides the settings in `/etc/locale.conf`. For more information, see **locale.conf(5)** and **locale(7)**.

For other kernel command line parameters understood by components of the core OS, please refer to **kernel-command-line(7)**.

OPTIONS

systemd is only very rarely invoked directly, since it is started early and is already running by the time users may interact with it. Normally, tools like **systemctl(1)** are used to give commands to the manager. Since **systemd** is usually not invoked directly, the options listed below are mostly useful for debugging and special purposes.

Introspection and debugging options

Those options are used for testing and introspection, and **systemd** may be invoked with them at any time:

--dump-configuration-items

Dump understood unit configuration items. This outputs a terse but complete list of configuration items understood in unit definition files.

--dump-bus-properties

Dump exposed bus properties. This outputs a terse but complete list of properties exposed on D-Bus.

--test

Determine the initial start-up transaction (i.e. the list of jobs enqueued at start-up), dump it and exit — without actually executing any of the determined jobs. This option is useful for debugging only.

Note that during regular service manager start-up additional units not shown by this operation may be started, because hardware, socket, bus or other kinds of activation might add additional jobs as the transaction is executed. Use **--system** to request the initial transaction of the system service manager (this is also the implied default), combine with **--user** to request the initial transaction of the per-user service manager instead.

--system, --user

When used in conjunction with **--test**, selects whether to calculate the initial transaction for the system instance or for a per-user instance. These options have no effect when invoked without **--test**, as during regular (i.e. non---**test**) invocations the service manager will automatically detect whether it shall operate in system or per-user mode, by checking whether the PID it is run as is 1 or not. Note that it is not supported booting and maintaining a system with the service manager running in **--system** mode but with a PID other than 1.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

Options that duplicate kernel command line settings

Those options correspond directly to options listed above in "Kernel Command Line". Both forms may be used equivalently for the system manager, but it is recommended to use the forms listed above in this

context, because they are properly namespaced. When an option is specified both on the kernel command line and as a normal command line argument, the latter has higher precedence.

When **systemd** is used as a user manager, the kernel command line is ignored and only the options described below are understood. Nevertheless, **systemd** is usually started in this mode through the **user@.service(5)** service, which is shared between all users. It may be more convenient to use configuration files to modify settings (see **systemd-user.conf(5)**), or environment variables. See the "Environment" section above for a discussion of how the environment block is set.

--unit=

Set default unit to activate on startup. If not specified, defaults to `default.target`. See `systemd.unit=` above.

--dump-core

Enable core dumping on crash. This switch has no effect when running as user instance. Same as `systemd.dump_core=` above.

--crash-vt=VT

Switch to a specific virtual console (VT) on crash. This switch has no effect when running as user instance. Same as `systemd.crash_chvt=` above (but not the different spelling!).

--crash-shell

Run a shell on crash. This switch has no effect when running as user instance. See `systemd.crash_shell=` above.

--crash-reboot

Automatically reboot the system on crash. This switch has no effect when running as user instance. See `systemd.crash_reboot` above.

--confirm-spawn

Ask for confirmation when spawning processes. This switch has no effect when run as user instance. See `systemd.confirm_spawn` above.

--show-status

Show terse unit status information on the console during boot-up and shutdown. See `systemd.show_status` above.

--log-color

Highlight important log messages. See `systemd.log_color` above.

--log-level=

Set log level. See `systemd.log_level` above.

--log-location

Include code location in log messages. See `systemd.log_location` above.

--log-target=

Set log target. See `systemd.log_target` above.

--log-time=

Prefix console messages with timestamp. See `systemd.log_time` above.

--machine-id=

Override the machine-id set on the hard drive. See `systemd.machine_id=` above.

--service-watchdogs

Globally enable/disable all service watchdog timeouts and emergency actions. See `systemd.service_watchdogs` above.

--default-standard-output=, --default-standard-error=

Sets the default output or error output for all services and sockets, respectively. See `systemd.default_standard_output=` and `systemd.default_standard_error=` above.

SOCKETS AND FIFOs

/run/systemd/notify

Daemon status notification socket. This is an **AF_UNIX** datagram socket and is used to implement the daemon notification logic as implemented by **sd_notify(3)**.

/run/systemd/private

Used internally as communication channel between **systemctl(1)** and the systemd process. This is an **AF_UNIX** stream socket. This interface is private to systemd and should not be used in external projects.

/dev/initctl

Limited compatibility support for the SysV client interface, as implemented by the **systemd-initctl.service** unit. This is a named pipe in the file system. This interface is obsolete and should not be used in new applications.

NAME

`systemd.kill` – Process killing procedure configuration

SYNOPSIS

`service.service, socket.socket, mount.mount, swap.swap, scope.scope`

DESCRIPTION

Unit configuration files for services, sockets, mount points, swap devices and scopes share a subset of configuration options which define the killing procedure of processes belonging to the unit.

This man page lists the configuration options shared by these five unit types. See **systemd.unit(5)** for the common options shared by all unit configuration files, and **systemd.service(5)**, **systemd.socket(5)**, **systemd.swap(5)**, **systemd.mount(5)** and **systemd.scope(5)** for more information on the configuration file options specific to each unit type.

The kill procedure configuration options are configured in the [Service], [Socket], [Mount] or [Swap] section, depending on the unit type.

OPTIONS

KillMode=

Specifies how processes of this unit shall be killed. One of **control-group**, **mixed**, **process**, **none**.

If set to **control-group**, all remaining processes in the control group of this unit will be killed on unit stop (for services: after the stop command is executed, as configured with *ExecStop*=). If set to **mixed**, the **SIGTERM** signal (see below) is sent to the main process while the subsequent **SIGKILL** signal (see below) is sent to all remaining processes of the unit's control group. If set to **process**, only the main process itself is killed (not recommended!). If set to **none**, no process is killed (strongly recommended against!). In this case, only the stop command will be executed on unit stop, but no process will be killed otherwise. Processes remaining alive after stop are left in their control group and the control group continues to exist after stop unless empty.

Note that it is not recommended to set *KillMode*= to **process** or even **none**, as this allows processes to escape the service manager's lifecycle and resource management, and to remain running even while their service is considered stopped and is assumed to not consume any resources.

Processes will first be terminated via **SIGTERM** (unless the signal to send is changed via *KillSignal*= or *RestartKillSignal*=). Optionally, this is immediately followed by a **SIGHUP** (if enabled with *SendSIGHUP*=). If processes still remain after the main process of a unit has exited or the delay configured via the *TimeoutStopSec*= has passed, the termination request is repeated with the **SIGKILL** signal or the signal specified via *FinalKillSignal*= (unless this is disabled via the *SendSIGKILL*= option). See **kill(2)** for more information.

Defaults to **control-group**.

KillSignal=

Specifies which signal to use when stopping a service. This controls the signal that is sent as first step of shutting down a unit (see above), and is usually followed by **SIGKILL** (see above and below). For a list of valid signals, see **signal(7)**. Defaults to **SIGTERM**.

Note that, right after sending the signal specified in this setting, systemd will always send **SIGCONT**, to ensure that even suspended tasks can be terminated cleanly.

RestartKillSignal=

Specifies which signal to use when restarting a service. The same as *KillSignal*= described above, with the exception that this setting is used in a restart job. Not set by default, and the value of *KillSignal*= is used.

SendSIGHUP=

Specifies whether to send **SIGHUP** to remaining processes immediately after sending the signal

configured with *KillSignal*=. This is useful to indicate to shells and shell-like programs that their connection has been severed. Takes a boolean value. Defaults to "no".

SendSIGKILL=

Specifies whether to send **SIGKILL** (or the signal specified by *FinalKillSignal*=) to remaining processes after a timeout, if the normal shutdown procedure left processes of the service around. When disabled, a *KillMode*= of **control-group** or **mixed** service will not restart if processes from prior services exist within the control group. Takes a boolean value. Defaults to "yes".

FinalKillSignal=

Specifies which signal to send to remaining processes after a timeout if *SendSIGKILL*= is enabled. The signal configured here should be one that is not typically caught and processed by services (**SIGTERM** is not suitable). Developers can find it useful to use this to generate a core dump to troubleshoot why a service did not terminate upon receiving the initial **SIGTERM** signal. This can be achieved by configuring *LimitCORE*= and setting *FinalKillSignal*= to either **SIGQUIT** or **SIGABRT**. Defaults to **SIGKILL**.

WatchdogSignal=

Specifies which signal to use to terminate the service when the watchdog timeout expires (enabled through *WatchdogSec*=). Defaults to **SIGABRT**.

NAME

`systemd.mount` – Mount unit configuration

SYNOPSIS

`mount.mount`

DESCRIPTION

A unit configuration file whose name ends in ".mount" encodes information about a file system mount point controlled and supervised by systemd.

This man page lists the configuration options specific to this unit type. See **systemd.unit(5)** for the common options of all unit configuration files. The common configuration items are configured in the generic [Unit] and [Install] sections. The mount specific configuration options are configured in the [Mount] section.

Additional options are listed in **systemd.exec(5)**, which define the execution environment the **mount(8)** program is executed in, and in **systemd.kill(5)**, which define the way the processes are terminated, and in **systemd.resource-control(5)**, which configure resource control settings for the processes of the service.

Note that the options *User=* and *Group=* are not useful for mount units. systemd passes two parameters to **mount(8)**; the values of *What=* and *Where=*. When invoked in this way, **mount(8)** does not read any options from /etc/fstab, and must be run as UID 0.

Mount units must be named after the mount point directories they control. Example: the mount point /home/lennart must be configured in a unit file `home-lennart.mount`. For details about the escaping logic used to convert a file system path to a unit name, see **systemd.unit(5)**. Note that mount units cannot be templated, nor is possible to add multiple names to a mount unit by creating additional symlinks to it.

Optionally, a mount unit may be accompanied by an automount unit, to allow on-demand or parallelized mounting. See **systemd.automount(5)**.

Mount points created at runtime (independently of unit files or /etc/fstab) will be monitored by systemd and appear like any other mount unit in systemd. See /proc/self/mountinfo description in **proc(5)**.

Some file systems have special semantics as API file systems for kernel-to-userspace and userspace-to-userspace interfaces. Some of them may not be changed via mount units, and cannot be disabled. For a longer discussion see [API File Systems^{\[1\]}](#).

The **systemd-mount(1)** command allows creating .mount and .automount units dynamically and transiently from the command line.

AUTOMATIC DEPENDENCIES**Implicit Dependencies**

The following dependencies are implicitly added:

- If a mount unit is beneath another mount unit in the file system hierarchy, both a requirement dependency and an ordering dependency between both units are created automatically.
- Block device backed file systems automatically gain *BindsTo=* and *After=* type dependencies on the device unit encapsulating the block device (see below).
- If traditional file system quota is enabled for a mount unit, automatic *Wants=* and *Before=* dependencies on `systemd-quotacheck.service` and `quotaon.service` are added.
- Additional implicit dependencies may be added as result of execution and resource control parameters as documented in **systemd.exec(5)** and **systemd.resource-control(5)**.

Default Dependencies

The following dependencies are added unless *DefaultDependencies=no* is set:

- All mount units acquire automatic *Before=* and *Conflicts=* on `umount.target` in order to be stopped during shutdown.
- Mount units referring to local file systems automatically gain an *After=* dependency on `local-fs-pre.target`, and a *Before=* dependency on `local-fs.target` unless **nofail** mount option is set.

- Network mount units automatically acquire *After=* dependencies on `remote-fs-pre.target`, `network.target` and `network-online.target`, and gain a *Before=* dependency on `remote-fs.target` unless `nofail` mount option is set. Towards the latter a *Wants=* unit is added as well.

Mount units referring to local and network file systems are distinguished by their file system type specification. In some cases this is not sufficient (for example network block device based mounts, such as iSCSI), in which case `_netdev` may be added to the mount option string of the unit, which forces systemd to consider the mount unit a network mount.

FSTAB

Mount units may either be configured via unit files, or via /etc/fstab (see **fstab(5)** for details). Mounts listed in /etc/fstab will be converted into native units dynamically at boot and when the configuration of the system manager is reloaded. In general, configuring mount points through /etc/fstab is the preferred approach. See **systemd-fstab-generator(8)** for details about the conversion.

The NFS mount option `bg` for NFS background mounts as documented in **nfs(5)** is detected by **systemd-fstab-generator** and the options are transformed so that systemd fulfills the job-control implications of that option. Specifically **systemd-fstab-generator** acts as though "x-systemd.mount-timeout=infinity,retry=10000" was prepended to the option list, and "fg,nofail" was appended. Depending on specific requirements, it may be appropriate to provide some of these options explicitly, or to make use of the "x-systemd.automount" option described below instead of using "bg".

When reading /etc/fstab a few special mount options are understood by systemd which influence how dependencies are created for mount points. systemd will create a dependency of type *Wants=* or *Requires=* (see option `nofail` below), from either `local-fs.target` or `remote-fs.target`, depending whether the file system is local or remote.

x–systemd.requires=

Configures a *Requires=* and an *After=* dependency between the created mount unit and another systemd unit, such as a device or mount unit. The argument should be a unit name, or an absolute path to a device node or mount point. This option may be specified more than once. This option is particularly useful for mount point declarations that need an additional device to be around (such as an external journal device for journal file systems) or an additional mount to be in place (such as an overlay file system that merges multiple mount points). See *After=* and *Requires=* in **systemd.unit(5)** for details.

Note that this option always applies to the created mount unit only regardless whether **x–systemd.automount** has been specified.

x–systemd.before=, x–systemd.after=

In the created mount unit, configures a *Before=* or *After=* dependency on another systemd unit, such as a mount unit. The argument should be a unit name or an absolute path to a mount point. This option may be specified more than once. This option is particularly useful for mount point declarations with `nofail` option that are mounted asynchronously but need to be mounted before or after some unit start, for example, before `local-fs.target` unit. See *Before=* and *After=* in **systemd.unit(5)** for details.

Note that these options always apply to the created mount unit only regardless whether **x–systemd.automount** has been specified.

x–systemd.wanted-by=, x–systemd.required-by=

In the created mount unit, configures a *WantedBy=* or *RequiredBy=* dependency on another unit. This option may be specified more than once. If this is specified, the normal automatic dependencies on the created mount unit, e.g., `local-fs.target`, are not automatically created. See *WantedBy=* and *RequiredBy=* in **systemd.unit(5)** for details.

x–systemd.requires-mounts-for=

Configures a *RequiresMountsFor=* dependency between the created mount unit and other mount units. The argument must be an absolute path. This option may be specified more than once. See *RequiresMountsFor=* in **systemd.unit(5)** for details.

x–systemd.device–bound

The block device backed file system will be upgraded to *BindsTo=* dependency. This option is only useful when mounting file systems manually with **mount(8)** as the default dependency in this case is *Requires=*. This option is already implied by entries in /etc/fstab or by mount units.

x–systemd.automount

An automount unit will be created for the file system. See **systemd.automount(5)** for details.

x–systemd.idle–timeout=

Configures the idle timeout of the automount unit. See *TimeoutIdleSec=* in **systemd.automount(5)** for details.

x–systemd.device–timeout=

Configure how long systemd should wait for a device to show up before giving up on an entry from /etc/fstab. Specify a time in seconds or explicitly append a unit such as "s", "min", "h", "ms".

Note that this option can only be used in /etc/fstab, and will be ignored when part of the *Options=* setting in a unit file.

x–systemd.mount–timeout=

Configure how long systemd should wait for the mount command to finish before giving up on an entry from /etc/fstab. Specify a time in seconds or explicitly append a unit such as "s", "min", "h", "ms".

Note that this option can only be used in /etc/fstab, and will be ignored when part of the *Options=* setting in a unit file.

See *TimeoutSec=* below for details.

x–systemd.makefs

The file system will be initialized on the device. If the device is not "empty", i.e. it contains any signature, the operation will be skipped. It is hence expected that this option remains set even after the device has been initialized.

Note that this option can only be used in /etc/fstab, and will be ignored when part of the *Options=* setting in a unit file.

See **systemd-makefs@.service(8)**.

wipefs(8) may be used to remove any signatures from a block device to force **x–systemd.makefs** to reinitialize the device.

x–systemd.growfs

The file system will be grown to occupy the full block device. If the file system is already at maximum size, no action will be performed. It is hence expected that this option remains set even after the file system has been grown. Only certain file system types are supported, see **systemd-makefs@.service(8)** for details.

Note that this option can only be used in /etc/fstab, and will be ignored when part of the *Options=* setting in a unit file.

x–systemd.rw–only

If a mount operation fails to mount the file system read–write, it normally tries mounting the file system read–only instead. This option disables that behaviour, and causes the mount to fail immediately instead. This option is translated into the *ReadWriteOnly=* setting in a unit file.

_netdev

Normally the file system type is used to determine if a mount is a "network mount", i.e. if it should only be started after the network is available. Using this option overrides this detection and specifies

that the mount requires network.

Network mount units are ordered between `remote-fs-pre.target` and `remote-fs.target`, instead of `local-fs-pre.target` and `local-fs.target`. They also pull in `network-online.target` and are ordered after it and `network.target`.

noauto, auto

With **noauto**, the mount unit will not be added as a dependency for `local-fs.target` or `remote-fs.target`. This means that it will not be mounted automatically during boot, unless it is pulled in by some other unit. The **auto** option has the opposite meaning and is the default.

Note that if **x-systemd.automount** (see above) is used, neither **auto** nor **noauto** have any effect. The matching automount unit will be added as a dependency to the appropriate target.

nofail

With **nofail**, this mount will be only wanted, not required, by `local-fs.target` or `remote-fs.target`. Moreover the mount unit is not ordered before these target units. This means that the boot will continue without waiting for the mount unit and regardless whether the mount point can be mounted successfully.

x-initrd.mount

An additional filesystem to be mounted in the initramfs. See `initrd-fs.target` description in **systemd.special(7)**.

If a mount point is configured in both `/etc/fstab` and a unit file that is stored below `/usr/`, the former will take precedence. If the unit file is stored below `/etc/`, it will take precedence. This means: native unit files take precedence over traditional configuration files, but this is superseded by the rule that configuration in `/etc/` will always take precedence over configuration in `/usr/`.

OPTIONS

Mount files must include a [Mount] section, which carries information about the file system mount points it supervises. A number of options that may be used in this section are shared with other unit types. These options are documented in **systemd.exec(5)** and **systemd.kill(5)**. The options specific to the [Mount] section of mount units are the following:

What=

Takes an absolute path of a device node, file or other resource to mount. See **mount(8)** for details. If this refers to a device node, a dependency on the respective device unit is automatically created. (See **systemd.device(5)** for more information.) This option is mandatory. Note that the usual specifier expansion is applied to this setting, literal percent characters should hence be written as "%%". If this mount is a bind mount and the specified path does not exist yet it is created as directory.

Where=

Takes an absolute path of a file or directory for the mount point; in particular, the destination cannot be a symbolic link. If the mount point does not exist at the time of mounting, it is created as directory. This string must be reflected in the unit filename. (See above.) This option is mandatory.

Type=

Takes a string for the file system type. See **mount(8)** for details. This setting is optional.

Options=

Mount options to use when mounting. This takes a comma-separated list of options. This setting is optional. Note that the usual specifier expansion is applied to this setting, literal percent characters should hence be written as "%%".

SloppyOptions=

Takes a boolean argument. If true, parsing of the options specified in *Options=* is relaxed, and unknown mount options are tolerated. This corresponds with **mount(8)**'s `-s` switch. Defaults to off.

LazyUnmount=

Takes a boolean argument. If true, detach the filesystem from the filesystem hierarchy at time of the

unmount operation, and clean up all references to the filesystem as soon as they are not busy anymore. This corresponds with **umount(8)**'s *-l* switch. Defaults to off.

ReadOnly=

Takes a boolean argument. If false, a mount point that shall be mounted read-write but cannot be mounted so is retried to be mounted read-only. If true the operation will fail immediately after the read-write mount attempt did not succeed. This corresponds with **mount(8)**'s *-w* switch. Defaults to off.

ForceUnmount=

Takes a boolean argument. If true, force an unmount (in case of an unreachable NFS system). This corresponds with **umount(8)**'s *-f* switch. Defaults to off.

DirectoryMode=

Directories of mount points (and any parent directories) are automatically created if needed. This option specifies the file system access mode used when creating these directories. Takes an access mode in octal notation. Defaults to 0755.

TimeoutSec=

Configures the time to wait for the mount command to finish. If a command does not exit within the configured time, the mount will be considered failed and be shut down again. All commands still running will be terminated forcibly via **SIGTERM**, and after another delay of this time with **SIGKILL**. (See **KillMode=** in **systemd.kill(5)**.) Takes a unit-less value in seconds, or a time span value such as "5min 20s". Pass 0 to disable the timeout logic. The default value is set from **DefaultTimeoutStartSec=** option in **systemd-system.conf(5)**.

Check **systemd.exec(5)** and **systemd.kill(5)** for more settings.

NOTES

1. API File Systems

<https://www.freedesktop.org/wiki/Software/systemd/APIFileSystems>

NAME

`systemd.network` – Network configuration

SYNOPSIS

network.network

DESCRIPTION

A plain ini–style text file that encodes network configuration for matching network interfaces, used by **systemd-networkd(8)**. See **systemd.syntax(7)** for a general description of the syntax.

The main network file must have the extension `.network`; other extensions are ignored. Networks are applied to links whenever the links appear.

The `.network` files are read from the files located in the system network directories `/lib/systemd/network` and `/usr/local/lib/systemd/network`, the volatile runtime network directory `/run/systemd/network` and the local administration network directory `/etc/systemd/network`. All configuration files are collectively sorted and processed in lexical order, regardless of the directories in which they live. However, files with identical filenames replace each other. Files in `/etc/` have the highest priority, files in `/run/` take precedence over files with the same name under `/usr/`. This can be used to override a system–supplied configuration file with a local file if needed. As a special case, an empty file (file size 0) or symlink with the same name pointing to `/dev/null` disables the configuration file entirely (it is "masked").

Along with the network file `foo.network`, a "drop–in" directory `foo.network.d/` may exist. All files with the suffix `".conf"` from this directory will be merged in the alphanumeric order and parsed after the main file itself has been parsed. This is useful to alter or add configuration settings, without having to modify the main configuration file. Each drop–in file must have appropriate section headers.

In addition to `/etc/systemd/network`, drop–in `".d"` directories can be placed in `/lib/systemd/network` or `/run/systemd/network` directories. Drop–in files in `/etc/` take precedence over those in `/run/` which in turn take precedence over those in `/lib/`. Drop–in files under any of these directories take precedence over the main network file wherever located.

[MATCH] SECTION OPTIONS

The network file contains a `[Match]` section, which determines if a given network file may be applied to a given device; and a `[Network]` section specifying how the device should be configured. The first (in lexical order) of the network files that matches a given device is applied, all later files are ignored, even if they match as well.

A network file is said to match a network interface if all matches specified by the `[Match]` section are satisfied. When a network file does not contain valid settings in `[Match]` section, then the file will match all interfaces and **systemd–networkd** warns about that. Hint: to avoid the warning and to make it clear that all interfaces shall be matched, add the following:

`Name=*`

The following keys are accepted:

MACAddress=

A whitespace–separated list of hardware addresses. Use full colon–, hyphen– or dot–delimited hexadecimal. See the example below. This option may appear more than once, in which case the lists are merged. If the empty string is assigned to this option, the list of hardware addresses defined prior to this is reset.

Example:

`MACAddress=01:23:45:67:89:ab 00–11–22–33–44–55 AABB.CCDD.EEFF`

PermanentMACAddress=

A whitespace–separated list of hardware's permanent addresses. While `MACAddress=` matches the device's current MAC address, this matches the device's permanent MAC address, which may be

different from the current one. Use full colon–, hyphen– or dot–delimited hexadecimal. This option may appear more than once, in which case the lists are merged. If the empty string is assigned to this option, the list of hardware addresses defined prior to this is reset.

Path=

A whitespace-separated list of shell-style globs matching the persistent path, as exposed by the udev property *ID_PATH*.

Driver=

A whitespace-separated list of shell-style globs matching the driver currently bound to the device, as exposed by the udev property *ID_NET_DRIVER* of its parent device, or if that is not set, the driver as exposed by **ethtool -i** of the device itself. If the list is prefixed with a "!", the test is inverted.

Type=

A whitespace-separated list of shell-style globs matching the device type, as exposed by **networkctl list**. If the list is prefixed with a "!", the test is inverted. Some valid values are "ether", "loopback", "wlan", "wwan". Valid types are named either from the udev "DEVTYPE" attribute, or "ARPHRD_" macros in `linux/if_arp.h`, so this is not comprehensive.

Property=

A whitespace-separated list of udev property names with their values after equals sign ("="). If multiple properties are specified, the test results are ANDed. If the list is prefixed with a "!", the test is inverted. If a value contains white spaces, then please quote whole key and value pair. If a value contains quotation, then please escape the quotation with "\\".

Example: if a .link file has the following:

```
Property=ID_MODEL_ID=9999 "ID_VENDOR_FROM_DATABASE=vendor name" "KEY=with \"quotation\""
```

then, the .link file matches only when an interface has all the above three properties.

Name=

A whitespace-separated list of shell-style globs matching the device name, as exposed by the udev property "INTERFACE", or device's alternative names. If the list is prefixed with a "!", the test is inverted.

WLANInterfaceType=

A whitespace-separated list of wireless network type. Supported values are "ad-hoc", "station", "ap", "ap-vlan", "wds", "monitor", "mesh-point", "p2p-client", "p2p-go", "p2p-device", "ocb", and "nan". If the list is prefixed with a "!", the test is inverted.

SSID=

A whitespace-separated list of shell-style globs matching the SSID of the currently connected wireless LAN. If the list is prefixed with a "!", the test is inverted.

BSSID=

A whitespace-separated list of hardware address of the currently connected wireless LAN. Use full colon–, hyphen– or dot–delimited hexadecimal. See the example in *MACAddress*=. This option may appear more than once, in which case the lists are merged. If the empty string is assigned to this option, the list is reset.

Host=

Matches against the hostname or machine ID of the host. See *ConditionHost*= in **systemd.unit(5)** for details. When prefixed with an exclamation mark ("!"), the result is negated. If an empty string is assigned, then previously assigned value is cleared.

Virtualization=

Checks whether the system is executed in a virtualized environment and optionally test whether it is a specific implementation. See *ConditionVirtualization*= in **systemd.unit(5)** for details. When prefixed with an exclamation mark ("!"), the result is negated. If an empty string is assigned, then previously

assigned value is cleared.

KernelCommandLine=

Checks whether a specific kernel command line option is set. See *ConditionKernelCommandLine*= in **systemd.unit(5)** for details. When prefixed with an exclamation mark ("!"), the result is negated. If an empty string is assigned, then previously assigned value is cleared.

KernelVersion=

Checks whether the kernel version (as reported by **uname -r**) matches a certain expression. See *ConditionKernelVersion*= in **systemd.unit(5)** for details. When prefixed with an exclamation mark ("!"), the result is negated. If an empty string is assigned, then previously assigned value is cleared.

Architecture=

Checks whether the system is running on a specific architecture. See *ConditionArchitecture*= in **systemd.unit(5)** for details. When prefixed with an exclamation mark ("!"), the result is negated. If an empty string is assigned, then previously assigned value is cleared.

Firmware=

Checks whether the system is running on a machine with the specified firmware. See *ConditionFirmware*= in **systemd.unit(5)** for details. When prefixed with an exclamation mark ("!"), the result is negated. If an empty string is assigned, then previously assigned value is cleared.

[LINK] SECTION OPTIONS

The [Link] section accepts the following keys:

MACAddress=

The hardware address to set for the device.

MTUBytes=

The maximum transmission unit in bytes to set for the device. The usual suffixes K, M, G, are supported and are understood to the base of 1024.

Note that if IPv6 is enabled on the interface, and the MTU is chosen below 1280 (the minimum MTU for IPv6) it will automatically be increased to this value.

ARP=

Takes a boolean. If set to true, the ARP (low-level Address Resolution Protocol) for this interface is enabled. When unset, the kernel's default will be used.

For example, disabling ARP is useful when creating multiple MACVLAN or VLAN virtual interfaces atop a single lower-level physical interface, which will then only serve as a link/"bridge" device aggregating traffic to the same physical link and not participate in the network otherwise. Defaults to unset.

Multicast=

Takes a boolean. If set to true, the multicast flag on the device is enabled. Defaults to unset.

AllMulticast=

Takes a boolean. If set to true, the driver retrieves all multicast packets from the network. This happens when multicast routing is enabled. Defaults to unset.

Promiscuous=

Takes a boolean. If set to true, promiscuous mode of the interface is enabled. Defaults to unset.

Unmanaged=

Takes a boolean. When "yes", no attempts are made to bring up or configure matching links, equivalent to when there are no matching network files. Defaults to "no".

This is useful for preventing later matching network files from interfering with certain interfaces that are fully controlled by other applications.

Group=

Link groups are similar to port ranges found in managed switches. When network interfaces are added to a numbered group, operations on all the interfaces from that group can be performed at once. Takes an unsigned integer in the range 0...4294967295. Defaults to unset.

RequiredForOnline=

Takes a boolean or a minimum operational state and an optional maximum operational state. Please see **networkctl**(1) for possible operational states. When "yes", the network is deemed required when determining whether the system is online (including when running **systemd–networkd–wait–online**). When "no", the network is ignored when determining the online state. When a minimum operational state and an optional maximum operational state are set, "yes" is implied, and this controls the minimum and maximum operational state required for the network interface to be considered online.

Defaults to "yes" when *ActivationPolicy*= is not set, or set to "up", "always-up", or "bound". Defaults to "no" when *ActivationPolicy*= is set to "manual" or "down". This is forced to "no" when *ActivationPolicy*= is set to "always-down".

The network will be brought up normally (as configured by *ActivationPolicy*=), but in the event that there is no address being assigned by DHCP or the cable is not plugged in, the link will simply remain offline and be skipped automatically by **systemd–networkd–wait–online** if "RequiredForOnline=no".

RequiredFamilyForOnline=

Takes an address family. When specified, an IP address in the given family is deemed required when determining whether the link is online (including when running **systemd–networkd–wait–online**). Takes one of "ipv4", "ipv6", "both", or "any". Defaults to "any". Note that this option has no effect if "RequiredForOnline=no", or if "RequiredForOnline=" specifies a minimum operational state below "degraded".

ActivationPolicy=

Specifies the policy for **systemd–networkd** managing the link administrative state. Specifically, this controls how **systemd–networkd** changes the network device's "IFF_UP" flag, which is sometimes controlled by system administrators by running e.g., **ip link set dev eth0 up** or **ip link set dev eth0 down**, and can also be changed with **networkctl up eth0** or **networkctl down eth0**.

Takes one of "up", "always-up", "manual", "always-down", "down", or "bound". When "manual", **systemd–networkd** will not change the link's admin state automatically; the system administrator must bring the interface up or down manually, as desired. When "up" (the default) or "always-up", or "down" or "always-down", **systemd–networkd** will set the link up or down, respectively, when the interface is (re)configured. When "always-up" or "always-down", **systemd–networkd** will set the link up or down, respectively, any time **systemd–networkd** detects a change in the administrative state. When *BindCarrier*= is also set, this is automatically set to "bound" and any other value is ignored.

When the policy is set to "down" or "manual", the default value of *RequiredForOnline*= is "no". When the policy is set to "always-down", the value of *RequiredForOnline*= forced to "no".

The administrative state is not the same as the carrier state, so using "always-up" does not mean the link will never lose carrier. The link carrier depends on both the administrative state as well as the network device's physical connection. However, to avoid reconfiguration failures, when using "always-up", *IgnoreCarrierLoss*= is forced to true.

[SR-IOV] SECTION OPTIONS

The [SR-IOV] section accepts the following keys. Specify several [SR-IOV] sections to configure several SR-IOVs. SR-IOV provides the ability to partition a single physical PCI resource into virtual PCI functions which can then be injected into a VM. In the case of network VFs, SR-IOV improves north-south network performance (that is, traffic with endpoints outside the host machine) by allowing traffic to bypass the host machine's network stack.

VirtualFunction=
 Specifies a Virtual Function (VF), lightweight PCIe function designed solely to move data in and out.
 Takes an unsigned integer in the range 0...2147483646. This option is compulsory.

VLANId=
 Specifies VLAN ID of the virtual function. Takes an unsigned integer in the range 1...4095.

QualityOfService=
 Specifies quality of service of the virtual function. Takes an unsigned integer in the range 1...4294967294.

VLANProtocol=
 Specifies VLAN protocol of the virtual function. Takes "802.1Q" or "802.1ad".

MACSpoofCheck=
 Takes a boolean. Controls the MAC spoof checking. When unset, the kernel's default will be used.

QueryReceiveSideScaling=
 Takes a boolean. Toggle the ability of querying the receive side scaling (RSS) configuration of the virtual function (VF). The VF RSS information like RSS hash key may be considered sensitive on some devices where this information is shared between VF and the physical function (PF). When unset, the kernel's default will be used.

Trust=
 Takes a boolean. Allows to set trust mode of the virtual function (VF). When set, VF users can set a specific feature which may impact security and/or performance. When unset, the kernel's default will be used.

LinkState=
 Allows to set the link state of the virtual function (VF). Takes a boolean or a special value "auto". Setting to "auto" means a reflection of the physical function (PF) link state, "yes" lets the VF to communicate with other VFs on this host even if the PF link state is down, "no" causes the hardware to drop any packets sent by the VF. When unset, the kernel's default will be used.

MACAddress=
 Specifies the MAC address for the virtual function.

[NETWORK] SECTION OPTIONS

The [Network] section accepts the following keys:

Description=
 A description of the device. This is only used for presentation purposes.

DHCP=
 Enables DHCPv4 and/or DHCPv6 client support. Accepts "yes", "no", "ipv4", or "ipv6". Defaults to "no".
 Note that DHCPv6 will by default be triggered by Router Advertisement, if that is enabled, regardless of this parameter. By enabling DHCPv6 support explicitly, the DHCPv6 client will be started regardless of the presence of routers on the link, or what flags the routers pass. See "IPv6AcceptRA=". Furthermore, note that by default the domain name specified through DHCP, on Ubuntu, are used for name resolution. See option **UseDomains**= below.
 See the [DHCPv4] or [DHCPv6] sections below for further configuration options for the DHCP client support.

DHCPServer=
 Takes a boolean. If set to "yes", DHCPv4 server will be started. Defaults to "no". Further settings for the DHCP server may be set in the [DHCPServer] section described below.

LinkLocalAddressing=

Enables link-local address autoconfiguration. Accepts **yes**, **no**, **ipv4**, and **ipv6**. An IPv6 link-local address is configured when **yes** or **ipv6**. An IPv4 link-local address is configured when **yes** or **ipv4** and when DHCPv4 autoconfiguration has been unsuccessful for some time. (IPv4 link-local address autoconfiguration will usually happen in parallel with repeated attempts to acquire a DHCPv4 lease).

Defaults to **no** when *Bridge*=**yes** is set, and **ipv6** otherwise.

IPv6LinkLocalAddressGenerationMode=

Specifies how IPv6 link local address is generated. Takes one of "eui64", "none", "stable-privacy" and "random". When unset, "stable-privacy" is used if *IPv6StableSecretAddress*= is specified, and if not, "eui64" is used. Note that if *LinkLocalAddressing*= is "no" or "ipv4", then

IPv6LinkLocalAddressGenerationMode= will be ignored. Also, even if *LinkLocalAddressing*= is "yes" or "ipv6", setting *IPv6LinkLocalAddressGenerationMode*=**none** disables to configure an IPv6 link-local address.

IPv6StableSecretAddress=

Takes an IPv6 address. The specified address will be used as a stable secret for generating IPv6 link-local address. If this setting is specified, and *IPv6LinkLocalAddressGenerationMode*= is unset, then *IPv6LinkLocalAddressGenerationMode*=**stable-privacy** is implied. If this setting is not specified, and "stable-privacy" is set to *IPv6LinkLocalAddressGenerationMode*=, then a stable secret address will be generated from the local machine ID and the interface name.

IPv4LLRoute=

Takes a boolean. If set to true, sets up the route needed for non-IPv4LL hosts to communicate with IPv4LL-only hosts. Defaults to false.

DefaultRouteOnDevice=

Takes a boolean. If set to true, sets up the default route bound to the interface. Defaults to false. This is useful when creating routes on point-to-point interfaces. This is equivalent to e.g. the following,

```
ip route add default dev veth99
```

or,

```
[Route]
Gateway=0.0.0.0
```

Currently, there are no way to specify e.g., the table for the route configured by this setting. To configure the default route with such an additional property, please use the following instead:

```
[Route]
Gateway=0.0.0.0
Table=1234
```

IPv6Token=

Specifies an optional address generation mode for the Stateless Address Autoconfiguration (SLAAC). Supported modes are "prefixstable" and "static".

When the mode is set to "static", an IPv6 address must be specified after a colon ":"), and the lower bits of the supplied address are combined with the upper bits of a prefix received in a Router Advertisement (RA) message to form a complete address. Note that if multiple prefixes are received in an RA message, or in multiple RA messages, addresses will be formed from each of them using the supplied address. This mode implements SLAAC but uses a static interface identifier instead of an identifier generated by using the EUI-64 algorithm. Because the interface identifier is static, if Duplicate Address Detection detects that the computed address is a duplicate (in use by another node on the link), then this mode will fail to provide an address for that prefix. If an IPv6 address without mode is specified, then "static" mode is assumed.

When the mode is set to "prefixstable" the [RFC 7217](#)^[1] algorithm for generating interface identifiers will be used. This mode can optionally take an IPv6 address separated with a colon (:). If an IPv6 address is specified, then an interface identifier is generated only when a prefix received in an RA message matches the supplied address.

If no address generation mode is specified (which is the default), or a received prefix does not match any of the addresses provided in "prefixstable" mode, then the EUI-64 algorithm will be used to form an interface identifier for that prefix. This mode is also SLAAC, but with a potentially stable interface identifier which does not directly map to the interface's hardware address.

Note that the "prefixstable" algorithm uses both the interface name and MAC address as input to the hash to compute the interface identifier, so if either of those are changed the resulting interface identifier (and address) will change, even if the prefix received in the RA message has not changed.

This setting can be specified multiple times. If an empty string is assigned, then all previous assignments are cleared.

Examples:

```
IPv6Token=::1a:2b:3c:4d
IPv6Token=static::1a:2b:3c:4d
IPv6Token=prefixstable
IPv6Token=prefixstable:2002:da8:1::
```

LLMNR=

Takes a boolean or "resolve". When true, enables [Link-Local Multicast Name Resolution](#)^[2] on the link. When set to "resolve", only resolution is enabled, but not host registration and announcement. Defaults to true. This setting is read by [systemd-resolved.service\(8\)](#).

MulticastDNS=

Takes a boolean or "resolve". When true, enables [Multicast DNS](#)^[3] support on the link. When set to "resolve", only resolution is enabled, but not host or service registration and announcement. Defaults to false. This setting is read by [systemd-resolved.service\(8\)](#).

DNSOverTLS=

Takes a boolean or "opportunistic". When true, enables [DNS-over-TLS](#)^[4] support on the link. When set to "opportunistic", compatibility with non-DNS-over-TLS servers is increased, by automatically turning off DNS-over-TLS servers in this case. This option defines a per-interface setting for [resolved.conf\(5\)](#)'s global *DNSOverTLS=* option. Defaults to false. This setting is read by [systemd-resolved.service\(8\)](#).

DNSSEC=

Takes a boolean or "allow-downgrade". When true, enables [DNSSEC](#)^[5] DNS validation support on the link. When set to "allow-downgrade", compatibility with non-DNSSEC capable networks is increased, by automatically turning off DNSSEC in this case. This option defines a per-interface setting for [resolved.conf\(5\)](#)'s global *DNSSEC=* option. Defaults to false. This setting is read by [systemd-resolved.service\(8\)](#).

DNSSECNegativeTrustAnchors=

A space-separated list of DNSSEC negative trust anchor domains. If specified and DNSSEC is enabled, look-ups done via the interface's DNS server will be subject to the list of negative trust anchors, and not require authentication for the specified domains, or anything below it. Use this to disable DNSSEC authentication for specific private domains, that cannot be proven valid using the Internet DNS hierarchy. Defaults to the empty list. This setting is read by [systemd-resolved.service\(8\)](#).

LLDP=

Controls support for Ethernet LLDP packet reception. LLDP is a link-layer protocol commonly

implemented on professional routers and bridges which announces which physical port a system is connected to, as well as other related data. Accepts a boolean or the special value "routers-only". When true, incoming LLDP packets are accepted and a database of all LLDP neighbors maintained. If "routers-only" is set only LLDP data of various types of routers is collected and LLDP data about other types of devices ignored (such as stations, telephones and others). If false, LLDP reception is disabled. Defaults to "routers-only". Use **networkctl**(1) to query the collected neighbor data. LLDP is only available on Ethernet links. See *EmitLLDP=* below for enabling LLDP packet emission from the local system.

EmitLLDP=

Controls support for Ethernet LLDP packet emission. Accepts a boolean parameter or the special values "nearest-bridge", "non-tpmr-bridge" and "customer-bridge". Defaults to false, which turns off LLDP packet emission. If not false, a short LLDP packet with information about the local system is sent out in regular intervals on the link. The LLDP packet will contain information about the local hostname, the local machine ID (as stored in **machine-id**(5)) and the local interface name, as well as the pretty hostname of the system (as set in **machine-info**(5)). LLDP emission is only available on Ethernet links. Note that this setting passes data suitable for identification of host to the network and should thus not be enabled on untrusted networks, where such identification data should not be made available. Use this option to permit other systems to identify on which interfaces they are connected to this system. The three special values control propagation of the LLDP packets. The "nearest-bridge" setting permits propagation only to the nearest connected bridge, "non-tpmr-bridge" permits propagation across Two-Port MAC Relays, but not any other bridges, and "customer-bridge" permits propagation until a customer bridge is reached. For details about these concepts, see [IEEE 802.1AB-2016^{\[6\]}](#). Note that configuring this setting to true is equivalent to "nearest-bridge", the recommended and most restricted level of propagation. See *LLDP=* above for an option to enable LLDP reception.

BindCarrier=

A link name or a list of link names. When set, controls the behavior of the current link. When all links in the list are in an operational down state, the current link is brought down. When at least one link has carrier, the current interface is brought up.

This forces *ActivationPolicy=* to be set to "bound".

Address=

A static IPv4 or IPv6 address and its prefix length, separated by a "/" character. Specify this key more than once to configure several addresses. The format of the address must be as described in **inet_pton**(3). This is a short-hand for an [Address] section only containing an Address key (see below). This option may be specified more than once.

If the specified address is "0.0.0.0" (for IPv4) or "::" (for IPv6), a new address range of the requested size is automatically allocated from a system-wide pool of unused ranges. Note that the prefix length must be equal or larger than 8 for IPv4, and 64 for IPv6. The allocated range is checked against all current network interfaces and all known network configuration files to avoid address range conflicts. The default system-wide pool consists of 192.168.0.0/16, 172.16.0.0/12 and 10.0.0.0/8 for IPv4, and fd00::/8 for IPv6. This functionality is useful to manage a large number of dynamically created network interfaces with the same network configuration and automatic address range assignment.

Gateway=

The gateway address, which must be in the format described in **inet_pton**(3). This is a short-hand for a [Route] section only containing a Gateway key. This option may be specified more than once.

DNS=

A DNS server address, which must be in the format described in **inet_pton**(3). This option may be specified more than once. Each address can optionally take a port number separated with ":"; a network interface name or index separated with "%", and a Server Name Indication (SNI) separated with "#". When IPv6 address is specified with a port number, then the address must be in the square

brackets. That is, the acceptable full formats are "111.222.333.444:9953%ifname#example.com" for IPv4 and "[1111:2222::3333]:9953%ifname#example.com" for IPv6. If an empty string is assigned, then all previous assignments are cleared. This setting is read by **systemd-resolved.service**(8).

Domains=

A whitespace-separated list of domains which should be resolved using the DNS servers on this link. Each item in the list should be a domain name, optionally prefixed with a tilde ("~"). The domains with the prefix are called "routing-only domains". The domains without the prefix are called "search domains" and are first used as search suffixes for extending single-label hostnames (hostnames containing no dots) to become fully qualified domain names (FQDNs). If a single-label hostname is resolved on this interface, each of the specified search domains are appended to it in turn, converting it into a fully qualified domain name, until one of them may be successfully resolved.

Both "search" and "routing-only" domains are used for routing of DNS queries: look-ups for hostnames ending in those domains (hence also single label names, if any "search domains" are listed), are routed to the DNS servers configured for this interface. The domain routing logic is particularly useful on multi-homed hosts with DNS servers serving particular private DNS zones on each interface.

The "routing-only" domain "~." (the tilde indicating definition of a routing domain, the dot referring to the DNS root domain which is the implied suffix of all valid DNS names) has special effect. It causes all DNS traffic which does not match another configured domain routing entry to be routed to DNS servers specified for this interface. This setting is useful to prefer a certain set of DNS servers if a link on which they are connected is available.

This setting is read by **systemd-resolved.service**(8). "Search domains" correspond to the *domain* and *search* entries in **resolv.conf**(5). Domain name routing has no equivalent in the traditional glibc API, which has no concept of domain name servers limited to a specific link.

DNSDefaultRoute=

Takes a boolean argument. If true, this link's configured DNS servers are used for resolving domain names that do not match any link's configured *Domains*= setting. If false, this link's configured DNS servers are never used for such domains, and are exclusively used for resolving names that match at least one of the domains configured on this link. If not specified defaults to an automatic mode: queries not matching any link's configured domains will be routed to this link if it has no routing-only domains configured.

NTP=

An NTP server address (either an IP address, or a hostname). This option may be specified more than once. This setting is read by **systemd-timesyncd.service**(8).

IPForward=

Configures IP packet forwarding for the system. If enabled, incoming packets on any network interface will be forwarded to any other interfaces according to the routing table. Takes a boolean, or the values "ipv4" or "ipv6", which only enable IP packet forwarding for the specified address family. This controls the net.ipv4.ip_forward and net.ipv6.conf.all.forwarding sysctl options of the network interface (see [ip-sysctl.txt](#)^[7] for details about sysctl options). Defaults to "no".

Note: this setting controls a global kernel option, and does so one way only: if a network that has this setting enabled is set up the global setting is turned on. However, it is never turned off again, even after all networks with this setting enabled are shut down again.

To allow IP packet forwarding only between specific network interfaces use a firewall.

IPMasquerade=

Configures IP masquerading for the network interface. If enabled, packets forwarded from the network interface will appear as coming from the local host. Takes one of "ipv4", "ipv6", "both", or "no".

Defaults to "no". If enabled, this automatically sets *IPForward=* to one of "ipv4", "ipv6" or "yes".

Note. Any positive boolean values such as "yes" or "true" are now deprecated. Please use one of the values in the above.

IPv6PrivacyExtensions=

Configures use of stateless temporary addresses that change over time (see [RFC 4941](#)^[8], Privacy Extensions for Stateless Address Autoconfiguration in IPv6). Takes a boolean or the special values "prefer-public" and "kernel". When true, enables the privacy extensions and prefers temporary addresses over public addresses. When "prefer-public", enables the privacy extensions, but prefers public addresses over temporary addresses. When false, the privacy extensions remain disabled. When "kernel", the kernel's default setting will be left in place. Defaults to "no".

IPv6AcceptRA=

Takes a boolean. Controls IPv6 Router Advertisement (RA) reception support for the interface. If true, RAs are accepted; if false, RAs are ignored. When RAs are accepted, they may trigger the start of the DHCPv6 client if the relevant flags are set in the RA data, or if no routers are found on the link. The default is to disable RA reception for bridge devices or when IP forwarding is enabled, and to enable it otherwise. Cannot be enabled on bond devices and when link local addressing is disabled.

Further settings for the IPv6 RA support may be configured in the [IPv6AcceptRA] section, see below.

Also see [ip-sysctl.txt](#)^[7] in the kernel documentation regarding "accept_ra", but note that systemd's setting of 1 (i.e. true) corresponds to kernel's setting of 2.

Note that kernel's implementation of the IPv6 RA protocol is always disabled, regardless of this setting. If this option is enabled, a userspace implementation of the IPv6 RA protocol is used, and the kernel's own implementation remains disabled, since **systemd-networkd** needs to know all details supplied in the advertisements, and these are not available from the kernel if the kernel's own implementation is used.

IPv6DuplicateAddressDetection=

Configures the amount of IPv6 Duplicate Address Detection (DAD) probes to send. When unset, the kernel's default will be used.

IPv6HopLimit=

Configures IPv6 Hop Limit. For each router that forwards the packet, the hop limit is decremented by 1. When the hop limit field reaches zero, the packet is discarded. When unset, the kernel's default will be used.

IPv4AcceptLocal=

Takes a boolean. Accept packets with local source addresses. In combination with suitable routing, this can be used to direct packets between two local interfaces over the wire and have them accepted properly. When unset, the kernel's default will be used.

IPv4RouteLocalnet=

Takes a boolean. When true, the kernel does not consider loopback addresses as martian source or destination while routing. This enables the use of 127.0.0.0/8 for local routing purposes. When unset, the kernel's default will be used.

IPv4ProxyARP=

Takes a boolean. Configures proxy ARP for IPv4. Proxy ARP is the technique in which one host, usually a router, answers ARP requests intended for another machine. By "faking" its identity, the router accepts responsibility for routing packets to the "real" destination. See [RFC 1027](#)^[9]. When unset, the kernel's default will be used.

IPv6ProxyNDP=

Takes a boolean. Configures proxy NDP for IPv6. Proxy NDP (Neighbor Discovery Protocol) is a technique for IPv6 to allow routing of addresses to a different destination when peers expect them to

be present on a certain physical link. In this case a router answers Neighbour Advertisement messages intended for another machine by offering its own MAC address as destination. Unlike proxy ARP for IPv4, it is not enabled globally, but will only send Neighbour Advertisement messages for addresses in the IPv6 neighbor proxy table, which can also be shown by **ip -6 neighbour show proxy**.
 systemd–networkd will control the per-interface ‘proxy_ndp’ switch for each configured interface depending on this option. When unset, the kernel’s default will be used.

IPv6ProxyNDPAddress=

An IPv6 address, for which Neighbour Advertisement messages will be proxied. This option may be specified more than once. systemd–networkd will add the **IPv6ProxyNDPAddress=** entries to the kernel’s IPv6 neighbor proxy table. This option implies **IPv6ProxyNDP=yes** but has no effect if **IPv6ProxyNDP** has been set to false. When unset, the kernel’s default will be used.

IPv6SendRA=

Whether to enable or disable Router Advertisement sending on a link. Takes a boolean value. When enabled, prefixes configured in [IPv6Prefix] sections and routes configured in [IPv6RoutePrefix] sections are distributed as defined in the [IPv6SendRA] section. If **DHCPv6PrefixDelegation=** is enabled, then the delegated prefixes are also distributed. See **DHCPv6PrefixDelegation=** setting and the [IPv6SendRA], [IPv6Prefix], [IPv6RoutePrefix], and [DHCPv6PrefixDelegation] sections for more configuration options.

DHCPv6PrefixDelegation=

Takes a boolean value. When enabled, requests prefixes using a DHCPv6 client configured on another link. By default, an address within each delegated prefix will be assigned, and the prefixes will be announced through IPv6 Router Advertisement when *IPv6SendRA=* is enabled. Such default settings can be configured in [DHCPv6PrefixDelegation] section. Defaults to disabled.

IPv6MTUBytes=

Configures IPv6 maximum transmission unit (MTU). An integer greater than or equal to 1280 bytes. When unset, the kernel’s default will be used.

BatmanAdvanced=, Bond=, Bridge=, VRF=

The name of the B.A.T.M.A.N. Advanced, bond, bridge, or VRF interface to add the link to. See **systemd.netdev(5)**.

IPVLAN=, IPVLTAP=, L2TP=, MACsec=, MACVLAN=, MACVTAP=, Tunnel=, VLAN=, VXLAN=, Xfrm=

The name of an IPVLAN, IPVLTAP, L2TP, MACsec, MACVLAN, MACVTAP, tunnel, VLAN, VXLAN, or Xfrm to be created on the link. See **systemd.netdev(5)**. This option may be specified more than once.

ActiveSlave=

Takes a boolean. Specifies the new active slave. The "ActiveSlave=" option is only valid for following modes: "active-backup", "balance-alb" and "balance-tlb". Defaults to false.

PrimarySlave=

Takes a boolean. Specifies which slave is the primary device. The specified device will always be the active slave while it is available. Only when the primary is off-line will alternate devices be used. This is useful when one slave is preferred over another, e.g. when one slave has higher throughput than another. The "PrimarySlave=" option is only valid for following modes: "active-backup", "balance-alb" and "balance-tlb". Defaults to false.

ConfigureWithoutCarrier=

Takes a boolean. Allows networkd to configure a specific link even if it has no carrier. Defaults to false. If **IgnoreCarrierLoss=** is not explicitly set, it will default to this value.

IgnoreCarrierLoss=

Takes a boolean. Allows networkd to retain both the static and dynamic configuration of the interface even if its carrier is lost. When unset, the value specified with **ConfigureWithoutCarrier=** is used.

When **ActivationPolicy=** is set to "always-up", this is forced to "true".

KeepConfiguration=

Takes a boolean or one of "static", "dhcp-on-stop", "dhcp". When "static", **systemd-networkd** will not drop static addresses and routes on starting up process. When set to "dhcp-on-stop", **systemd-networkd** will not drop addresses and routes on stopping the daemon. When "dhcp", the addresses and routes provided by a DHCP server will never be dropped even if the DHCP lease expires. This is contrary to the DHCP specification, but may be the best choice if, e.g., the root filesystem relies on this connection. The setting "dhcp" implies "dhcp-on-stop", and "yes" implies "dhcp" and "static". Defaults to "no".

[ADDRESS] SECTION OPTIONS

An [Address] section accepts the following keys. Specify several [Address] sections to configure several addresses.

Address=

As in the [Network] section. This key is mandatory. Each [Address] section can contain one *Address=* setting.

Peer=

The peer address in a point-to-point connection. Accepts the same format as the *Address=* key.

Broadcast=

Takes an IPv4 address or boolean value. The address must be in the format described in **inet_nton(3)**. If set to true, then the IPv4 broadcast address will be derived from the *Address=* setting. If set to false, then the broadcast address will not be set. Defaults to true, except for wireguard interfaces, where it default to false.

Label=

An address label.

PreferredLifetime=

Allows the default "preferred lifetime" of the address to be overridden. Only three settings are accepted: "forever", "infinity", which is the default and means that the address never expires, and "0", which means that the address is considered immediately "expired" and will not be used, unless explicitly requested. A setting of **PreferredLifetime=0** is useful for addresses which are added to be used only by a specific application, which is then configured to use them explicitly.

Scope=

The scope of the address, which can be "global" (valid everywhere on the network, even through a gateway), "link" (only valid on this device, will not traverse a gateway) or "host" (only valid within the device itself, e.g. 127.0.0.1) or an unsigned integer in the range 0...255. Defaults to "global".

RouteMetric=

The metric of the prefix route, which is pointing to the subnet of the configured IP address, taking the configured prefix length into account. Takes an unsigned integer in the range 0...4294967295. When unset or set to 0, the kernel's default value is used. This setting will be ignored when *AddPrefixRoute=* is false.

HomeAddress=

Takes a boolean. Designates this address the "home address" as defined in [RFC 6275](#)^[10]. Supported only on IPv6. Defaults to false.

DuplicateAddressDetection=

Takes one of "ipv4", "ipv6", "both", "none". When "ipv4", performs IPv4 Address Conflict Detection. See [RFC 5227](#)^[11]. When "ipv6", performs IPv6 Duplicate Address Detection. See [RFC 4862](#)^[12]. Defaults to "ipv4" for IPv4 link-local addresses, "ipv6" for IPv6 addresses, and "none" otherwise.

ManageTemporaryAddress=

Takes a boolean. If true the kernel manage temporary addresses created from this one as template on behalf of Privacy Extensions [RFC 3041](#)^[13]. For this to become active, the `use_tempaddr` sysctl setting has to be set to a value greater than zero. The given address needs to have a prefix length of 64. This flag allows using privacy extensions in a manually configured network, just like if stateless

auto-configuration was active. Defaults to false.

AddPrefixRoute=

Takes a boolean. When true, the prefix route for the address is automatically added. Defaults to true.

AutoJoin=

Takes a boolean. Joining multicast group on ethernet level via **ip maddr** command would not work if we have an Ethernet switch that does IGMP snooping since the switch would not replicate multicast packets on ports that did not have IGMP reports for the multicast addresses. Linux vxlan interfaces created via **ip link add vxlan** or networkd's netdev kind vxlan have the group option that enables them to do the required join. By extending ip address command with option "autojoin" we can get similar functionality for openvswitch (OVS) vxlan interfaces as well as other tunneling mechanisms that need to receive multicast traffic. Defaults to "no".

[NEIGHBOR] SECTION OPTIONS

A [Neighbor] section accepts the following keys. The neighbor section adds a permanent, static entry to the neighbor table (IPv6) or ARP table (IPv4) for the given hardware address on the links matched for the network. Specify several [Neighbor] sections to configure several static neighbors.

Address=

The IP address of the neighbor.

LinkLayerAddress=

The link layer address (MAC address or IP address) of the neighbor.

[IPV6ADDRESSLABEL] SECTION OPTIONS

An [IPv6AddressLabel] section accepts the following keys. Specify several [IPv6AddressLabel] sections to configure several address labels. IPv6 address labels are used for address selection. See [RFC 3484^{\[14\]}](#). Precedence is managed by userspace, and only the label itself is stored in the kernel.

Label=

The label for the prefix, an unsigned integer in the range 0–4294967294. 0xffffffff is reserved. This setting is mandatory.

Prefix=

IPv6 prefix is an address with a prefix length, separated by a slash "/" character. This key is mandatory.

[ROUTINGPOLICYRULE] SECTION OPTIONS

An [RoutingPolicyRule] section accepts the following keys. Specify several [RoutingPolicyRule] sections to configure several rules.

TypeOfService=

Takes a number between 0 and 255 that specifies the type of service to match.

From=

Specifies the source address prefix to match. Possibly followed by a slash and the prefix length.

To=

Specifies the destination address prefix to match. Possibly followed by a slash and the prefix length.

FirewallMark=

Specifies the iptables firewall mark value to match (a number between 1 and 4294967295). Optionally, the firewall mask (also a number between 1 and 4294967295) can be suffixed with a slash ("/"), e.g., "7/255".

Table=

Specifies the routing table identifier to lookup if the rule selector matches. Takes one of predefined names "default", "main", and "local", and names defined in *RouteTable*= in **networkd.conf(5)**, or a number between 1 and 4294967295. Defaults to "main".

Priority=

Specifies the priority of this rule. *Priority*= is an unsigned integer in the range 0...4294967295.

Higher number means lower priority, and rules get processed in order of increasing number. Defaults to unset, and the kernel will pick a value dynamically.

IncomingInterface=

Specifies incoming device to match. If the interface is loopback, the rule only matches packets originating from this host.

OutgoingInterface=

Specifies the outgoing device to match. The outgoing interface is only available for packets originating from local sockets that are bound to a device.

SourcePort=

Specifies the source IP port or IP port range match in forwarding information base (FIB) rules. A port range is specified by the lower and upper port separated by a dash. Defaults to unset.

DestinationPort=

Specifies the destination IP port or IP port range match in forwarding information base (FIB) rules. A port range is specified by the lower and upper port separated by a dash. Defaults to unset.

IPProtocol=

Specifies the IP protocol to match in forwarding information base (FIB) rules. Takes IP protocol name such as "tcp", "udp" or "sctp", or IP protocol number such as "6" for "tcp" or "17" for "udp". Defaults to unset.

InvertRule=

A boolean. Specifies whether the rule is to be inverted. Defaults to false.

Family=

Takes a special value "ipv4", "ipv6", or "both". By default, the address family is determined by the address specified in *To*= or *From*=. If neither *To*= nor *From*= are specified, then defaults to "ipv4".

User=

Takes a username, a user ID, or a range of user IDs separated by a dash. Defaults to unset.

SuppressPrefixLength=

Takes a number *N* in the range 0...128 and rejects routing decisions that have a prefix length of *N* or less. Defaults to unset.

Type=

Specifies Routing Policy Database (RPDB) rule type. Takes one of "blackhole", "unreachable" or "prohibit".

[NEXTHOP] SECTION OPTIONS

The [NextHop] section is used to manipulate entries in the kernel's "nexthop" tables. The [NextHop] section accepts the following keys. Specify several [NextHop] sections to configure several hops.

Id=

The id of the next hop. Takes an unsigned integer in the range 1...4294967295. If left unspecified, then automatically chosen by kernel.

Gateway=

As in the [Network] section.

Family=

Takes one of the special values "ipv4" or "ipv6". By default, the family is determined by the address specified in *Gateway*=. If *Gateway*= is not specified, then defaults to "ipv4".

OnLink=

Takes a boolean. If set to true, the kernel does not have to check if the gateway is reachable directly by the current machine (i.e., attached to the local network), so that we can insert the nexthop in the kernel table without it being complained about. Defaults to "no".

Blackhole=

Takes a boolean. If enabled, packets to the corresponding routes are discarded silently, and *Gateway*=

cannot be specified. Defaults to "no".

Group=

Takes a whitespace separated list of nexthop IDs. Each ID must be in the range 1...4294967295.

Optionally, each nexthop ID can take a weight after a colon ("id[:weight]"). The weight must be in the range 1...255. If the weight is not specified, then it is assumed that the weight is 1. This setting cannot be specified with *Gateway=*, *Family=*, *Blackhole=*. This setting can be specified multiple times. If an empty string is assigned, then all previous assignments are cleared. Defaults to unset.

[ROUTE] SECTION OPTIONS

The [Route] section accepts the following keys. Specify several [Route] sections to configure several routes.

Gateway=

Takes the gateway address or the special values "_dhcp4" and "_ipv6ra". If "_dhcp4" or "_ipv6ra" is set, then the gateway address provided by DHCPv4 or IPv6 RA is used.

GatewayOnLink=

Takes a boolean. If set to true, the kernel does not have to check if the gateway is reachable directly by the current machine (i.e., attached to the local network), so that we can insert the route in the kernel table without it being complained about. Defaults to "no".

Destination=

The destination prefix of the route. Possibly followed by a slash and the prefix length. If omitted, a full-length host route is assumed.

Source=

The source prefix of the route. Possibly followed by a slash and the prefix length. If omitted, a full-length host route is assumed.

Metric=

The metric of the route. Takes an unsigned integer in the range 0...4294967295. Defaults to unset, and the kernel's default will be used.

IPv6Preference=

Specifies the route preference as defined in [RFC 4191](#)^[15] for Router Discovery messages. Which can be one of "low" the route has a lowest priority, "medium" the route has a default priority or "high" the route has a highest priority.

Scope=

The scope of the IPv4 route, which can be "global", "site", "link", "host", or "nowhere":

- "global" means the route can reach hosts more than one hop away.
- "site" means an interior route in the local autonomous system.
- "link" means the route can only reach hosts on the local network (one hop away).
- "host" means the route will not leave the local machine (used for internal addresses like 127.0.0.1).
- "nowhere" means the destination doesn't exist.

For IPv4 route, defaults to "host" if *Type=* is "local" or "nat", and "link" if *Type=* is "broadcast", "multicast", or "anycast". In other cases, defaults to "global". The value is not used for IPv6.

PreferredSource=

The preferred source address of the route. The address must be in the format described in [inet_nton\(3\)](#).

Table=

The table identifier for the route. Takes one of predefined names "default", "main", and "local", and names defined in *RouteTable=* in [networkd.conf\(5\)](#), or a number between 1 and 4294967295. The table can be retrieved using **ip route show table num**. If unset and *Type=* is "local", "broadcast", "anycast", or "nat", then "local" is used. In other cases, defaults to "main".

Protocol=

The protocol identifier for the route. Takes a number between 0 and 255 or the special values "kernel", "boot", "static", "ra" and "dhcp". Defaults to "static".

Type=

Specifies the type for the route. Takes one of "unicast", "local", "broadcast", "anycast", "multicast", "blackhole", "unreachable", "prohibit", "throw", "nat", and "xresolve". If "unicast", a regular route is defined, i.e. a route indicating the path to take to a destination network address. If "blackhole", packets to the defined route are discarded silently. If "unreachable", packets to the defined route are discarded and the ICMP message "Host Unreachable" is generated. If "prohibit", packets to the defined route are discarded and the ICMP message "Communication Administratively Prohibited" is generated. If "throw", route lookup in the current routing table will fail and the route selection process will return to Routing Policy Database (RPDB). Defaults to "unicast".

InitialCongestionWindow=

The TCP initial congestion window is used during the start of a TCP connection. During the start of a TCP session, when a client requests a resource, the server's initial congestion window determines how many packets will be sent during the initial burst of data without waiting for acknowledgement. Takes a number between 1 and 1023. Note that 100 is considered an extremely large value for this option. When unset, the kernel's default (typically 10) will be used.

InitialAdvertisedReceiveWindow=

The TCP initial advertised receive window is the amount of receive data (in bytes) that can initially be buffered at one time on a connection. The sending host can send only that amount of data before waiting for an acknowledgment and window update from the receiving host. Takes a number between 1 and 1023. Note that 100 is considered an extremely large value for this option. When unset, the kernel's default will be used.

QuickAck=

Takes a boolean. When true enables TCP quick ack mode for the route. When unset, the kernel's default will be used.

FastOpenNoCookie=

Takes a boolean. When true enables TCP fastopen without a cookie on a per-route basis. When unset, the kernel's default will be used.

TTLPropagate=

Takes a boolean. When true enables TTL propagation at Label Switched Path (LSP) egress. When unset, the kernel's default will be used.

MTUBytes=

The maximum transmission unit in bytes to set for the route. The usual suffixes K, M, G, are supported and are understood to the base of 1024.

Note that if IPv6 is enabled on the interface, and the MTU is chosen below 1280 (the minimum MTU for IPv6) it will automatically be increased to this value.

IPServiceType=

Takes string; "CS6" or "CS4". Used to set IP service type to CS6 (network control) or CS4 (Realtime). Defaults to CS6.

TCPAdvertisedMaximumSegmentSize=

Specifies the Path MSS (in bytes) hints given on TCP layer. The usual suffixes K, M, G, are supported and are understood to the base of 1024. An unsigned integer in the range 1–4294967294. When unset, the kernel's default will be used.

MultiPathRoute=address[@name] [weight]

Configures multipath route. Multipath routing is the technique of using multiple alternative paths through a network. Takes gateway address. Optionally, takes a network interface name or index separated with "@", and a weight in 1..256 for this multipath route separated with whitespace. This

setting can be specified multiple times. If an empty string is assigned, then all previous assignments are cleared.

NextHop=

Specifies the nexthop id. Takes an unsigned integer in the range 1...4294967295. If set, the corresponding [NextHop] section must be configured. Defaults to unset.

[DHCPV4] SECTION OPTIONS

The [DHCPv4] section configures the DHCPv4 client, if it is enabled with the *DHCP=* setting described above:

SendHostname=

When true (the default), the machine's hostname (or the value specified with *Hostname=*, described below) will be sent to the DHCP server. Note that the hostname must consist only of 7-bit ASCII lower-case characters and no spaces or dots, and be formatted as a valid DNS domain name. Otherwise, the hostname is not sent even if this option is true.

Hostname=

Use this value for the hostname which is sent to the DHCP server, instead of machine's hostname. Note that the specified hostname must consist only of 7-bit ASCII lower-case characters and no spaces or dots, and be formatted as a valid DNS domain name.

MUDURL=

When configured, the specified Manufacturer Usage Description (MUD) URL will be sent to the DHCPv4 server. Takes a URL of length up to 255 characters. A superficial verification that the string is a valid URL will be performed. DHCPv4 clients are intended to have at most one MUD URL associated with them. See [RFC 8520](#)^[16].

MUD is an embedded software standard defined by the IETF that allows IoT device makers to advertise device specifications, including the intended communication patterns for their device when it connects to the network. The network can then use this to author a context-specific access policy, so the device functions only within those parameters.

ClientIdentifier=

The DHCPv4 client identifier to use. Takes one of **mac**, **duid** or **duid-only**. If set to **mac**, the MAC address of the link is used. If set to **duid**, an RFC4361-compliant Client ID, which is the combination of IAID and DUID (see below), is used. If set to **duid-only**, only DUID is used, this may not be RFC compliant, but some setups may require to use this. Defaults to **duid**.

VendorClassIdentifier=

The vendor class identifier used to identify vendor type and configuration.

UserClass=

A DHCPv4 client can use UserClass option to identify the type or category of user or applications it represents. The information contained in this option is a string that represents the user class of which the client is a member. Each class sets an identifying string of information to be used by the DHCP service to classify clients. Takes a whitespace-separated list of strings.

DUIDType=

Override the global *DUIDType=* setting for this network. See **networkd.conf(5)** for a description of possible values.

DUIDRawData=

Override the global *DUIDRawData=* setting for this network. See **networkd.conf(5)** for a description of possible values.

IAID=

The DHCP Identity Association Identifier (IAID) for the interface, a 32-bit unsigned integer.

Anonymize=

Takes a boolean. When true, the options sent to the DHCP server will follow the [RFC 7844](#)^[17] (Anonymity Profiles for DHCP Clients) to minimize disclosure of identifying information. Defaults to

false.

This option should only be set to true when *MACAddressPolicy*= is set to **random** (see [systemd.link\(5\)](#)).

When true, *SendHostname*=, *ClientIdentifier*=, *VendorClassIdentifier*=, *UserClass*=, *RequestOptions*=, *SendOption*=, *SendVendorOption*=, and *MUDURL*= are ignored.

With this option enabled DHCP requests will mimic those generated by Microsoft Windows, in order to reduce the ability to fingerprint and recognize installations. This means DHCP request sizes will grow and lease data will be more comprehensive than normally, though most of the requested data is not actually used.

RequestOptions=

Sets request options to be sent to the server in the DHCPv4 request options list. A whitespace-separated list of integers in the range 1...254. Defaults to unset.

SendOption=

Send an arbitrary raw option in the DHCPv4 request. Takes a DHCP option number, data type and data separated with a colon ("option:type:value"). The option number must be an integer in the range 1...254. The type takes one of "uint8", "uint16", "uint32", "ipv4address", or "string". Special characters in the data string may be escaped using [C-style escapes](#)^[18]. This setting can be specified multiple times. If an empty string is specified, then all options specified earlier are cleared. Defaults to unset.

SendVendorOption=

Send an arbitrary vendor option in the DHCPv4 request. Takes a DHCP option number, data type and data separated with a colon ("option:type:value"). The option number must be an integer in the range 1...254. The type takes one of "uint8", "uint16", "uint32", "ipv4address", or "string". Special characters in the data string may be escaped using [C-style escapes](#)^[18]. This setting can be specified multiple times. If an empty string is specified, then all options specified earlier are cleared. Defaults to unset.

UseDNS=

When true (the default), the DNS servers received from the DHCP server will be used.

This corresponds to the **nameserver** option in [resolv.conf\(5\)](#).

RoutesToDNS=

When true, the routes to the DNS servers received from the DHCP server will be configured. When *UseDNS*= is disabled, this setting is ignored. Defaults to true.

UseNTP=

When true (the default), the NTP servers received from the DHCP server will be used by [systemd-timesyncd.service](#).

RoutesToNTP=

When true, the routes to the NTP servers received from the DHCP server will be configured. When *UseNTP*= is disabled, this setting is ignored. Defaults to true.

UseSIP=

When true (the default), the SIP servers received from the DHCP server will be collected and made available to client programs.

UseMTU=

When true, the interface maximum transmission unit from the DHCP server will be used on the current link. If *MTUBytes*= is set, then this setting is ignored. Defaults to false.

UseHostname=

When true (the default), the hostname received from the DHCP server will be set as the transient

hostname of the system.

UseDomains=

Takes a boolean, or the special value **route**. When true, the domain name received from the DHCP server will be used as DNS search domain over this link, similar to the effect of the **Domains=** setting. If set to **route**, the domain name received from the DHCP server will be used for routing DNS queries only, but not for searching, similar to the effect of the **Domains=** setting when the argument is prefixed with `"~"`. Defaults to true on Ubuntu.

It is recommended to enable this option only on trusted networks, as setting this affects resolution of all hostnames, in particular of single-label names. It is generally safer to use the supplied domain only as routing domain, rather than as search domain, in order to not have it affect local resolution of single-label names.

When set to true, this setting corresponds to the **domain** option in **resolv.conf(5)**.

UseRoutes=

When true (the default), the static routes will be requested from the DHCP server and added to the routing table with a metric of 1024, and a scope of **global**, **link** or **host**, depending on the route's destination and gateway. If the destination is on the local host, e.g., 127.x.x.x, or the same as the link's own address, the scope will be set to **host**. Otherwise if the gateway is null (a direct route), a **link** scope will be used. For anything else, scope defaults to **global**.

RouteMetric=

Set the routing metric for routes specified by the DHCP server. Takes an unsigned integer in the range 0...4294967295. Defaults to 1024.

RouteTable=num

The table identifier for DHCP routes (a number between 1 and 4294967295, or 0 to unset). The table can be retrieved using **ip route show table num**.

When used in combination with **VRF=**, the VRF's routing table is used when this parameter is not specified.

RouteMTUBytes=

Specifies the MTU for the DHCP routes. Please see the [Route] section for further details.

UseGateway=

When true, the gateway will be requested from the DHCP server and added to the routing table with a metric of 1024, and a scope of **link**. When unset, the value specified with *UseRoutes=* is used.

UseTimezone=

When true, the timezone received from the DHCP server will be set as timezone of the local system. Defaults to false.

FallbackLeaseLifetimeSec=

Allows to set DHCPv4 lease lifetime when DHCPv4 server does not send the lease lifetime. Takes one of "forever" or "infinity". The latter means that the address never expires. Defaults to unset.

RequestBroadcast=

Request the server to use broadcast messages before the IP address has been configured. This is necessary for devices that cannot receive RAW packets, or that cannot receive packets at all before an IP address has been configured. On the other hand, this must not be enabled on networks where broadcasts are filtered out.

MaxAttempts=

Specifies how many times the DHCPv4 client configuration should be attempted. Takes a number or "infinity". Defaults to "infinity". Note that the time between retries is increased exponentially, up to approximately one per minute, so the network will not be overloaded even if this number is high. The default is suitable in most circumstances.

ListenPort=

Set the port from which the DHCP client packets originate.

DenyList=

A whitespace-separated list of IPv4 addresses. DHCP offers from servers in the list are rejected. Note that if *AllowList=* is configured then *DenyList=* is ignored.

AllowList=

A whitespace-separated list of IPv4 addresses. DHCP offers from servers in the list are accepted.

SendRelease=

When true, the DHCPv4 client sends a DHCP release packet when it stops. Defaults to true.

SendDecline=

A boolean. When "true", the DHCPv4 client receives the IP address from the DHCP server. After a new IP is received, the DHCPv4 client performs IPv4 Duplicate Address Detection. If duplicate use is detected, the DHCPv4 client rejects the IP by sending a **DHCPDECLINE** packet and tries to obtain an IP address again. See [RFC 5224](#)^[11]. Defaults to "unset".

[DHCPV6] SECTION OPTIONS

The [DHCPv6] section configures the DHCPv6 client, if it is enabled with the *DHCP=* setting described above, or invoked by the IPv6 Router Advertisement:

MUDURL=, IAID=, DUIDType=, DUIDRawData=, RequestOptions=

As in the [DHCPv4] section.

SendOption=

As in the [DHCPv4] section, however because DHCPv6 uses 16-bit fields to store option numbers, the option number is an integer in the range 1...65536.

SendVendorOption=

Send an arbitrary vendor option in the DHCPv6 request. Takes an enterprise identifier, DHCP option number, data type, and data separated with a colon ("enterprise identifier:option:type:value"). Enterprise identifier is an unsigned integer in the range 1...4294967294. The option number must be an integer in the range 1...254. Data type takes one of "uint8", "uint16", "uint32", "ipv4address", "ipv6address", or "string". Special characters in the data string may be escaped using **C-style escapes**^[18]. This setting can be specified multiple times. If an empty string is specified, then all options specified earlier are cleared. Defaults to unset.

UserClass=

A DHCPv6 client can use User Class option to identify the type or category of user or applications it represents. The information contained in this option is a string that represents the user class of which the client is a member. Each class sets an identifying string of information to be used by the DHCP service to classify clients. Special characters in the data string may be escaped using **C-style escapes**^[18]. This setting can be specified multiple times. If an empty string is specified, then all options specified earlier are cleared. Takes a whitespace-separated list of strings. Note that currently **NUL** bytes are not allowed.

VendorClass=

A DHCPv6 client can use VendorClass option to identify the vendor that manufactured the hardware on which the client is running. The information contained in the data area of this option is contained in one or more opaque fields that identify details of the hardware configuration. Takes a whitespace-separated list of strings.

PrefixDelegationHint=

Takes an IPv6 address with prefix length in the same format as the *Address=* in the [Network] section. The DHCPv6 client will include a prefix hint in the DHCPv6 solicitation sent to the server. The prefix length must be in the range 1–128. Defaults to unset.

UseAddress=

When true (the default), the IP addresses provided by the DHCPv6 server will be assigned.

UseDNS=, *UseNTP=*, *UseHostname=*, *UseDomains=*
As in the [DHCPv4] section.

ForceDHCPv6PDOtherInformation=

Takes a boolean that enforces DHCPv6 stateful mode when the 'Other information' bit is set in Router Advertisement messages. By default setting only the 'O' bit in Router Advertisements makes DHCPv6 request network information in a stateless manner using a two-message Information Request and Information Reply message exchange. [RFC 7084](#)^[19], requirement WPD-4, updates this behavior for a Customer Edge router so that stateful DHCPv6 Prefix Delegation is also requested when only the 'O' bit is set in Router Advertisements. This option enables such a CE behavior as it is impossible to automatically distinguish the intention of the 'O' bit otherwise. By default this option is set to false, enable it if no prefixes are delegated when the device should be acting as a CE router.

WithoutRA=

Allows DHCPv6 client to start without router advertisements's managed or other address configuration flag. Takes one of "solicit" or "information-request". Defaults to unset.

RapidCommit=

Takes a boolean. The DHCPv6 client can obtain configuration parameters from a DHCPv6 server through a rapid two-message exchange (solicit and reply). When the rapid commit option is enabled by both the DHCPv6 client and the DHCPv6 server, the two-message exchange is used, rather than the default four-message exchange (solicit, advertise, request, and reply). The two-message exchange provides faster client configuration and is beneficial in environments in which networks are under a heavy load. See [RFC 3315](#)^[20] for details. Defaults to true.

[DHCPV6PREFIXDELEGATION] SECTION OPTIONS

The [DHCPv6PrefixDelegation] section configures delegated prefixes assigned by DHCPv6 server. The settings in this section are used only when *DHCPv6PrefixDelegation=* setting is enabled.

SubnetId=

Configure a specific subnet ID on the interface from a (previously) received prefix delegation. You can either set "auto" (the default) or a specific subnet ID (as defined in [RFC 4291](#)^[21], section 2.5.4), in which case the allowed value is hexadecimal, from 0 to 0xfffffffffffff inclusive.

Announce=

Takes a boolean. When enabled, and *IPv6SendRA=* in [Network] section is enabled, the delegated prefixes are distributed through the IPv6 Router Advertisement. Defaults to yes.

Assign=

Takes a boolean. Specifies whether to add an address from the delegated prefixes which are received from the WAN interface by the DHCPv6 Prefix Delegation. When true (on LAN interface), the EUI-64 algorithm will be used by default to form an interface identifier from the delegated prefixes. See also *Token=* setting below. Defaults to yes.

Token=

Specifies an optional address generation mode for assigning an address in each delegated prefix. Takes an IPv6 address. When set, the lower bits of the supplied address is combined with the upper bits of each delegatad prefix received from the WAN interface by the DHCPv6 Prefix Delegation to form a complete address. When *Assign=* is disabled, this setting is ignored. When unset, the EUI-64 algorithm will be used to form addresses. Defaults to unset.

ManageTemporaryAddress=

As in the [Address] section, but defaults to true.

RouteMetric=

The metric of the route to the delegated prefix subnet. Takes an unsigned integer in the range 0...4294967295. When unset or set to 0, the kernel's default value is used.

[IPV6ACCEPTRA] SECTION OPTIONS

The [IPv6AcceptRA] section configures the IPv6 Router Advertisement (RA) client, if it is enabled with the *IPv6AcceptRA=* setting described above:

UseDNS=

When true (the default), the DNS servers received in the Router Advertisement will be used.

This corresponds to the **nameserver** option in **resolv.conf(5)**.

UseDomains=

Takes a boolean, or the special value "route". When true, the domain name received via IPv6 Router Advertisement (RA) will be used as DNS search domain over this link, similar to the effect of the **Domains=** setting. If set to "route", the domain name received via IPv6 RA will be used for routing DNS queries only, but not for searching, similar to the effect of the **Domains=** setting when the argument is prefixed with "~". Defaults to true on Ubuntu.

It is recommended to enable this option only on trusted networks, as setting this affects resolution of all hostnames, in particular of single-label names. It is generally safer to use the supplied domain only as routing domain, rather than as search domain, in order to not have it affect local resolution of single-label names.

When set to true, this setting corresponds to the **domain** option in **resolv.conf(5)**.

RouteTable=num

The table identifier for the routes received in the Router Advertisement (a number between 1 and 4294967295, or 0 to unset). The table can be retrieved using **ip route show table num**.

RouteMetric=

Set the routing metric for the routes received in the Router Advertisement. Takes an unsigned integer in the range 0...4294967295. Defaults to 1024.

UseAutonomousPrefix=

When true (the default), the autonomous prefix received in the Router Advertisement will be used and take precedence over any statically configured ones.

UseOnLinkPrefix=

When true (the default), the onlink prefix received in the Router Advertisement will be used and takes precedence over any statically configured ones.

RouterDenyList=

A whitespace-separated list of IPv6 router addresses. Any information advertised by the listed router is ignored.

RouterAllowList=

A whitespace-separated list of IPv6 router addresses. Only information advertised by the listed router is accepted. Note that if *RouterAllowList=* is configured then *RouterDenyList=* is ignored.

PrefixDenyList=

A whitespace-separated list of IPv6 prefixes. IPv6 prefixes supplied via router advertisements in the list are ignored.

PrefixAllowList=

A whitespace-separated list of IPv6 prefixes. IPv6 prefixes supplied via router advertisements in the list are allowed. Note that if *PrefixAllowList=* is configured then *PrefixDenyList=* is ignored.

RouteDenyList=

A whitespace-separated list of IPv6 route prefixes. IPv6 route prefixes supplied via router advertisements in the list are ignored.

RouteAllowList=

A whitespace-separated list of IPv6 route prefixes. IPv6 route prefixes supplied via router advertisements in the list are allowed. Note that if *RouteAllowList=* is configured then *RouteDenyList=* is ignored.

DHCPv6Client=

Takes a boolean, or the special value "always". When true or "always", the DHCPv6 client will be

started when the RA has the managed or other information flag. If set to "always", the DHCPv6 client will also be started in managed mode when neither managed nor other information flag is set in the RA. Defaults to true.

[DHCPSERVER] SECTION OPTIONS

The [DHCPServer] section contains settings for the DHCP server, if enabled via the *DHCPServer=* option described above:

ServerAddress=

Specifies server address for the DHCP server. Takes an IPv4 address with prefix length, for example "192.168.0.1/24". This setting may be useful when the link on which the DHCP server is running has multiple static addresses. When unset, one of static addresses in the link will be automatically selected. Defaults to unset.

PoolOffset=, PoolSize=

Configures the pool of addresses to hand out. The pool is a contiguous sequence of IP addresses in the subnet configured for the server address, which does not include the subnet nor the broadcast address.

PoolOffset= takes the offset of the pool from the start of subnet, or zero to use the default value.

PoolSize= takes the number of IP addresses in the pool or zero to use the default value. By default, the pool starts at the first address after the subnet address and takes up the rest of the subnet, excluding the broadcast address. If the pool includes the server address (the default), this is reserved and not handed out to clients.

DefaultLeaseTimeSec=, MaxLeaseTimeSec=

Control the default and maximum DHCP lease time to pass to clients. These settings take time values in seconds or another common time unit, depending on the suffix. The default lease time is used for clients that did not ask for a specific lease time. If a client asks for a lease time longer than the maximum lease time, it is automatically shortened to the specified time. The default lease time defaults to 1h, the maximum lease time to 12h. Shorter lease times are beneficial if the configuration data in DHCP leases changes frequently and clients shall learn the new settings with shorter latencies. Longer lease times reduce the generated DHCP network traffic.

UplinkInterface=

Specifies name or index of uplink interface, or one of the special values ":none" and ":auto". When emitting DNS, NTP, or SIP servers are enabled but no servers are specified, the servers configured in the uplink interface will be emitted. When ":auto", the link which has default gateway with higher priority will be automatically selected. When ":none", no uplink interface will be selected. Defaults to ":auto".

EmitDNS=, DNS=

EmitDNS= takes a boolean. Configures whether the DHCP leases handed out to clients shall contain DNS server information. Defaults to "yes". The DNS servers to pass to clients may be configured with the *DNS=* option, which takes a list of IPv4 addresses. If the *EmitDNS=* option is enabled but no servers configured, the servers are automatically propagated from an "uplink" interface that has appropriate servers set. The "uplink" interface is determined by the default route of the system with the highest priority. Note that this information is acquired at the time the lease is handed out, and does not take uplink interfaces into account that acquire DNS server information at a later point. If no suitable uplink interface is found the DNS server data from /etc/resolv.conf is used. Also, note that the leases are not refreshed if the uplink network configuration changes. To ensure clients regularly acquire the most current uplink DNS server information, it is thus advisable to shorten the DHCP lease time via *MaxLeaseTimeSec=* described above.

EmitNTP=, NTP=, EmitSIP=, SIP=, EmitPOP3=, POP3=, EmitSMTP=, SMTP=, EmitLPR=, LPR=

Similar to the *EmitDNS=* and *DNS=* settings described above, these settings configure whether and what server information for the indicate protocol shall be emitted as part of the DHCP lease. The same syntax, propagation semantics and defaults apply as for *EmitDNS=* and *DNS=*.

EmitRouter=

Similar to the *EmitDNS=* setting described above, this setting configures whether the DHCP lease

should contain the router option. The same syntax, propagation semantics and defaults apply as for *EmitDNS*=.

EmitTimezone=, *Timezone*=

Takes a boolean. Configures whether the DHCP leases handed out to clients shall contain timezone information. Defaults to "yes". The *Timezone*= setting takes a timezone string (such as "Europe/Berlin" or "UTC") to pass to clients. If no explicit timezone is set, the system timezone of the local host is propagated, as determined by the /etc/localtime symlink.

SendOption=

Send a raw option with value via DHCPv4 server. Takes a DHCP option number, data type and data ("option:type:value"). The option number is an integer in the range 1...254. The type takes one of "uint8", "uint16", "uint32", "ipv4address", "ipv6address", or "string". Special characters in the data string may be escaped using **C-style escapes**^[18]. This setting can be specified multiple times. If an empty string is specified, then all options specified earlier are cleared. Defaults to unset.

SendVendorOption=

Send a vendor option with value via DHCPv4 server. Takes a DHCP option number, data type and data ("option:type:value"). The option number is an integer in the range 1...254. The type takes one of "uint8", "uint16", "uint32", "ipv4address", or "string". Special characters in the data string may be escaped using **C-style escapes**^[18]. This setting can be specified multiple times. If an empty string is specified, then all options specified earlier are cleared. Defaults to unset.

BindToInterface=

Takes a boolean value. When "yes", DHCP server socket will be bound to its network interface and all socket communication will be restricted to this interface. Defaults to "yes", except if *RelayTarget*= is used (see below), in which case it defaults to "no".

RelayTarget=

Takes an IPv4 address, which must be in the format described in **inet_pton**(3). Turns this DHCP server into a DHCP relay agent. See **RFC 1542**^[22]. The address is the address of DHCP server or another relay agent to forward DHCP messages to and from.

RelayAgentCircuitId=

Specifies value for Agent Circuit ID suboption of Relay Agent Information option. Takes a string, which must be in the format "string:value", where "value" should be replaced with the value of the suboption. Defaults to unset (means no Agent Circuit ID suboption is generated). Ignored if *RelayTarget*= is not specified.

RelayAgentRemoteId=

Specifies value for Agent Remote ID suboption of Relay Agent Information option. Takes a string, which must be in the format "string:value", where "value" should be replaced with the value of the suboption. Defaults to unset (means no Agent Remote ID suboption is generated). Ignored if *RelayTarget*= is not specified.

[DHCPSERVERSTATICLEASE] SECTION OPTIONS

The "[DHCPServerStaticLease]" section configures a static DHCP lease to assign a fixed IPv4 address to a specific device based on its MAC address. This section can be specified multiple times.

MACAddress=

The hardware address of a device to match. This key is mandatory.

Address=

The IPv4 address that should be assigned to the device that was matched with *MACAddress*=. This key is mandatory.

[IPV6SENDRA] SECTION OPTIONS

The [IPv6SendRA] section contains settings for sending IPv6 Router Advertisements and whether to act as a router, if enabled via the *IPv6SendRA*= option described above. IPv6 network prefixes or routes are defined with one or more [IPv6Prefix] or [IPv6RoutePrefix] sections.

Managed=, *OtherInformation*=

Takes a boolean. Controls whether a DHCPv6 server is used to acquire IPv6 addresses on the network link when *Managed*= is set to "true" or if only additional network information can be obtained via DHCPv6 for the network link when *OtherInformation*= is set to "true". Both settings default to "false", which means that a DHCPv6 server is not being used.

RouterLifetimeSec=

Takes a timespan. Configures the IPv6 router lifetime in seconds. When set to 0, the host is not acting as a router. Defaults to 30 minutes.

RouterPreference=

Configures IPv6 router preference if *RouterLifetimeSec*= is non-zero. Valid values are "high", "medium" and "low", with "normal" and "default" added as synonyms for "medium" just to make configuration easier. See [RFC 4191](#)^[15] for details. Defaults to "medium".

EmitDNS=, *DNS*=

DNS= specifies a list of recursive DNS server IPv6 addresses that are distributed via Router Advertisement messages when *EmitDNS*= is true. *DNS*= also takes special value "_link_local"; in that case the IPv6 link local address is distributed. If *DNS*= is empty, DNS servers are read from the [Network] section. If the [Network] section does not contain any DNS servers either, DNS servers from the uplink with the highest priority default route are used. When *EmitDNS*= is false, no DNS server information is sent in Router Advertisement messages. *EmitDNS*= defaults to true.

EmitDomains=, *Domains*=

A list of DNS search domains distributed via Router Advertisement messages when *EmitDomains*= is true. If *Domains*= is empty, DNS search domains are read from the [Network] section. If the [Network] section does not contain any DNS search domains either, DNS search domains from the uplink with the highest priority default route are used. When *EmitDomains*= is false, no DNS search domain information is sent in Router Advertisement messages. *EmitDomains*= defaults to true.

DNSLifetimeSec=

Lifetime in seconds for the DNS server addresses listed in *DNS*= and search domains listed in *Domains*=.

[IPV6PREFIX] SECTION OPTIONS

One or more [IPv6Prefix] sections contain the IPv6 prefixes that are announced via Router Advertisements. See [RFC 4861](#)^[23] for further details.

AddressAutoconfiguration=, *OnLink*=

Takes a boolean to specify whether IPv6 addresses can be autoconfigured with this prefix and whether the prefix can be used for onlink determination. Both settings default to "true" in order to ease configuration.

Prefix=

The IPv6 prefix that is to be distributed to hosts. Similarly to configuring static IPv6 addresses, the setting is configured as an IPv6 prefix and its prefix length, separated by a "/" character. Use multiple [IPv6Prefix] sections to configure multiple IPv6 prefixes since prefix lifetimes, address autoconfiguration and onlink status may differ from one prefix to another.

PreferredLifetimeSec=, *ValidLifetimeSec*=

Preferred and valid lifetimes for the prefix measured in seconds. *PreferredLifetimeSec*= defaults to 604800 seconds (one week) and *ValidLifetimeSec*= defaults to 2592000 seconds (30 days).

Assign=

Takes a boolean. When true, adds an address from the prefix. Default to false.

RouteMetric=

The metric of the prefix route. Takes an unsigned integer in the range 0...4294967295. When unset or set to 0, the kernel's default value is used. This setting is ignored when *Assign*= is false.

[IPV6ROUTEPREFIX] SECTION OPTIONS

One or more [IPv6RoutePrefix] sections contain the IPv6 prefix routes that are announced via Router Advertisements. See [RFC 4191](#)^[15] for further details.

Route=

The IPv6 route that is to be distributed to hosts. Similarly to configuring static IPv6 routes, the setting is configured as an IPv6 prefix routes and its prefix route length, separated by a "/" character. Use multiple [IPv6PrefixRoutes] sections to configure multiple IPv6 prefix routes.

LifetimeSec=

Lifetime for the route prefix measured in seconds. *LifetimeSec=* defaults to 604800 seconds (one week).

[BRIDGE] SECTION OPTIONS

The [Bridge] section accepts the following keys:

UnicastFlood=

Takes a boolean. Controls whether the bridge should flood traffic for which an FDB entry is missing and the destination is unknown through this port. When unset, the kernel's default will be used.

MulticastFlood=

Takes a boolean. Controls whether the bridge should flood traffic for which an MDB entry is missing and the destination is unknown through this port. When unset, the kernel's default will be used.

MulticastToUnicast=

Takes a boolean. Multicast to unicast works on top of the multicast snooping feature of the bridge. Which means unicast copies are only delivered to hosts which are interested in it. When unset, the kernel's default will be used.

NeighborSuppression=

Takes a boolean. Configures whether ARP and ND neighbor suppression is enabled for this port. When unset, the kernel's default will be used.

Learning=

Takes a boolean. Configures whether MAC address learning is enabled for this port. When unset, the kernel's default will be used.

HairPin=

Takes a boolean. Configures whether traffic may be sent back out of the port on which it was received. When this flag is false, then the bridge will not forward traffic back out of the receiving port. When unset, the kernel's default will be used.

UseBPDU=

Takes a boolean. Configures whether STP Bridge Protocol Data Units will be processed by the bridge port. When unset, the kernel's default will be used.

FastLeave=

Takes a boolean. This flag allows the bridge to immediately stop multicast traffic on a port that receives an IGMP Leave message. It is only used with IGMP snooping if enabled on the bridge. When unset, the kernel's default will be used.

AllowPortToBeRoot=

Takes a boolean. Configures whether a given port is allowed to become a root port. Only used when STP is enabled on the bridge. When unset, the kernel's default will be used.

ProxyARP=

Takes a boolean. Configures whether proxy ARP to be enabled on this port. When unset, the kernel's default will be used.

ProxyARPWiFi=

Takes a boolean. Configures whether proxy ARP to be enabled on this port which meets extended requirements by IEEE 802.11 and Hotspot 2.0 specifications. When unset, the kernel's default will be used.

MulticastRouter=

Configures this port for having multicast routers attached. A port with a multicast router will receive all multicast traffic. Takes one of "no" to disable multicast routers on this port, "query" to let the

system detect the presence of routers, "permanent" to permanently enable multicast traffic forwarding on this port, or "temporary" to enable multicast routers temporarily on this port, not depending on incoming queries. When unset, the kernel's default will be used.

Cost=

Sets the "cost" of sending packets of this interface. Each port in a bridge may have a different speed and the cost is used to decide which link to use. Faster interfaces should have lower costs. It is an integer value between 1 and 65535.

Priority=

Sets the "priority" of sending packets on this interface. Each port in a bridge may have a different priority which is used to decide which link to use. Lower value means higher priority. It is an integer value between 0 to 63. Networkd does not set any default, meaning the kernel default value of 32 is used.

[BRIDGEFDB] SECTION OPTIONS

The [BridgeFDB] section manages the forwarding database table of a port and accepts the following keys. Specify several [BridgeFDB] sections to configure several static MAC table entries.

MACAddress=

As in the [Network] section. This key is mandatory.

Destination=

Takes an IP address of the destination VXLAN tunnel endpoint.

VLANId=

The VLAN ID for the new static MAC table entry. If omitted, no VLAN ID information is appended to the new static MAC table entry.

VNI=

The VXLAN Network Identifier (or VXLAN Segment ID) to use to connect to the remote VXLAN tunnel endpoint. Takes a number in the range 1...16777215. Defaults to unset.

AssociatedWith=

Specifies where the address is associated with. Takes one of "use", "self", "master" or "router". "use" means the address is in use. User space can use this option to indicate to the kernel that the fdb entry is in use. "self" means the address is associated with the port drivers fdb. Usually hardware. "master" means the address is associated with master devices fdb. "router" means the destination address is associated with a router. Note that it's valid if the referenced device is a VXLAN type device and has route shortcircuit enabled. Defaults to "self".

OutgoingInterface=

Specifies the name or index of the outgoing interface for the VXLAN device driver to reach the remote VXLAN tunnel endpoint. Defaults to unset.

[BRIDGEMDB] SECTION OPTIONS

The [BridgeMDB] section manages the multicast membership entries forwarding database table of a port and accepts the following keys. Specify several [BridgeMDB] sections to configure several permanent multicast membership entries.

MulticastGroupAddress=

Specifies the IPv4 or IPv6 multicast group address to add. This setting is mandatory.

VLANId=

The VLAN ID for the new entry. Valid ranges are 0 (no VLAN) to 4094. Optional, defaults to 0.

[LLDP] SECTION OPTIONS

The [LLDP] section manages the Link Layer Discovery Protocol (LLDP) and accepts the following keys:

MUDURL=

When configured, the specified Manufacturer Usage Descriptions (MUD) URL will be sent in LLDP packets. The syntax and semantics are the same as for *MUDURL*= in the [DHCPv4] section described above.

The MUD URLs received via LLDP packets are saved and can be read using the `sd_lldp_neighbor_get_mud_url()` function.

[CAN] SECTION OPTIONS

The [CAN] section manages the Controller Area Network (CAN bus) and accepts the following keys:

BitRate=

The bitrate of CAN device in bits per second. The usual SI prefixes (K, M) with the base of 1000 can be used here. Takes a number in the range 1...4294967295.

SamplePoint=

Optional sample point in percent with one decimal (e.g. "75%", "87.5%") or permille (e.g. "875‰").

DataBitRate=, *DataSamplePoint*=

The bitrate and sample point for the data phase, if CAN-FD is used. These settings are analogous to the *BitRate*= and *SamplePoint*= keys.

FDMode=

Takes a boolean. When "yes", CAN-FD mode is enabled for the interface. Note, that a bitrate and optional sample point should also be set for the CAN-FD data phase using the *DataBitRate*= and *DataSamplePoint*= keys.

FDNonISO=

Takes a boolean. When "yes", non-ISO CAN-FD mode is enabled for the interface. When unset, the kernel's default will be used.

RestartSec=

Automatic restart delay time. If set to a non-zero value, a restart of the CAN controller will be triggered automatically in case of a bus-off condition after the specified delay time. Subsecond delays can be specified using decimals (e.g. "0.1s") or a "ms" or "us" postfix. Using "infinity" or "0" will turn the automatic restart off. By default automatic restart is disabled.

Termination=

Takes a boolean. When "yes", the termination resistor will be selected for the bias network. When unset, the kernel's default will be used.

TripleSampling=

Takes a boolean. When "yes", three samples (instead of one) are used to determine the value of a received bit by majority rule. When unset, the kernel's default will be used.

BusErrorReporting=

Takes a boolean. When "yes", reporting of CAN bus errors is activated (those include single bit, frame format, and bit stuffing errors, unable to send dominant bit, unable to send recessive bit, bus overload, active error announcement, error occurred on transmission). When unset, the kernel's default will be used. Note: in case of a CAN bus with a single CAN device, sending a CAN frame may result in a huge number of CAN bus errors.

ListenOnly=

Takes a boolean. When "yes", listen-only mode is enabled. When the interface is in listen-only mode, the interface neither transmit CAN frames nor send ACK bit. Listen-only mode is important to debug CAN networks without interfering with the communication or acknowledge the CAN frame. When unset, the kernel's default will be used.

[QDISC] SECTION OPTIONS

The [QDisc] section manages the traffic control queueing discipline (qdisc).

Parent=

Specifies the parent Queueing Discipline (qdisc). Takes one of "clsact" or "ingress". This is mandatory.

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

[NETWORKEMULATOR] SECTION OPTIONS

The [NetworkEmulator] section manages the queueing discipline (qdisc) of the network emulator. It can be used to configure the kernel packet scheduler and simulate packet delay and loss for UDP or TCP applications, or limit the bandwidth usage of a particular service to simulate internet connections.

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

DelaySec=

Specifies the fixed amount of delay to be added to all packets going out of the interface. Defaults to unset.

DelayJitterSec=

Specifies the chosen delay to be added to the packets outgoing to the network interface. Defaults to unset.

PacketLimit=

Specifies the maximum number of packets the qdisc may hold queued at a time. An unsigned integer in the range 0–4294967294. Defaults to 1000.

LossRate=

Specifies an independent loss probability to be added to the packets outgoing from the network interface. Takes a percentage value, suffixed with "%". Defaults to unset.

DuplicateRate=

Specifies that the chosen percent of packets is duplicated before queuing them. Takes a percentage value, suffixed with "%". Defaults to unset.

[TOKENBUCKETFILTER] SECTION OPTIONS

The [TokenBucketFilter] section manages the queueing discipline (qdisc) of token bucket filter (tbf).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

LatencySec=

Specifies the latency parameter, which specifies the maximum amount of time a packet can sit in the Token Bucket Filter (TBF). Defaults to unset.

LimitBytes=

Takes the number of bytes that can be queued waiting for tokens to become available. When the size is suffixed with K, M, or G, it is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset.

BurstBytes=

Specifies the size of the bucket. This is the maximum amount of bytes that tokens can be available for instantaneous transfer. When the size is suffixed with K, M, or G, it is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset.

Rate=

Specifies the device specific bandwidth. When suffixed with K, M, or G, the specified bandwidth is parsed as Kilobits, Megabits, or Gigabits, respectively, to the base of 1000. Defaults to unset.

MPUBytes=

The Minimum Packet Unit (MPU) determines the minimal token usage (specified in bytes) for a packet. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to zero.

PeakRate=

Takes the maximum depletion rate of the bucket. When suffixed with K, M, or G, the specified size is parsed as Kilobits, Megabits, or Gigabits, respectively, to the base of 1000. Defaults to unset.

MTUBytes=

Specifies the size of the peakrate bucket. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset.

[PIE] SECTION OPTIONS

The [PIE] section manages the queueing discipline (qdisc) of Proportional Integral controller–Enhanced (PIE).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the queue size in number of packets. When this limit is reached, incoming packets are dropped. An unsigned integer in the range 1...4294967294. Defaults to unset and kernel's default is used.

[FLOWQUEUEPIE] SECTION OPTIONS

The "[FlowQueuePIE]" section manages the queueing discipline (qdisc) of Flow Queue Proportional Integral controller–Enhanced (fq_pie).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the queue size in number of packets. When this limit is reached, incoming packets are dropped. An unsigned integer ranges 1 to 4294967294. Defaults to unset and kernel's default is used.

[STOCHASTICFAIRBLUE] SECTION OPTIONS

The [StochasticFairBlue] section manages the queueing discipline (qdisc) of stochastic fair blue (sfb).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the queue size in number of packets. When this limit is reached, incoming

packets are dropped. An unsigned integer in the range 0–4294967294. Defaults to unset and kernel's default is used.

[STOCHASTICFAIRNESSQUEUEING] SECTION OPTIONS

The [StochasticFairnessQueueing] section manages the queueing discipline (qdisc) of stochastic fairness queueing (sfq).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PerturbPeriodSec=

Specifies the interval in seconds for queue algorithm perturbation. Defaults to unset.

[BFIFO] SECTION OPTIONS

The [BFIFO] section manages the queueing discipline (qdisc) of Byte limited Packet First In First Out (bfifo).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

LimitBytes=

Specifies the hard limit in bytes on the FIFO buffer size. The size limit prevents overflow in case the kernel is unable to dequeue packets as quickly as it receives them. When this limit is reached, incoming packets are dropped. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset and kernel default is used.

[PFIFO] SECTION OPTIONS

The [PFIFO] section manages the queueing discipline (qdisc) of Packet First In First Out (pfifo).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the number of packets in the FIFO queue. The size limit prevents overflow in case the kernel is unable to dequeue packets as quickly as it receives them. When this limit is reached, incoming packets are dropped. An unsigned integer in the range 0–4294967294. Defaults to unset and kernel's default is used.

[PFIFOHEADDROP] SECTION OPTIONS

The [PFIFOHeadDrop] section manages the queueing discipline (qdisc) of Packet First In First Out Head Drop (pfifo_head_drop).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class

identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

As in [PFIFO] section.

[PFIFOFAST] SECTION OPTIONS

The [PFIFOFast] section manages the queueing discipline (qdisc) of Packet First In First Out Fast (pfifo_fast).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

[CAKE] SECTION OPTIONS

The [CAKE] section manages the queueing discipline (qdisc) of Common Applications Kept Enhanced (CAKE).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

OverheadBytes=

Specifies that bytes to be added to the size of each packet. Bytes may be negative. Takes an integer in the range from -64 to 256. Defaults to unset and kernel's default is used.

Bandwidth=

Specifies the shaper bandwidth. When suffixed with K, M, or G, the specified size is parsed as Kilobits, Megabits, or Gigabits, respectively, to the base of 1000. Defaults to unset and kernel's default is used.

[CONTROLLEDDELAY] SECTION OPTIONS

The [ControlledDelay] section manages the queueing discipline (qdisc) of controlled delay (CoDel).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the queue size in number of packets. When this limit is reached, incoming packets are dropped. An unsigned integer in the range 0–4294967294. Defaults to unset and kernel's default is used.

TargetSec=

Takes a timespan. Specifies the acceptable minimum standing/persistent queue delay. Defaults to unset and kernel's default is used.

IntervalSec=

Takes a timespan. This is used to ensure that the measured minimum delay does not become too stale. Defaults to unset and kernel's default is used.

ECN=

Takes a boolean. This can be used to mark packets instead of dropping them. Defaults to unset and kernel's default is used.

CEThresholdSec=

Takes a timespan. This sets a threshold above which all packets are marked with ECN Congestion Experienced (CE). Defaults to unset and kernel's default is used.

[DEFICITROUNDROBINSCHEDULER] SECTION OPTIONS

The [DeficitRoundRobinScheduler] section manages the queueing discipline (qdisc) of Deficit Round Robin Scheduler (DRR).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

[DEFICITROUNDROBINSCHEDULERCLASS] SECTION OPTIONS

The [DeficitRoundRobinSchedulerClass] section manages the traffic control class of Deficit Round Robin Scheduler (DRR).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", or a qdisc identifier. The qdisc identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

ClassId=

Configures the unique identifier of the class. It is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to unset.

QuantumBytes=

Specifies the amount of bytes a flow is allowed to dequeue before the scheduler moves to the next class. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to the MTU of the interface.

[ENHANCEDTRANSMISSIONSELECTION] SECTION OPTIONS

The [EnhancedTransmissionSelection] section manages the queueing discipline (qdisc) of Enhanced Transmission Selection (ETS).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

Bands=

Specifies the number of bands. An unsigned integer in the range 1–16. This value has to be at least large enough to cover the strict bands specified through the *StrictBands*= and bandwidth-sharing bands specified in *QuantumBytes*=.

StrictBands=

Specifies the number of bands that should be created in strict mode. An unsigned integer in the range 1–16.

QuantumBytes=

Specifies the white-space separated list of quantum used in band-sharing bands. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. This setting can be specified multiple times. If an empty string is assigned, then the all previous assignments are cleared.

PriorityMap=

The priority map maps the priority of a packet to a band. The argument is a whitespace separated list of numbers. The first number indicates which band the packets with priority 0 should be put to, the second is for priority 1, and so on. There can be up to 16 numbers in the list. If there are fewer, the default band that traffic with one of the unmentioned priorities goes to is the last one. Each band number must be in the range 0...255. This setting can be specified multiple times. If an empty string is assigned, then the all previous assignments are cleared.

[GENERICRANDOMEARLYDETECTION] SECTION OPTIONS

The [GenericRandomEarlyDetection] section manages the queueing discipline (qdisc) of Generic Random Early Detection (GRED).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

VirtualQueues=

Specifies the number of virtual queues. Takes an integer in the range 1...16. Defaults to unset and kernel's default is used.

DefaultVirtualQueue=

Specifies the number of default virtual queue. This must be less than *VirtualQueue=*. Defaults to unset and kernel's default is used.

GenericRIO=

Takes a boolean. It turns on the RIO-like buffering scheme. Defaults to unset and kernel's default is used.

[FAIRQUEUEINGCONTROLLEDDELAY] SECTION OPTIONS

The [FairQueueingControlledDelay] section manages the queueing discipline (qdisc) of fair queuing controlled delay (FQ-CoDel).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the real queue size. When this limit is reached, incoming packets are dropped. Defaults to unset and kernel's default is used.

MemoryLimitBytes=

Specifies the limit on the total number of bytes that can be queued in this FQ-CoDel instance. When

suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset and kernel's default is used.

Flows=

Specifies the number of flows into which the incoming packets are classified. Defaults to unset and kernel's default is used.

TargetSec=

Takes a timespan. Specifies the acceptable minimum standing/persistent queue delay. Defaults to unset and kernel's default is used.

IntervalSec=

Takes a timespan. This is used to ensure that the measured minimum delay does not become too stale. Defaults to unset and kernel's default is used.

QuantumBytes=

Specifies the number of bytes used as the "deficit" in the fair queuing algorithm timespan. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset and kernel's default is used.

ECN=

Takes a boolean. This can be used to mark packets instead of dropping them. Defaults to unset and kernel's default is used.

CEThresholdSec=

Takes a timespan. This sets a threshold above which all packets are marked with ECN Congestion Experienced (CE). Defaults to unset and kernel's default is used.

[FAIRQUEUEING] SECTION OPTIONS

The [FairQueueing] section manages the queueing discipline (qdisc) of fair queue traffic policing (FQ).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the real queue size. When this limit is reached, incoming packets are dropped. Defaults to unset and kernel's default is used.

FlowLimit=

Specifies the hard limit on the maximum number of packets queued per flow. Defaults to unset and kernel's default is used.

QuantumBytes=

Specifies the credit per dequeue RR round, i.e. the amount of bytes a flow is allowed to dequeue at once. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset and kernel's default is used.

InitialQuantumBytes=

Specifies the initial sending rate credit, i.e. the amount of bytes a new flow is allowed to dequeue initially. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. Defaults to unset and kernel's default is used.

MaximumRate=

Specifies the maximum sending rate of a flow. When suffixed with K, M, or G, the specified size is parsed as Kilobits, Megabits, or Gigabits, respectively, to the base of 1000. Defaults to unset and kernel's default is used.

Buckets=

Specifies the size of the hash table used for flow lookups. Defaults to unset and kernel's default is used.

OrphanMask=

Takes an unsigned integer. For packets not owned by a socket, fq is able to mask a part of hash and reduce number of buckets associated with the traffic. Defaults to unset and kernel's default is used.

Pacing=

Takes a boolean, and enables or disables flow pacing. Defaults to unset and kernel's default is used.

CEThresholdSec=

Takes a timespan. This sets a threshold above which all packets are marked with ECN Congestion Experienced (CE). Defaults to unset and kernel's default is used.

[TRIVIALLINKEQUALIZER] SECTION OPTIONS

The [TrivialLinkEqualizer] section manages the queueing discipline (qdisc) of trivial link equalizer (teql).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

Id=

Specifies the interface ID "N" of teql. Defaults to "0". Note that when teql is used, currently, the module **sch_teql** with **max_equalizers=N+1** option must be loaded before **systemd-networkd** is started.

[HIERARCHYTOKENBUCKET] SECTION OPTIONS

The [HierarchyTokenBucket] section manages the queueing discipline (qdisc) of hierarchy token bucket (htb).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

DefaultClass=

Takes the minor id in hexadecimal of the default class. Unclassified traffic gets sent to the class. Defaults to unset.

RateToQuantum=

Takes an unsigned integer. The DRR quantums are calculated by dividing the value configured in **Rate=** by **RateToQuantum=**.

[HIERARCHYTOKENBUCKETCLASS] SECTION OPTIONS

The [HierarchyTokenBucketClass] section manages the traffic control class of hierarchy token bucket (htb).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", or a qdisc identifier. The qdisc identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

ClassId=

Configures the unique identifier of the class. It is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to unset.

Priority=

Specifies the priority of the class. In the round-robin process, classes with the lowest priority field are tried for packets first.

QuantumBytes=

Specifies how many bytes to serve from leaf at once. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024.

MTUBytes=

Specifies the maximum packet size we create. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024.

OverheadBytes=

Takes an unsigned integer which specifies per-packet size overhead used in rate computations. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024.

Rate=

Specifies the maximum rate this class and all its children are guaranteed. When suffixed with K, M, or G, the specified size is parsed as Kilobits, Megabits, or Gigabits, respectively, to the base of 1000. This setting is mandatory.

CeilRate=

Specifies the maximum rate at which a class can send, if its parent has bandwidth to spare. When suffixed with K, M, or G, the specified size is parsed as Kilobits, Megabits, or Gigabits, respectively, to the base of 1000. When unset, the value specified with *Rate*= is used.

BufferBytes=

Specifies the maximum bytes burst which can be accumulated during idle period. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024.

CeilBufferBytes=

Specifies the maximum bytes burst for ceil which can be accumulated during idle period. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024.

[HEAVYHITTERFILTER] SECTION OPTIONS

The [HeavyHitterFilter] section manages the queueing discipline (qdisc) of Heavy Hitter Filter (hhf).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

PacketLimit=

Specifies the hard limit on the queue size in number of packets. When this limit is reached, incoming packets are dropped. An unsigned integer in the range 0–4294967294. Defaults to unset and kernel's default is used.

[QUICKFAIRQUEUEING] SECTION OPTIONS

The [QuickFairQueueing] section manages the queueing discipline (qdisc) of Quick Fair Queueing (QFQ).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", "clsact", "ingress" or a class identifier. The class identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

Handle=

Configures the major number of unique identifier of the qdisc, known as the handle. Takes a hexadecimal number in the range 0x1–0xffff. Defaults to unset.

[QUICKFAIRQUEUEINGCLASS] SECTION OPTIONS

The [QuickFairQueueingClass] section manages the traffic control class of Quick Fair Queueing (qfq).

Parent=

Configures the parent Queueing Discipline (qdisc). Takes one of "root", or a qdisc identifier. The qdisc identifier is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to "root".

ClassId=

Configures the unique identifier of the class. It is specified as the major and minor numbers in hexadecimal in the range 0x1–0xffff separated with a colon ("major:minor"). Defaults to unset.

Weight=

Specifies the weight of the class. Takes an integer in the range 1...1023. Defaults to unset in which case the kernel default is used.

MaxPacketBytes=

Specifies the maximum packet size in bytes for the class. When suffixed with K, M, or G, the specified size is parsed as Kilobytes, Megabytes, or Gigabytes, respectively, to the base of 1024. When unset, the kernel default is used.

[BRIDGEVLAN] SECTION OPTIONS

The [BridgeVLAN] section manages the VLAN ID configuration of a bridge port and accepts the following keys. Specify several [BridgeVLAN] sections to configure several VLAN entries. The *VLANFiltering*= option has to be enabled, see the [Bridge] section in **systemd.netdev(5)**.

VLAN=

The VLAN ID allowed on the port. This can be either a single ID or a range M–N. VLAN IDs are valid from 1 to 4094.

EgressUntagged=

The VLAN ID specified here will be used to untag frames on egress. Configuring *EgressUntagged*= implicates the use of *VLAN*= above and will enable the VLAN ID for ingress as well. This can be either a single ID or a range M–N.

PVID=

The Port VLAN ID specified here is assigned to all untagged frames at ingress. *PVID*= can be used only once. Configuring *PVID*= implicates the use of *VLAN*= above and will enable the VLAN ID for ingress as well.

EXAMPLES

Example 1. Static network configuration

```
# /etc/systemd/network/50-static.network
[Match]
Name=enp2s0

[Network]
Address=192.168.0.15/24
Gateway=192.168.0.1
```

This brings interface "enp2s0" up with a static address. The specified gateway will be used for a default route.

Example 2. DHCP on ethernet links

```
# /etc/systemd/network/80-dhcp.network
[Match]
Name=en*
```

```
[Network]
DHCP=yes
```

This will enable DHCPv4 and DHCPv6 on all interfaces with names starting with "en" (i.e. ethernet interfaces).

Example 3. IPv6 Prefix Delegation

```
# /etc/systemd/network/55-ipv6-pd-upstream.network
[Match]
Name=enp1s0
```

```
[Network]
DHCP=ipv6
```

```
# /etc/systemd/network/56-ipv6-pd-downstream.network
[Match]
Name=enp2s0
```

```
[Network]
IPv6SendRA=yes
DHCPv6PrefixDelegation=yes
```

This will enable DHCPv6-PD on the interface enp1s0 as an upstream interface where the DHCPv6 client is running and enp2s0 as a downstream interface where the prefix is delegated to. The delegated prefixes are distributed by IPv6 Router Advertisement on the downstream network.

Example 4. A bridge with two enslaved links

```
# /etc/systemd/network/25-bridge-static.network
[Match]
Name=bridge0
```

```
[Network]
Address=192.168.0.15/24
Gateway=192.168.0.1
DNS=192.168.0.1
```

```
# /etc/systemd/network/25-bridge-slave-interface-1.network
[Match]
Name=enp2s0
```

```
[Network]
Bridge=bridge0
```

```
# /etc/systemd/network/25-bridge-slave-interface-2.network
[Match]
Name=wlp3s0
```

```
[Network]
Bridge=bridge0
```

This creates a bridge and attaches devices "enp2s0" and "wlp3s0" to it. The bridge will have the specified static address and network assigned, and a default route via the specified gateway will be added. The specified DNS server will be added to the global list of DNS resolvers.

Example 5. Bridge port with VLAN forwarding

```
# /etc/systemd/network/25-bridge-slave-interface-1.network
[Match]
Name=enp2s0

[Network]
Bridge=bridge0

[BridgeVLAN]
VLAN=1-32
PVID=42
EgressUntagged=42

[BridgeVLAN]
VLAN=100-200

[BridgeVLAN]
EgressUntagged=300-400
```

This overrides the configuration specified in the previous example for the interface "enp2s0", and enables VLAN on that bridge port. VLAN IDs 1–32, 42, 100–400 will be allowed. Packets tagged with VLAN IDs 42, 300–400 will be untagged when they leave on this interface. Untagged packets which arrive on this interface will be assigned VLAN ID 42.

Example 6. Various tunnels

```
/etc/systemd/network/25-tunnels.network
[Match]
Name=ens1
```

```
[Network]
Tunnel=ipip-tun
Tunnel=sit-tun
Tunnel=gre-tun
Tunnel=vti-tun
```

```
/etc/systemd/network/25-tunnel-ipip.netdev
[NetDev]
Name=ipip-tun
Kind=ipip
```

```
/etc/systemd/network/25-tunnel-sit.netdev
[NetDev]
Name=sit-tun
Kind=sit
```

```
/etc/systemd/network/25-tunnel-gre.netdev
[NetDev]
Name=gre-tun
Kind=gre
```

```
/etc/systemd/network/25-tunnel-vti.netdev
[NetDev]
```

```
Name=vti-tun
Kind=vti
```

This will bring interface "ens1" up and create an IPIP tunnel, a SIT tunnel, a GRE tunnel, and a VTI tunnel using it.

Example 7. A bond device

```
# /etc/systemd/network/30-bond1.network
[Match]
Name=bond1

[Network]
DHCP=ipv6

# /etc/systemd/network/30-bond1.netdev
[NetDev]
Name=bond1
Kind=bond

# /etc/systemd/network/30-bond1-dev1.network
[Match]
MACAddress=52:54:00:e9:64:41

[Network]
Bond=bond1

# /etc/systemd/network/30-bond1-dev2.network
[Match]
MACAddress=52:54:00:e9:64:42

[Network]
Bond=bond1
```

This will create a bond device "bond1" and enslave the two devices with MAC addresses 52:54:00:e9:64:41 and 52:54:00:e9:64:42 to it. IPv6 DHCP will be used to acquire an address.

Example 8. Virtual Routing and Forwarding (VRF)

Add the "bond1" interface to the VRF master interface "vrf1". This will redirect routes generated on this interface to be within the routing table defined during VRF creation. For kernels before 4.8 traffic won't be redirected towards the VRFs routing table unless specific ip-rules are added.

```
# /etc/systemd/network/25-vrf.network
[Match]
Name=bond1

[Network]
VRF=vrf1
```

Example 9. MacVTap

This brings up a network interface "macvtap-test" and attaches it to "enp0s25".

```
# /lib/systemd/network/25-macvtap.network
[Match]
Name=enp0s25
```

```
[Network]
MACVTAP=macvtap-test
```

Example 10. A Xfrm interface with physical underlying device.

```
# /etc/systemd/network/27-xfrm.netdev
```

```
[NetDev]
Name=xfrm0
Kind=xfrm
```

```
[Xfrm]
InterfaceId=7
```

```
# /etc/systemd/network/27-eth0.network
```

```
[Match]
Name=eth0
```

```
[Network]
Xfrm=xfrm0
```

This creates a "xfrm0" interface and binds it to the "eth0" device. This allows hardware based ipsec offloading to the "eth0" nic. If offloading is not needed, xfrm interfaces can be assigned to the "lo" device.

NAME

systemd.service – Service unit configuration

SYNOPSIS

service.service

DESCRIPTION

A unit configuration file whose name ends in ".service" encodes information about a process controlled and supervised by systemd.

This man page lists the configuration options specific to this unit type. See **systemd.unit(5)** for the common options of all unit configuration files. The common configuration items are configured in the generic [Unit] and [Install] sections. The service specific configuration options are configured in the [Service] section.

Additional options are listed in **systemd.exec(5)**, which define the execution environment the commands are executed in, and in **systemd.kill(5)**, which define the way the processes of the service are terminated, and in **systemd.resource-control(5)**, which configure resource control settings for the processes of the service.

If a service is requested under a certain name but no unit configuration file is found, systemd looks for a SysV init script by the same name (with the .service suffix removed) and dynamically creates a service unit from that script. This is useful for compatibility with SysV. Note that this compatibility is quite comprehensive but not 100%. For details about the incompatibilities, see the [Incompatibilities with SysV^{\[1\]}](#) document.

The **systemd-run(1)** command allows creating .service and .scope units dynamically and transiently from the command line.

SERVICE TEMPLATES

It is possible for **systemd** services to take a single argument via the "*service@argument.service*" syntax. Such services are called "instantiated" services, while the unit definition without the *argument* parameter is called a "template". An example could be a dhcpcd@.service service template which takes a network interface as a parameter to form an instantiated service. Within the service file, this parameter or "instance name" can be accessed with %–specifiers. See **systemd.unit(5)** for details.

AUTOMATIC DEPENDENCIES

Implicit Dependencies

The following dependencies are implicitly added:

- Services with *Type=dbus* set automatically acquire dependencies of type *Requires=* and *After=* on *dbus.socket*.
- Socket activated services are automatically ordered after their activating .socket units via an automatic *After=* dependency. Services also pull in all .socket units listed in *Sockets=* via automatic *Wants=* and *After=* dependencies.

Additional implicit dependencies may be added as result of execution and resource control parameters as documented in **systemd.exec(5)** and **systemd.resource-control(5)**.

Default Dependencies

The following dependencies are added unless *DefaultDependencies=no* is set:

- Service units will have dependencies of type *Requires=* and *After=* on *sysinit.target*, a dependency of type *After=* on *basic.target* as well as dependencies of type *Conflicts=* and *Before=* on *shutdown.target*. These ensure that normal service units pull in basic system initialization, and are terminated cleanly prior to system shutdown. Only services involved with early boot or late system shutdown should disable this option.
- Instanced service units (i.e. service units with an "@" in their name) are assigned by default a per-template slice unit (see **systemd.slice(5)**), named after the template unit, containing all instances of the specific template. This slice is normally stopped at shutdown, together with all template instances. If that is not desired, set *DefaultDependencies=no* in the template unit, and

either define your own per-template slice unit file that also sets *DefaultDependencies=no*, or set *Slice=system.slice* (or another suitable slice) in the template unit. Also see **systemd.resource-control(5)**.

OPTIONS

Service files must include a [Service] section, which carries information about the service and the process it supervises. A number of options that may be used in this section are shared with other unit types. These options are documented in **systemd.exec(5)**, **systemd.kill(5)** and **systemd.resource-control(5)**. The options specific to the [Service] section of service units are the following:

Type=

Configures the process start-up type for this service unit. One of **simple**, **exec**, **forking**, **oneshot**, **dbus**, **notify** or **idle**:

- If set to **simple** (the default if *ExecStart=* is specified but neither *Type=* nor *BusName=* are), the service manager will consider the unit started immediately after the main service process has been forked off. It is expected that the process configured with *ExecStart=* is the main process of the service. In this mode, if the process offers functionality to other processes on the system, its communication channels should be installed before the service is started up (e.g. sockets set up by systemd, via socket activation), as the service manager will immediately proceed starting follow-up units, right after creating the main service process, and before executing the service's binary. Note that this means **systemctl start** command lines for **simple** services will report success even if the service's binary cannot be invoked successfully (for example because the selected *User=* doesn't exist, or the service binary is missing).
- The **exec** type is similar to **simple**, but the service manager will consider the unit started immediately after the main service binary has been executed. The service manager will delay starting of follow-up units until that point. (Or in other words: **simple** proceeds with further jobs right after **fork()** returns, while **exec** will not proceed before both **fork()** and **execve()** in the service process succeeded.) Note that this means **systemctl start** command lines for **exec** services will report failure when the service's binary cannot be invoked successfully (for example because the selected *User=* doesn't exist, or the service binary is missing).
- If set to **forking**, it is expected that the process configured with *ExecStart=* will call **fork()** as part of its start-up. The parent process is expected to exit when start-up is complete and all communication channels are set up. The child continues to run as the main service process, and the service manager will consider the unit started when the parent process exits. This is the behavior of traditional UNIX services. If this setting is used, it is recommended to also use the *PIDFile=* option, so that systemd can reliably identify the main process of the service. systemd will proceed with starting follow-up units as soon as the parent process exits.
- Behavior of **oneshot** is similar to **simple**; however, the service manager will consider the unit up after the main process exits. It will then start follow-up units. *RemainAfterExit=* is particularly useful for this type of service. *Type=oneshot* is the implied default if neither *Type=* nor *ExecStart=* are specified. Note that if this option is used without *RemainAfterExit=* the service will never enter "active" unit state, but directly transition from "activating" to "deactivating" or "dead" since no process is configured that shall run continuously. In particular this means that after a service of this type ran (and which has *RemainAfterExit=* not set) it will not show up as started afterwards, but as dead.
- Behavior of **dbus** is similar to **simple**; however, it is expected that the service acquires a name on the D-Bus bus, as configured by *BusName=*. systemd will proceed with starting follow-up units after the D-Bus bus name has been acquired. Service units with this option configured implicitly gain dependencies on the **dbus.socket** unit. This type is the default if *BusName=* is specified. A service unit of this type is considered to be in the activating state until the specified bus name is acquired. It is considered activated while the bus name is taken. Once the bus name is released the service is considered being no longer functional which has the effect that the service manager attempts to terminate any remaining processes belonging to the service. Services that drop their bus name as part of their shutdown logic thus should be

prepared to receive a **SIGTERM** (or whichever signal is configured in *KillSignal*=) as result.

- Behavior of **notify** is similar to **exec**; however, it is expected that the service sends a notification message via **sd_notify**(3) or an equivalent call when it has finished starting up. systemd will proceed with starting follow-up units after this notification message has been sent. If this option is used, *NotifyAccess*= (see below) should be set to open access to the notification socket provided by systemd. If *NotifyAccess*= is missing or set to **none**, it will be forcibly set to **main**.
- Behavior of **idle** is very similar to **simple**; however, actual execution of the service program is delayed until all active jobs are dispatched. This may be used to avoid interleaving of output of shell services with the status output on the console. Note that this type is useful only to improve console output, it is not useful as a general unit ordering tool, and the effect of this service type is subject to a 5s timeout, after which the service program is invoked anyway.

It is generally recommended to use *Type=simple* for long-running services whenever possible, as it is the simplest and fastest option. However, as this service type won't propagate service start-up failures and doesn't allow ordering of other units against completion of initialization of the service (which for example is useful if clients need to connect to the service through some form of IPC, and the IPC channel is only established by the service itself — in contrast to doing this ahead of time through socket or bus activation or similar), it might not be sufficient for many cases. If so, **notify** or **dbus** (the latter only in case the service provides a D-Bus interface) are the preferred options as they allow service program code to precisely schedule when to consider the service started up successfully and when to proceed with follow-up units. The **notify** service type requires explicit support in the service codebase (as **sd_notify()** or an equivalent API needs to be invoked by the service at the appropriate time) — if it's not supported, then **forking** is an alternative: it supports the traditional UNIX service start-up protocol. Finally, **exec** might be an option for cases where it is enough to ensure the service binary is invoked, and where the service binary itself executes no or little initialization on its own (and its initialization is unlikely to fail). Note that using any type other than **simple** possibly delays the boot process, as the service manager needs to wait for service initialization to complete. It is hence recommended not to needlessly use any types other than **simple**. (Also note it is generally not recommended to use **idle** or **oneshot** for long-running services.)

RemainAfterExit=

Takes a boolean value that specifies whether the service shall be considered active even when all its processes exited. Defaults to **no**.

GuessMainPID=

Takes a boolean value that specifies whether systemd should try to guess the main PID of a service if it cannot be determined reliably. This option is ignored unless **Type=forking** is set and **PIDFile**= is unset because for the other types or with an explicitly configured PID file, the main PID is always known. The guessing algorithm might come to incorrect conclusions if a daemon consists of more than one process. If the main PID cannot be determined, failure detection and automatic restarting of a service will not work reliably. Defaults to **yes**.

PIDFile=

Takes a path referring to the PID file of the service. Usage of this option is recommended for services where *Type*= is set to **forking**. The path specified typically points to a file below /run/. If a relative path is specified it is hence prefixed with /run/. The service manager will read the PID of the main process of the service from this file after start-up of the service. The service manager will not write to the file configured here, although it will remove the file after the service has shut down if it still exists. The PID file does not need to be owned by a privileged user, but if it is owned by an unprivileged user additional safety restrictions are enforced: the file may not be a symlink to a file owned by a different user (neither directly nor indirectly), and the PID file must refer to a process already belonging to the service.

Note that PID files should be avoided in modern projects. Use **Type=notify** or **Type=simple** where

possible, which does not require use of PID files to determine the main process of a service and avoids needless forking.

BusName=

Takes a D-Bus destination name that this service shall use. This option is mandatory for services where *Type*= is set to **dbus**. It is recommended to always set this property if known to make it easy to map the service name to the D-Bus destination. In particular, **systemctl** **service-log-level**/**service-log-target** verbs make use of this.

ExecStart=

Commands with their arguments that are executed when this service is started. The value is split into zero or more command lines according to the rules described below (see section "Command Lines" below).

Unless *Type*= is **oneshot**, exactly one command must be given. When *Type=oneshot* is used, zero or more commands may be specified. Commands may be specified by providing multiple command lines in the same directive, or alternatively, this directive may be specified more than once with the same effect. If the empty string is assigned to this option, the list of commands to start is reset, prior assignments of this option will have no effect. If no *ExecStart*= is specified, then the service must have *RemainAfterExit=yes* and at least one *ExecStop*= line set. (Services lacking both *ExecStart*= and *ExecStop*= are not valid.)

For each of the specified commands, the first argument must be either an absolute path to an executable or a simple file name without any slashes. Optionally, this filename may be prefixed with a number of special characters:

Table 1. Special executable prefixes

"@", "-", ":" , and one of "+"|"!"|"!!" may be used together and they can appear in any order. However, only one of "+", "!", "!!" may be used at a time. Note that these prefixes are also supported for the other command line settings, i.e. *ExecStartPre=*, *ExecStartPost=*, *ExecReload=*, *ExecStop=* and *ExecStopPost=*.

If more than one command is specified, the commands are invoked sequentially in the order they appear in the unit file. If one of the commands fails (and is not prefixed with "-"), other lines are not executed, and the unit is considered failed.

Unless *Type=forking* is set, the process started via this command line will be considered the main process of the daemon.

ExecStartPre=, *ExecStartPost=*

Additional commands that are executed before or after the command in *ExecStart=*, respectively. Syntax is the same as for *ExecStart=*, except that multiple command lines are allowed and the commands are executed one after the other, serially.

If any of those commands (not prefixed with "-") fail, the rest are not executed and the unit is considered failed.

ExecStart= commands are only run after all *ExecStartPre=* commands that were not prefixed with a "-" exit successfully.

ExecStartPost= commands are only run after the commands specified in *ExecStart=* have been invoked successfully, as determined by *Type* (i.e. the process has been started for *Type=simple* or *Type=idle*, the last *ExecStart=* process exited successfully for *Type=oneshot*, the initial process exited successfully for *Type=forking*, "READY=1" is sent for *Type=notify*, or the *BusName=* has been taken for *Type=dbus*).

Note that *ExecStartPre=* may not be used to start long-running processes. All processes forked off by processes invoked via *ExecStartPre=* will be killed before the next service process is run.

Note that if any of the commands specified in *ExecStartPre=*, *ExecStart=*, or *ExecStartPost=* fail (and are not prefixed with "-", see above) or time out before the service is fully up, execution continues with commands specified in *ExecStopPost=*, the commands in *ExecStop=* are skipped.

Note that the execution of *ExecStartPost=* is taken into account for the purpose of *Before=/After=* ordering constraints.

ExecCondition=

Optional commands that are executed before the command(s) in *ExecStartPre=*. Syntax is the same as for *ExecStart=*, except that multiple command lines are allowed and the commands are executed one after the other, serially.

The behavior is like an *ExecStartPre=* and condition check hybrid: when an *ExecCondition=* command exits with exit code 1 through 254 (inclusive), the remaining commands are skipped and the unit is *not* marked as failed. However, if an *ExecCondition=* command exits with 255 or abnormally (e.g. timeout, killed by a signal, etc.), the unit will be considered failed (and remaining commands will be skipped). Exit code of 0 or those matching *SuccessExitStatus=* will continue execution to the next command(s).

The same recommendations about not running long-running processes in *ExecStartPre=* also applies to *ExecCondition=*. *ExecCondition=* will also run the commands in *ExecStopPost=*, as part of stopping the service, in the case of any non-zero or abnormal exits, like the ones described above.

ExecReload=

Commands to execute to trigger a configuration reload in the service. This argument takes multiple command lines, following the same scheme as described for *ExecStart=* above. Use of this setting is optional. Specifier and environment variable substitution is supported here following the same scheme as for *ExecStart=*.

One additional, special environment variable is set: if known, *\$MAINPID* is set to the main process of the daemon, and may be used for command lines like the following:

```
ExecReload=kill -HUP $MAINPID
```

Note however that reloading a daemon by sending a signal (as with the example line above) is usually not a good choice, because this is an asynchronous operation and hence not suitable to order reloads of multiple services against each other. It is strongly recommended to set *ExecReload=* to a command that not only triggers a configuration reload of the daemon, but also synchronously waits for it to complete. For example, **dbus-broker**(1) uses the following:

```
ExecReload=busctl call org.freedesktop.DBus \
    /org/freedesktop/DBus org.freedesktop.DBus \
    ReloadConfig
```

ExecStop=

Commands to execute to stop the service started via *ExecStart=*. This argument takes multiple command lines, following the same scheme as described for *ExecStart=* above. Use of this setting is optional. After the commands configured in this option are run, it is implied that the service is stopped, and any processes remaining for it are terminated according to the *KillMode=* setting (see **systemd.kill**(5)). If this option is not specified, the process is terminated by sending the signal specified in *KillSignal=* or *RestartKillSignal=* when service stop is requested. Specifier and environment variable substitution is supported (including *\$MAINPID*, see above).

Note that it is usually not sufficient to specify a command for this setting that only asks the service to terminate (for example, by sending some form of termination signal to it), but does not wait for it to do so. Since the remaining processes of the services are killed according to *KillMode=* and *KillSignal=* or *RestartKillSignal=* as described above immediately after the command exited, this may not result in a clean stop. The specified command should hence be a synchronous operation, not an asynchronous one.

Note that the commands specified in *ExecStop=* are only executed when the service started successfully first. They are not invoked if the service was never started at all, or in case its start-up failed, for example because any of the commands specified in *ExecStart=*, *ExecStartPre=* or *ExecStartPost=* failed (and weren't prefixed with "-", see above) or timed out. Use *ExecStopPost=* to invoke commands when a service failed to start up correctly and is shut down again. Also note that the stop operation is always performed if the service started successfully, even if the processes in the service terminated on their own or were killed. The stop commands must be prepared to deal with that case. *\$MAINPID* will be unset if systemd knows that the main process exited by the time the stop commands are called.

Service restart requests are implemented as stop operations followed by start operations. This means that *ExecStop=* and *ExecStopPost=* are executed during a service restart operation.

It is recommended to use this setting for commands that communicate with the service requesting clean termination. For post-mortem clean-up steps use *ExecStopPost=* instead.

ExecStopPost=

Additional commands that are executed after the service is stopped. This includes cases where the commands configured in *ExecStop=* were used, where the service does not have any *ExecStop=* defined, or where the service exited unexpectedly. This argument takes multiple command lines,

following the same scheme as described for *ExecStart=*. Use of these settings is optional. Specifier and environment variable substitution is supported. Note that – unlike *ExecStop=* – commands specified with this setting are invoked when a service failed to start up correctly and is shut down again.

It is recommended to use this setting for clean-up operations that shall be executed even when the service failed to start up correctly. Commands configured with this setting need to be able to operate even if the service failed starting up half-way and left incompletely initialized data around. As the service's processes have been terminated already when the commands specified with this setting are executed they should not attempt to communicate with them.

Note that all commands that are configured with this setting are invoked with the result code of the service, as well as the main process' exit code and status, set in the *\$SERVICE_RESULT*, *\$EXIT_CODE* and *\$EXIT_STATUS* environment variables, see **systemd.exec(5)** for details.

Note that the execution of *ExecStopPost=* is taken into account for the purpose of *Before=/After=* ordering constraints.

RestartSec=

Configures the time to sleep before restarting a service (as configured with *Restart=*). Takes a unit-less value in seconds, or a time span value such as "5min 20s". Defaults to 100ms.

TimeoutStartSec=

Configures the time to wait for start-up. If a daemon service does not signal start-up completion within the configured time, the service will be considered failed and will be shut down again. The precise action depends on the *TimeoutStartFailureMode=* option. Takes a unit-less value in seconds, or a time span value such as "5min 20s". Pass "infinity" to disable the timeout logic. Defaults to *DefaultTimeoutStartSec=* from the manager configuration file, except when *Type=oneshot* is used, in which case the timeout is disabled by default (see **systemd-system.conf(5)**).

If a service of *Type=notify* sends "EXTEND_TIMEOUT_USEC=...", this may cause the start time to be extended beyond *TimeoutStartSec=*. The first receipt of this message must occur before *TimeoutStartSec=* is exceeded, and once the start time has extended beyond *TimeoutStartSec=*, the service manager will allow the service to continue to start, provided the service repeats "EXTEND_TIMEOUT_USEC=..." within the interval specified until the service startup status is finished by "READY=1". (see **sd_notify(3)**).

TimeoutStopSec=

This option serves two purposes. First, it configures the time to wait for each *ExecStop=* command. If any of them times out, subsequent *ExecStop=* commands are skipped and the service will be terminated by **SIGTERM**. If no *ExecStop=* commands are specified, the service gets the **SIGTERM** immediately. This default behavior can be changed by the *TimeoutStopFailureMode=* option. Second, it configures the time to wait for the service itself to stop. If it doesn't terminate in the specified time, it will be forcibly terminated by **SIGKILL** (see *KillMode=* in **systemd.kill(5)**). Takes a unit-less value in seconds, or a time span value such as "5min 20s". Pass "infinity" to disable the timeout logic. Defaults to *DefaultTimeoutStopSec=* from the manager configuration file (see **systemd-system.conf(5)**).

If a service of *Type=notify* sends "EXTEND_TIMEOUT_USEC=...", this may cause the stop time to be extended beyond *TimeoutStopSec=*. The first receipt of this message must occur before *TimeoutStopSec=* is exceeded, and once the stop time has extended beyond *TimeoutStopSec=*, the service manager will allow the service to continue to stop, provided the service repeats "EXTEND_TIMEOUT_USEC=..." within the interval specified, or terminates itself (see **sd_notify(3)**).

TimeoutAbortSec=

This option configures the time to wait for the service to terminate when it was aborted due to a

watchdog timeout (see *WatchdogSec*=). If the service has a short *TimeoutStopSec*= this option can be used to give the system more time to write a core dump of the service. Upon expiration the service will be forcibly terminated by **SIGKILL** (see *KillMode*= in **systemd.kill(5)**). The core file will be truncated in this case. Use *TimeoutAbortSec*= to set a sensible timeout for the core dumping per service that is large enough to write all expected data while also being short enough to handle the service failure in due time.

Takes a unit-less value in seconds, or a time span value such as "5min 20s". Pass an empty value to skip the dedicated watchdog abort timeout handling and fall back *TimeoutStopSec*=. Pass "infinity" to disable the timeout logic. Defaults to *DefaultTimeoutAbortSec*= from the manager configuration file (see **systemd-system.conf(5)**).

If a service of *Type=notify* handles **SIGABRT** itself (instead of relying on the kernel to write a core dump) it can send "EXTEND_TIMEOUT_USEC=..." to extend the abort time beyond *TimeoutAbortSec*=. The first receipt of this message must occur before *TimeoutAbortSec*= is exceeded, and once the abort time has extended beyond *TimeoutAbortSec*=, the service manager will allow the service to continue to abort, provided the service repeats "EXTEND_TIMEOUT_USEC=..." within the interval specified, or terminates itself (see **sd_notify(3)**).

TimeoutSec=

A shorthand for configuring both *TimeoutStartSec*= and *TimeoutStopSec*= to the specified value.

TimeoutStartFailureMode=, *TimeoutStopFailureMode*=

These options configure the action that is taken in case a daemon service does not signal start-up within its configured *TimeoutStartSec*=, respectively if it does not stop within *TimeoutStopSec*=. Takes one of **terminate**, **abort** and **kill**. Both options default to **terminate**.

If **terminate** is set the service will be gracefully terminated by sending the signal specified in *KillSignal*= (defaults to **SIGTERM**, see **systemd.kill(5)**). If the service does not terminate the *FinalKillSignal*= is sent after *TimeoutStopSec*=. If **abort** is set, *WatchdogSignal*= is sent instead and *TimeoutAbortSec*= applies before sending *FinalKillSignal*=. This setting may be used to analyze services that fail to start-up or shut-down intermittently. By using **kill** the service is immediately terminated by sending *FinalKillSignal*= without any further timeout. This setting can be used to expedite the shutdown of failing services.

RuntimeMaxSec=

Configures a maximum time for the service to run. If this is used and the service has been active for longer than the specified time it is terminated and put into a failure state. Note that this setting does not have any effect on *Type=oneshot* services, as they terminate immediately after activation completed. Pass "infinity" (the default) to configure no runtime limit.

If a service of *Type=notify* sends "EXTEND_TIMEOUT_USEC=...", this may cause the runtime to be extended beyond *RuntimeMaxSec*=. The first receipt of this message must occur before *RuntimeMaxSec*= is exceeded, and once the runtime has extended beyond *RuntimeMaxSec*=, the service manager will allow the service to continue to run, provided the service repeats "EXTEND_TIMEOUT_USEC=..." within the interval specified until the service shutdown is achieved by "STOPPING=1" (or termination). (see **sd_notify(3)**).

WatchdogSec=

Configures the watchdog timeout for a service. The watchdog is activated when the start-up is completed. The service must call **sd_notify(3)** regularly with "WATCHDOG=1" (i.e. the "keep-alive ping"). If the time between two such calls is larger than the configured time, then the service is placed in a failed state and it will be terminated with **SIGABRT** (or the signal specified by *WatchdogSignal*=). By setting *Restart*= to **on-failure**, **on-watchdog**, **on-abnormal** or **always**, the service will be automatically restarted. The time configured here will be passed to the executed service process in the *WATCHDOG_USEC*= environment variable. This allows daemons to automatically enable the keep-alive pinging logic if watchdog support is enabled for the service. If this option is

used, *NotifyAccess*= (see below) should be set to open access to the notification socket provided by systemd. If *NotifyAccess*= is not set, it will be implicitly set to **main**. Defaults to 0, which disables this feature. The service can check whether the service manager expects watchdog keep-alive notifications. See **sd_watchdog_enabled(3)** for details. **sd_event_set_watchdog(3)** may be used to enable automatic watchdog notification support.

Restart=

Configures whether the service shall be restarted when the service process exits, is killed, or a timeout is reached. The service process may be the main service process, but it may also be one of the processes specified with *ExecStartPre*=, *ExecStartPost*=, *ExecStop*=, *ExecStopPost*=, or *ExecReload*=. When the death of the process is a result of systemd operation (e.g. service stop or restart), the service will not be restarted. Timeouts include missing the watchdog "keep-alive ping" deadline and a service start, reload, and stop operation timeouts.

Takes one of **no**, **on-success**, **on-failure**, **on-abnormal**, **on-watchdog**, **on-abort**, or **always**. If set to **no** (the default), the service will not be restarted. If set to **on-success**, it will be restarted only when the service process exits cleanly. In this context, a clean exit means any of the following:

- exit code of 0;
- for types other than *Type=oneshot*, one of the signals **SIGHUP**, **SIGINT**, **SIGTERM**, or **SIGPIPE**;
- exit statuses and signals specified in *SuccessExitStatus*=.

If set to **on-failure**, the service will be restarted when the process exits with a non-zero exit code, is terminated by a signal (including on core dump, but excluding the aforementioned four signals), when an operation (such as service reload) times out, and when the configured watchdog timeout is triggered. If set to **on-abnormal**, the service will be restarted when the process is terminated by a signal (including on core dump, excluding the aforementioned four signals), when an operation times out, or when the watchdog timeout is triggered. If set to **on-abort**, the service will be restarted only if the service process exits due to an uncaught signal not specified as a clean exit status. If set to **on-watchdog**, the service will be restarted only if the watchdog timeout for the service expires. If set to **always**, the service will be restarted regardless of whether it exited cleanly or not, got terminated abnormally by a signal, or hit a timeout.

Table 2. Exit causes and the effect of the *Restart*= settings

Restart settings/Exit causes	no	always	on-success	on-failure	on-abnormal	on-abort	on-watchdog
Clean exit code or signal		X	X				
Unclean exit code		X		X			
Unclean signal		X		X	X	X	
Timeout		X		X	X		
Watchdog		X		X	X		X

As exceptions to the setting above, the service will not be restarted if the exit code or signal is specified in *RestartPreventExitStatus*= (see below) or the service is stopped with **systemctl stop** or an equivalent operation. Also, the services will always be restarted if the exit code or signal is specified in *RestartForceExitStatus*= (see below).

Note that service restart is subject to unit start rate limiting configured with *StartLimitIntervalSec*=

and *StartLimitBurst*=, see **systemd.unit(5)** for details. A restarted service enters the failed state only after the start limits are reached.

Setting this to **on-failure** is the recommended choice for long-running services, in order to increase reliability by attempting automatic recovery from errors. For services that shall be able to terminate on their own choice (and avoid immediate restarting), **on-abnormal** is an alternative choice.

SuccessExitStatus=

Takes a list of exit status definitions that, when returned by the main service process, will be considered successful termination, in addition to the normal successful exit status 0 and, except for *Type=oneshot*, the signals **SIGHUP**, **SIGINT**, **SIGTERM**, and **SIGPIPE**. Exit status definitions can be numeric termination statuses, termination status names, or termination signal names, separated by spaces. See the Process Exit Codes section in **systemd.exec(5)** for a list of termination status names (for this setting only the part without the "EXIT_" or "EX_" prefix should be used). See **signal(7)** for a list of signal names.

Note that this setting does not change the mapping between numeric exit statuses and their names, i.e. regardless how this setting is used 0 will still be mapped to "SUCCESS" (and thus typically shown as "0/SUCCESS" in tool outputs) and 1 to "FAILURE" (and thus typically shown as "1/FAILURE"), and so on. It only controls what happens as effect of these exit statuses, and how it propagates to the state of the service as a whole.

This option may appear more than once, in which case the list of successful exit statuses is merged. If the empty string is assigned to this option, the list is reset, all prior assignments of this option will have no effect.

Example 1. A service with the *SuccessExitStatus*= setting

```
SuccessExitStatus=TEMPFAIL 250 SIGKILL
```

Exit status 75 (**TEMPFAIL**), 250, and the termination signal **SIGKILL** are considered clean service terminations.

Note: **systemd-analyze exit-status** may be used to list exit statuses and translate between numerical status values and names.

RestartPreventExitStatus=

Takes a list of exit status definitions that, when returned by the main service process, will prevent automatic service restarts, regardless of the restart setting configured with *Restart*=. Exit status definitions can either be numeric exit codes or termination signal names, and are separated by spaces. Defaults to the empty list, so that, by default, no exit status is excluded from the configured restart logic. For example:

```
RestartPreventExitStatus=1 6 SIGABRT
```

ensures that exit codes 1 and 6 and the termination signal **SIGABRT** will not result in automatic service restarting. This option may appear more than once, in which case the list of restart-preventing statuses is merged. If the empty string is assigned to this option, the list is reset and all prior assignments of this option will have no effect.

Note that this setting has no effect on processes configured via *ExecStartPre*=, *ExecStartPost*=, *ExecStop*=, *ExecStopPost*= or *ExecReload*=, but only on the main service process, i.e. either the one invoked by *ExecStart*= or (depending on *Type*=, *PIDFile*=, ...) the otherwise configured main process.

RestartForceExitStatus=

Takes a list of exit status definitions that, when returned by the main service process, will force automatic service restarts, regardless of the restart setting configured with *Restart*=. The argument

format is similar to *RestartPreventExitStatus*=.

RootDirectoryStartOnly=

Takes a boolean argument. If true, the root directory, as configured with the *RootDirectory*= option (see **systemd.exec(5)** for more information), is only applied to the process started with *ExecStart*=, and not to the various other *ExecStartPre*=, *ExecStartPost*=, *ExecReload*=, *ExecStop*=, and *ExecStopPost*= commands. If false, the setting is applied to all configured commands the same way. Defaults to false.

NonBlocking=

Set the **O_NONBLOCK** flag for all file descriptors passed via socket-based activation. If true, all file descriptors ≥ 3 (i.e. all except stdin, stdout, stderr), excluding those passed in via the file descriptor storage logic (see *FileDescriptorStoreMax*= for details), will have the **O_NONBLOCK** flag set and hence are in non-blocking mode. This option is only useful in conjunction with a socket unit, as described in **systemd.socket(5)** and has no effect on file descriptors which were previously saved in the file-descriptor store for example. Defaults to false.

NotifyAccess=

Controls access to the service status notification socket, as accessible via the **sd_notify**(3) call. Takes one of **none** (the default), **main**, **exec** or **all**. If **none**, no daemon status updates are accepted from the service processes, all status update messages are ignored. If **main**, only service updates sent from the main process of the service are accepted. If **exec**, only service updates sent from any of the main or control processes originating from one of the *Exec*=* commands are accepted. If **all**, all services updates from all members of the service's control group are accepted. This option should be set to open access to the notification socket when using *Type=notify* or *WatchdogSec*= (see above). If those options are used but *NotifyAccess*= is not configured, it will be implicitly set to **main**.

Note that **sd_notify()** notifications may be attributed to units correctly only if either the sending process is still around at the time PID 1 processes the message, or if the sending process is explicitly runtime-tracked by the service manager. The latter is the case if the service manager originally forked off the process, i.e. on all processes that match **main** or **exec**. Conversely, if an auxiliary process of the unit sends an **sd_notify()** message and immediately exits, the service manager might not be able to properly attribute the message to the unit, and thus will ignore it, even if *NotifyAccess=all* is set for it.

Hence, to eliminate all race conditions involving lookup of the client's unit and attribution of notifications to units correctly, **sd_notify_barrier()** may be used. This call acts as a synchronization point and ensures all notifications sent before this call have been picked up by the service manager when it returns successfully. Use of **sd_notify_barrier()** is needed for clients which are not invoked by the service manager, otherwise this synchronization mechanism is unnecessary for attribution of notifications to the unit.

Sockets=

Specifies the name of the socket units this service shall inherit socket file descriptors from when the service is started. Normally, it should not be necessary to use this setting, as all socket file descriptors whose unit shares the same name as the service (subject to the different unit name suffix of course) are passed to the spawned process.

Note that the same socket file descriptors may be passed to multiple processes simultaneously. Also note that a different service may be activated on incoming socket traffic than the one which is ultimately configured to inherit the socket file descriptors. Or, in other words: the *Service*= setting of .socket units does not have to match the inverse of the *Sockets*= setting of the .service it refers to.

This option may appear more than once, in which case the list of socket units is merged. Note that once set, clearing the list of sockets again (for example, by assigning the empty string to this option) is not supported.

FileDescriptorStoreMax=

Configure how many file descriptors may be stored in the service manager for the service using `sd_pid_notify_with_fds(3)`'s "FDSTORE=1" messages. This is useful for implementing services that can restart after an explicit request or a crash without losing state. Any open sockets and other file descriptors which should not be closed during the restart may be stored this way. Application state can either be serialized to a file in /run/, or better, stored in a `memfd_create(2)` memory file descriptor. Defaults to 0, i.e. no file descriptors may be stored in the service manager. All file descriptors passed to the service manager from a specific service are passed back to the service's main process on the next service restart (see `sd_listen_fds(3)` for details about the precise protocol used and the order in which the file descriptors are passed). Any file descriptors passed to the service manager are automatically closed when **POLLHUP** or **POLLERR** is seen on them, or when the service is fully stopped and no job is queued or being executed for it. If this option is used, `NotifyAccess=` (see above) should be set to open access to the notification socket provided by systemd. If `NotifyAccess=` is not set, it will be implicitly set to **main**.

USBFunctionDescriptors=

Configure the location of a file containing **USB FunctionFS**^[2] descriptors, for implementation of USB gadget functions. This is used only in conjunction with a socket unit with `ListenUSBFunction=` configured. The contents of this file are written to the ep0 file after it is opened.

USBFunctionStrings=

Configure the location of a file containing USB FunctionFS strings. Behavior is similar to `USBFunctionDescriptors=` above.

OOMPolicy=

Configure the Out-Of-Memory (OOM) killer policy. On Linux, when memory becomes scarce the kernel might decide to kill a running process in order to free up memory and reduce memory pressure. This setting takes one of **continue**, **stop** or **kill**. If set to **continue** and a process of the service is killed by the kernel's OOM killer this is logged but the service continues running. If set to **stop** the event is logged but the service is terminated cleanly by the service manager. If set to **kill** and one of the service's processes is killed by the OOM killer the kernel is instructed to kill all remaining processes of the service, too. Defaults to the setting `DefaultOOMPolicy=` in `systemd-system.conf(5)` is set to, except for services where `Delegate=` is turned on, where it defaults to **continue**.

Use the `OOMScoreAdjust=` setting to configure whether processes of the unit shall be considered preferred or less preferred candidates for process termination by the Linux OOM killer logic. See `systemd.exec(5)` for details.

Check `systemd.exec(5)` and `systemd.kill(5)` for more settings.

COMMAND LINES

This section describes command line parsing and variable and specifier substitutions for `ExecStart=`, `ExecStartPre=`, `ExecStartPost=`, `ExecReload=`, `ExecStop=`, and `ExecStopPost=` options.

Multiple command lines may be concatenated in a single directive by separating them with semicolons (these semicolons must be passed as separate words). Lone semicolons may be escaped as "\;".

Each command line is unquoted using the rules described in "Quoting" section in `systemd.syntax(7)`. The first item becomes the command to execute, and the subsequent items the arguments.

This syntax is inspired by shell syntax, but only the meta-characters and expansions described in the following paragraphs are understood, and the expansion of variables is different. Specifically, redirection using "<", "<<", ">", and ">>", pipes using "|", running programs in the background using "&", and *other elements of shell syntax are not supported*.

The command to execute may contain spaces, but control characters are not allowed.

The command line accepts "%" specifiers as described in `systemd.unit(5)`.

Basic environment variable substitution is supported. Use "\${FOO}" as part of a word, or as a word of its own, on the command line, in which case it will be erased and replaced by the exact value of the environment variable (if any) including all whitespace it contains, always resulting in exactly a single

argument. Use "\$FOO" as a separate word on the command line, in which case it will be replaced by the value of the environment variable split at whitespace, resulting in zero or more arguments. For this type of expansion, quotes are respected when splitting into words, and afterwards removed.

If the command is not a full (absolute) path, it will be resolved to a full path using a fixed search path determined at compilation time. Searched directories include /usr/local/bin/, /usr/bin/, /bin/ on systems using split /usr/bin/ and /bin/ directories, and their sbin/ counterparts on systems using split bin/ and sbin/. It is thus safe to use just the executable name in case of executables located in any of the "standard" directories, and an absolute path must be used in other cases. Using an absolute path is recommended to avoid ambiguity. Hint: this search path may be queried using **systemd-path search-binaries-default**.

Example:

```
Environment="ONE=one" "TWO=two two"
ExecStart=echo $ONE ${TWO}
```

This will execute **/bin/echo** with four arguments: "one", "two", "two", and "two two".

Example:

```
Environment=ONE='one' "TWO='two two' too" THREE=
ExecStart=/bin/echo ${ONE} ${TWO} ${THREE}
ExecStart=/bin/echo $ONE ${TWO} ${THREE}
```

This results in **/bin/echo** being called twice, the first time with arguments "'one'", "'two two' too", "", and the second time with arguments "one", "two two", "too".

To pass a literal dollar sign, use "\$\$". Variables whose value is not known at expansion time are treated as empty strings. Note that the first argument (i.e. the program to execute) may not be a variable.

Variables to be used in this fashion may be defined through *Environment=* and *EnvironmentFile=*. In addition, variables listed in the section "Environment variables in spawned processes" in **systemd.exec(5)**, which are considered "static configuration", may be used (this includes e.g. *\$USER*, but not *\$TERM*).

Note that shell command lines are not directly supported. If shell command lines are to be used, they need to be passed explicitly to a shell implementation of some kind. Example:

```
ExecStart=sh -c 'dmesg | tac'
```

Example:

```
ExecStart=echo one ; echo "two two"
```

This will execute **echo** two times, each time with one argument: "one" and "two two", respectively. Because two commands are specified, *Type=oneshot* must be used.

Example:

```
ExecStart=echo / >/dev/null & \
ls
```

This will execute **echo** with five arguments: "/", ">/dev/null", "&", ";", and "ls".

EXAMPLES

Example 2. Simple service

The following unit file creates a service that will execute **/usr/sbin/foo-daemon**. Since no *Type=* is specified, the default *Type=simple* will be assumed. **systemd** will assume the unit to be started immediately after the program has begun executing.

```
[Unit]
Description=Foo
```

```
[Service]
ExecStart=/usr/sbin/foo-daemon
```

```
[Install]
WantedBy=multi-user.target
```

Note that systemd assumes here that the process started by systemd will continue running until the service terminates. If the program daemonizes itself (i.e. forks), please use *Type=forking* instead.

Since no *ExecStop=* was specified, systemd will send SIGTERM to all processes started from this service, and after a timeout also SIGKILL. This behavior can be modified, see **systemd.kill(5)** for details.

Note that this unit type does not include any type of notification when a service has completed initialization. For this, you should use other unit types, such as *Type=notify* if the service understands systemd's notification protocol, *Type=forking* if the service can background itself or *Type=dbus* if the unit acquires a DBus name once initialization is complete. See below.

Example 3. Oneshot service

Sometimes, units should just execute an action without keeping active processes, such as a filesystem check or a cleanup action on boot. For this, *Type=oneshot* exists. Units of this type will wait until the process specified terminates and then fall back to being inactive. The following unit will perform a cleanup action:

```
[Unit]
Description=Cleanup old Foo data
```

```
[Service]
Type=oneshot
ExecStart=/usr/sbin/foo-cleanup
```

```
[Install]
WantedBy=multi-user.target
```

Note that systemd will consider the unit to be in the state "starting" until the program has terminated, so ordered dependencies will wait for the program to finish before starting themselves. The unit will revert to the "inactive" state after the execution is done, never reaching the "active" state. That means another request to start the unit will perform the action again.

Type=oneshot are the only service units that may have more than one *ExecStart=* specified. For units with multiple commands (*Type=oneshot*), all commands will be run again.

For *Type=oneshot*, *Restart=always* and *Restart=on-success* are *not* allowed.

Example 4. Stoppable oneshot service

Similarly to the oneshot services, there are sometimes units that need to execute a program to set up something and then execute another to shut it down, but no process remains active while they are considered "started". Network configuration can sometimes fall into this category. Another use case is if a oneshot service shall not be executed each time when they are pulled in as a dependency, but only the first time.

For this, systemd knows the setting *RemainAfterExit=yes*, which causes systemd to consider the unit to be active if the start action exited successfully. This directive can be used with all types, but is most useful with *Type=oneshot* and *Type=simple*. With *Type=oneshot*, systemd waits until the start action has completed before it considers the unit to be active, so dependencies start only after the start action has succeeded. With *Type=simple*, dependencies will start immediately after the start action has been dispatched. The following unit provides an example for a simple static firewall.

```
[Unit]
Description=Simple firewall
```

```
[Service]
Type=oneshot
RemainAfterExit=yes
ExecStart=/usr/local/sbin/simple-firewall-start
ExecStop=/usr/local/sbin/simple-firewall-stop
```

```
[Install]
WantedBy=multi-user.target
```

Since the unit is considered to be running after the start action has exited, invoking **systemctl start** on that unit again will cause no action to be taken.

Example 5. Traditional forking services

Many traditional daemons/services background (i.e. fork, daemonize) themselves when starting. Set **Type=forking** in the service's unit file to support this mode of operation. systemd will consider the service to be in the process of initialization while the original program is still running. Once it exits successfully and at least a process remains (and *RemainAfterExit=no*), the service is considered started.

Often, a traditional daemon only consists of one process. Therefore, if only one process is left after the original process terminates, systemd will consider that process the main process of the service. In that case, the **\$MAINPID** variable will be available in *ExecReload*=, *ExecStop*=, etc.

In case more than one process remains, systemd will be unable to determine the main process, so it will not assume there is one. In that case, **\$MAINPID** will not expand to anything. However, if the process decides to write a traditional PID file, systemd will be able to read the main PID from there. Please set **PIDFile**= accordingly. Note that the daemon should write that file before finishing with its initialization. Otherwise, systemd might try to read the file before it exists.

The following example shows a simple daemon that forks and just starts one process in the background:

```
[Unit]
Description=Some simple daemon
```

```
[Service]
Type=forking
ExecStart=/usr/sbin/my-simple-daemon -d
```

```
[Install]
WantedBy=multi-user.target
```

Please see **systemd.kill(5)** for details on how you can influence the way systemd terminates the service.

Example 6. DBus services

For services that acquire a name on the DBus system bus, use **Type=dbus** and set **BusName**= accordingly. The service should not fork (daemonize). systemd will consider the service to be initialized once the name has been acquired on the system bus. The following example shows a typical DBus service:

```
[Unit]
Description=Simple DBus service
```

```
[Service]
Type=dbus
BusName=org.example.simple-dbus-service
ExecStart=/usr/sbin/simple-dbus-service
```

```
[Install]
WantedBy=multi-user.target
```

For *bus-activatable* services, do not include a [Install] section in the systemd service file, but use the *SystemdService=* option in the corresponding DBus service file, for example (`/usr/share/dbus-1/system-services/org.example.simple-dbus-service.service`):

```
[D-BUS Service]
Name=org.example.simple-dbus-service
Exec=/usr/sbin/simple-dbus-service
User=root
SystemdService=simple-dbus-service.service
```

Please see **systemd.kill(5)** for details on how you can influence the way systemd terminates the service.

Example 7. Services that notify systemd about their initialization

Type=simple services are really easy to write, but have the major disadvantage of systemd not being able to tell when initialization of the given service is complete. For this reason, systemd supports a simple notification protocol that allows daemons to make systemd aware that they are done initializing. Use *Type=notify* for this. A typical service file for such a daemon would look like this:

```
[Unit]
Description=Simple notifying service

[Service]
Type=notify
ExecStart=/usr/sbin/simple-notifying-service

[Install]
WantedBy=multi-user.target
```

Note that the daemon has to support systemd's notification protocol, else systemd will think the service has not started yet and kill it after a timeout. For an example of how to update daemons to support this protocol transparently, take a look at **sd_notify(3)**. systemd will consider the unit to be in the 'starting' state until a readiness notification has arrived.

Please see **systemd.kill(5)** for details on how you can influence the way systemd terminates the service.

NAME

systemd.time – Time and date specifications

DESCRIPTION

In systemd, timestamps, time spans, and calendar events are displayed and may be specified in closely related syntaxes.

DISPLAYING TIME SPANS

Time spans refer to time durations. On display, systemd will present time spans as a space-separated series of time values each suffixed by a time unit. Example:

2h 30min

All specified time values are meant to be added up. The above hence refers to 150 minutes. Display is locale-independent, only English names for the time units are used.

PARSING TIME SPANS

When parsing, systemd will accept the same time span syntax. Separating spaces may be omitted. The following time units are understood:

- usec, us, μ s
- msec, ms
- seconds, second, sec, s
- minutes, minute, min, m
- hours, hour, hr, h
- days, day, d
- weeks, week, w
- months, month, M (defined as 30.44 days)
- years, year, y (defined as 365.25 days)

If no time unit is specified, generally seconds are assumed, but some exceptions exist and are marked as such. In a few cases "ns", "nsec" is accepted too, where the granularity of the time span permits this. Parsing is generally locale-independent, non-English names for the time units are not accepted.

Examples for valid time span specifications:

2 h

2hours

48hr

1y 12month

55s500ms

300ms20s 5day

One can use the **timespan** command of **systemd-analyze(1)** to normalise a textual time span for testing and validation purposes.

Internally, systemd generally operates with microsecond time granularity, while the default time unit in user-configurable time spans is usually seconds (see above). This disparity becomes visible when comparing the same settings in the (high-level) unit file syntax with the matching (more low-level) D-Bus properties (which are what **systemctl(1)**'s **show** command displays). The former typically are suffixed with "...Sec" to indicate the default unit of seconds, the latter are typically suffixed with "...USec" to indicate the underlying low-level time unit, even if they both encapsulate the very same settings.

DISPLAYING TIMESTAMPSP

Timestamps refer to specific, unique points in time. On display, systemd will format these in the local timezone as follows:

Fri 2012-11-23 23:02:15 CET

The weekday is printed in the abbreviated English language form. The formatting is locale-independent.

In some cases timestamps are shown in the UTC timezone instead of the local timezone, which is indicated via the "UTC" timezone specifier in the output.

In some cases timestamps are shown with microsecond granularity. In this case the sub-second remainder is separated by a full stop from the seconds component.

PARSING TIMESTAMPS

When parsing, systemd will accept a similar syntax, but expects no timezone specification, unless it is given as the literal string "UTC" (for the UTC timezone), or is specified to be the locally configured timezone, or the timezone name in the IANA timezone database format. The complete list of timezones supported on your system can be obtained using the "timedatectl list-timezones" (see [timedatectl\(1\)](#)). Using IANA format is recommended over local timezone names, as less prone to errors (e.g. with local timezone it's possible to specify daylight saving time in winter, even though that is not correct). The weekday specification is optional, but when the weekday is specified, it must either be in the abbreviated ("Wed") or non-abbreviated ("Wednesday") English language form (case does not matter), and is not subject to the locale choice of the user. Either the date, or the time part may be omitted, in which case the current date or 00:00:00, respectively, is assumed. The seconds component of the time may also be omitted, in which case ":00" is assumed. Year numbers may be specified in full or may be abbreviated (omitting the century).

A timestamp is considered invalid if a weekday is specified and the date does not match the specified day of the week.

When parsing, systemd will also accept a few special placeholders instead of timestamps: "now" may be used to refer to the current time (or of the invocation of the command that is currently executed). "today", "yesterday", and "tomorrow" refer to 00:00:00 of the current day, the day before, or the next day, respectively.

When parsing, systemd will also accept relative time specifications. A time span (see above) that is prefixed with "+" is evaluated to the current time plus the specified time span. Correspondingly, a time span that is prefixed with "-" is evaluated to the current time minus the specified time span. Instead of prefixing the time span with "+" or "-", it may also be suffixed with a space and the word "left" or "ago".

Finally, a timespan prefixed with "@" is evaluated relative to the UNIX time epoch 1st Jan, 1970, 00:00.

Examples for valid timestamps and their normalized form (assuming the current time was 2012-11-23 18:15:22 and the timezone was UTC+8, for example "TZ=:Asia/Shanghai"):

```

Fri 2012-11-23 11:12:13 → Fri 2012-11-23 11:12:13
2012-11-23 11:12:13 → Fri 2012-11-23 11:12:13
2012-11-23 11:12:13 UTC → Fri 2012-11-23 19:12:13
2012-11-23 → Fri 2012-11-23 00:00:00
12-11-23 → Fri 2012-11-23 00:00:00
11:12:13 → Fri 2012-11-23 11:12:13
11:12 → Fri 2012-11-23 11:12:00
now → Fri 2012-11-23 18:15:22
today → Fri 2012-11-23 00:00:00
today UTC → Fri 2012-11-23 16:00:00
yesterday → Fri 2012-11-22 00:00:00
tomorrow → Fri 2012-11-24 00:00:00
tomorrow Pacific/Auckland → Thu 2012-11-23 19:00:00
+3h30min → Fri 2012-11-23 21:45:22
-5s → Fri 2012-11-23 18:15:17
11min ago → Fri 2012-11-23 18:04:22
@1395716396 → Tue 2014-03-25 03:59:56

```

Note that timestamps displayed by remote systems with a non-matching timezone are usually not parsable

locally, as the timezone component is not understood (unless it happens to be "UTC").

Timestamps may also be specified with microsecond granularity. The sub-second remainder is expected separated by a full stop from the seconds component. Example:

2014-03-25 03:59:56.654563

In some cases, systemd will display a relative timestamp (relative to the current time, or the time of invocation of the command) instead of or in addition to an absolute timestamp as described above. A relative timestamp is formatted as follows:

2 months 5 days ago

Note that a relative timestamp is also accepted where a timestamp is expected (see above).

Use the **timestamp** command of **systemd-analyze(1)** to validate and normalize timestamps for testing purposes.

CALENDAR EVENTS

Calendar events may be used to refer to one or more points in time in a single expression. They form a superset of the absolute timestamps explained above:

Thu,Fri 2012-*–1,5 11:12:13

The above refers to 11:12:13 of the first or fifth day of any month of the year 2012, but only if that day is a Thursday or Friday.

The weekday specification is optional. If specified, it should consist of one or more English language weekday names, either in the abbreviated (Wed) or non-abbreviated (Wednesday) form (case does not matter), separated by commas. Specifying two weekdays separated by ".." refers to a range of continuous weekdays. "," and ".." may be combined freely.

In the date and time specifications, any component may be specified as "*" in which case any value will match. Alternatively, each component can be specified as a list of values separated by commas. Values may be suffixed with "/" and a repetition value, which indicates that the value itself and the value plus all multiples of the repetition value are matched. Two values separated by ".." may be used to indicate a range of values; ranges may also be followed with "/" and a repetition value, in which case the expression matches all times starting with the start value, and continuing with all multiples of the repetition value relative to the start value, ending at the end value the latest.

A date specification may use "~" to indicate the last day(s) in a month. For example, "*–02~03" means "the third last day in February," and "Mon *–05~07/1" means "the last Monday in May."

The seconds component may contain decimal fractions both in the value and the repetition. All fractions are rounded to 6 decimal places.

Either time or date specification may be omitted, in which case the current day and 00:00:00 is implied, respectively. If the second component is not specified, ":00" is assumed.

Timezone can be specified as the literal string "UTC", or the local timezone, similar to the supported syntax of timestamps (see above), or the timezone in the IANA timezone database format (also see above).

The following special expressions may be used as shorthands for longer normalized forms:

```

minutely → *-*-* *.*:00
hourly → *-*-* *:00:00
daily → *-*-* 00:00:00
monthly → *-*–01 00:00:00
weekly → Mon *-*-* 00:00:00
yearly → *–01–01 00:00:00
quarterly → *–01,04,07,10–01 00:00:00
semianually → *–01,07–01 00:00:00

```

Examples for valid timestamps and their normalized form:

```

Sat,Thu,Mon..Wed,Sat..Sun → Mon..Thu,Sat,Sun *-*-* 00:00:00
Mon,Sun 12-*-* 2,1:23 → Mon,Sun 2012-*-* 01,02:23:00
    Wed *-1 → Wed *-*01 00:00:00
    Wed..Wed,Wed *-1 → Wed *-*01 00:00:00
    Wed, 17:48 → Wed *-*-* 17:48:00
Wed..Sat,Tue 12-10-15 1:2:3 → Tue..Sat 2012-10-15 01:02:03
    *-*7 0:0:0 → *-*07 00:00:00
    10-15 → *-10-15 00:00:00
    monday *-12-* 17:00 → Mon *-12-* 17:00:00
Mon,Fri *-*3,1,2 *:30:45 → Mon,Fri *-*01,02,03 *:30:45
    12,14,13,12:20,10,30 → *-*12,13,14:10,20,30:00
    12..14:10,20,30 → *-*12..14:10,20,30:00
mon,fri *-1/2-1,3 *:30:45 → Mon,Fri *-01/2-01,03 *:30:45
    03-05 08:05:40 → *-03-05 08:05:40
    08:05:40 → *-*-* 08:05:40
    05:40 → *-*-* 05:40:00
Sat,Sun 12-05 08:05:40 → Sat,Sun *-12-05 08:05:40
    Sat,Sun 08:05:40 → Sat,Sun *-*-* 08:05:40
    2003-03-05 05:40 → 2003-03-05 05:40:00
05:40:23.420000/3.1700005 → *-*-* 05:40:23.420000/3.170001
    2003-02..04-05 → 2003-02..04-05 00:00:00
2003-03-05 05:40 UTC → 2003-03-05 05:40:00 UTC
    2003-03-05 → 2003-03-05 00:00:00
    03-05 → *-03-05 00:00:00
    hourly → *-*-* *:00:00
    daily → *-*-* 00:00:00
    daily UTC → *-*-* 00:00:00 UTC
    monthly → *-*-*01 00:00:00
    weekly → Mon *-*-* 00:00:00
weekly Pacific/Auckland → Mon *-*-* 00:00:00 Pacific/Auckland
    yearly → *-01-01 00:00:00
    annually → *-01-01 00:00:00
    *:2/3 → *-*-* *:02/3:00

```

Calendar events are used by timer units, see **systemd.timer(5)** for details.

Use the **calendar** command of **systemd-analyze(1)** to validate and normalize calendar time specifications for testing purposes. The tool also calculates when a specified calendar event would occur next.

NAME

tail – output the last part of files

SYNOPSIS

tail [*OPTION*]... [*FILE*]...

DESCRIPTION

Print the last 10 lines of each FILE to standard output. With more than one FILE, precede each with a header giving the file name.

With no FILE, or when FILE is **-**, read standard input.

Mandatory arguments to long options are mandatory for short options too.

-c, --bytes=[+]NUM

output the last NUM bytes; or use **-c +NUM** to output starting with byte NUM of each file

-f, --follow[={name|descriptor}]

output appended data as the file grows;

an absent option argument means 'descriptor'

-F same as **--follow=name --retry**

-n, --lines=[+]NUM

output the last NUM lines, instead of the last 10; or use **-n +NUM** to output starting with line NUM

--max-unchanged-stats=N

with **--follow=name**, reopen a FILE which has not

changed size after N (default 5) iterations to see if it has been unlinked or renamed (this is the usual case of rotated log files); with inotify, this option is rarely useful

--pid=PID

with **-f**, terminate after process ID, PID dies

-q, --quiet, --silent

never output headers giving file names

--retry

keep trying to open a file if it is inaccessible

-s, --sleep-interval=N

with **-f**, sleep for approximately N seconds (default 1.0) between iterations; with inotify and **--pid=P**, check process P at least once every N seconds

-v, --verbose

always output headers giving file names

-z, --zero-terminated

line delimiter is NUL, not newline

--help display this help and exit

--version

output version information and exit

NUM may have a multiplier suffix: b 512, kB 1000, K 1024, MB 1000*1000, M 1024*1024, GB 1000*1000*1000, G 1024*1024*1024, and so on for T, P, E, Z, Y. Binary prefixes can be used, too: KiB=K, MiB=M, and so on.

With **--follow** (**-f**), tail defaults to following the file descriptor, which means that even if a tail'ed file is renamed, tail will continue to track its end. This default behavior is not desirable when you really want to track the actual name of the file, not the file descriptor (e.g., log rotation). Use **--follow=name** in that case. That causes tail to track the named file in a way that accommodates renaming, removal and creation.

NAME

tar – an archiving utility

SYNOPSIS**Traditional usage**

```
tar {A|c|d|r|t|u|x}[GnSkUWOmpsMBiajJzZhPlRvwo] [ARG...]
```

UNIX-style usage

```
tar -A [OPTIONS] ARCHIVE ARCHIVE
```

```
tar -c [-f ARCHIVE] [OPTIONS] [FILE...]
```

```
tar -d [-f ARCHIVE] [OPTIONS] [FILE...]
```

```
tar -t [-f ARCHIVE] [OPTIONS] [MEMBER...]
```

```
tar -r [-f ARCHIVE] [OPTIONS] [FILE...]
```

```
tar -u [-f ARCHIVE] [OPTIONS] [FILE...]
```

```
tar -x [-f ARCHIVE] [OPTIONS] [MEMBER...]
```

GNU-style usage

```
tar {--catenate|--concatenate} [OPTIONS] ARCHIVE ARCHIVE
```

```
tar --create [--file ARCHIVE] [OPTIONS] [FILE...]
```

```
tar {--diff|--compare} [--file ARCHIVE] [OPTIONS] [FILE...]
```

```
tar --delete [--file ARCHIVE] [OPTIONS] [MEMBER...]
```

```
tar --append [-f ARCHIVE] [OPTIONS] [FILE...]
```

```
tar --list [-f ARCHIVE] [OPTIONS] [MEMBER...]
```

```
tar --test-label [--file ARCHIVE] [OPTIONS] [LABEL...]
```

```
tar --update [--file ARCHIVE] [OPTIONS] [FILE...]
```

```
tar --update [-f ARCHIVE] [OPTIONS] [FILE...]
```

```
tar {--extract|--get} [-f ARCHIVE] [OPTIONS] [MEMBER...]
```

NOTE

This manpage is a short description of GNU **tar**. For a detailed discussion, including examples and usage recommendations, refer to the **GNU Tar Manual** available in texinfo format. If the **info** reader and the tar documentation are properly installed on your system, the command

```
info tar
```

should give you access to the complete manual.

You can also view the manual using the info mode in **emacs(1)**, or find it in various formats online at

```
http://www.gnu.org/software/tar/manual
```

If any discrepancies occur between this manpage and the **GNU Tar Manual**, the later shall be considered the authoritative source.

DESCRIPTION

GNU **tar** is an archiving program designed to store multiple files in a single file (an **archive**), and to manipulate such archives. The archive can be either a regular file or a device (e.g. a tape drive, hence the name of the program, which stands for **tape archiver**), which can be located either on the local or on a remote machine.

Option styles

Options to GNU **tar** can be given in three different styles. In **traditional style**, the first argument is a cluster of option letters and all subsequent arguments supply arguments to those options that require them. The arguments are read in the same order as the option letters. Any command line words that remain after all options have been processed are treated as non-optional arguments: file or archive member names.

For example, the **c** option requires creating the archive, the **v** option requests the verbose operation, and the **f** option takes an argument that sets the name of the archive to operate upon. The following command, written in the traditional style, instructs tar to store all files from the directory **/etc** into the archive file **etc.tar** verbosely listing the files being archived:

```
tar cfv etc.tar /etc
```

In **UNIX** or **short-option style**, each option letter is prefixed with a single dash, as in other command line utilities. If an option takes argument, the argument follows it, either as a separate command line word, or immediately following the option. However, if the option takes an **optional** argument, the argument must follow the option letter without any intervening whitespace, as in **-g/tmp/snar.db**.

Any number of options not taking arguments can be clustered together after a single dash, e.g. **-vkp**. Options that take arguments (whether mandatory or optional), can appear at the end of such a cluster, e.g. **-vkpf a.tar**.

The example command above written in the **short-option style** could look like:

```
tar -cvf etc.tar /etc
or
tar -c -v -f etc.tar /etc
```

In **GNU** or **long-option style**, each option begins with two dashes and has a meaningful name, consisting of lower-case letters and dashes. When used, the long option can be abbreviated to its initial letters, provided that this does not create ambiguity. Arguments to long options are supplied either as a separate command line word, immediately following the option, or separated from the option by an equals sign with no intervening whitespace. Optional arguments must always use the latter method.

Here are several ways of writing the example command in this style:

```
tar --create --file etc.tar --verbose /etc
or (abbreviating some options):
tar --cre --file=etc.tar --verb /etc
```

The options in all three styles can be intermixed, although doing so with old options is not encouraged.

Operation mode

The options listed in the table below tell GNU **tar** what operation it is to perform. Exactly one of them must be given. Meaning of non-optional arguments depends on the operation mode requested.

-A, --catenate, --concatenate

Append archive to the end of another archive. The arguments are treated as the names of archives to append. All archives must be of the same format as the archive they are appended to, otherwise the resulting archive might be unusable with non-GNU implementations of **tar**. Notice also that when more than one archive is given, the members from archives other than the first one will be accessible in the resulting archive only if using the **-i** (**--ignore-zeros**) option.

Compressed archives cannot be concatenated.

-c, --create

Create a new archive. Arguments supply the names of the files to be archived. Directories are archived recursively, unless the **--no-recursion** option is given.

-d, --diff, --compare

Find differences between archive and file system. The arguments are optional and specify archive members to compare. If not given, the current working directory is assumed.

--delete

Delete from the archive. The arguments supply names of the archive members to be removed. At least one argument must be given.

This option does not operate on compressed archives. There is no short option equivalent.

-r, --append

Append files to the end of an archive. Arguments have the same meaning as for **-c** (**--create**).

-t, --list

List the contents of an archive. Arguments are optional. When given, they specify the names of the members to list.

--test-label

Test the archive volume label and exit. When used without arguments, it prints the volume label (if any) and exits with status **0**. When one or more command line arguments are given, **tar** compares the volume label with each argument. It exits with code **0** if a match is found, and with code **1** otherwise. No output is displayed, unless used together with the **-v** (**--verbose**) option.

There is no short option equivalent for this option.

-u, --update

Append files which are newer than the corresponding copy in the archive. Arguments have the same meaning as with **-c** and **-r** options. Notice, that newer files don't replace their old archive copies, but instead are appended to the end of archive. The resulting archive can thus contain several members of the same name, corresponding to various versions of the same file.

-x, --extract, --get

Extract files from an archive. Arguments are optional. When given, they specify names of the archive members to be extracted.

--show-defaults

Show built-in defaults for various **tar** options and exit. No arguments are allowed.

-?, --help

Display a short option summary and exit. No arguments allowed.

--usage

Display a list of available options and exit. No arguments allowed.

--version

Print program version and copyright information and exit.

OPTIONS**Operation modifiers****--check-device**

Check device numbers when creating incremental archives (default).

-g, --listed-incremental=FILE

Handle new GNU-format incremental backups. *FILE* is the name of a **snapshot file**, where tar stores additional information which is used to decide which files changed since the previous incremental dump and, consequently, must be dumped again. If *FILE* does not exist when creating an archive, it will be created and all files will be added to the resulting archive (the **level 0** dump). To create incremental archives of non-zero level *N*, create a copy of the snapshot file created during

the level **N-1**, and use it as *FILE*.

When listing or extracting, the actual contents of *FILE* is not inspected, it is needed only due to syntactical requirements. It is therefore common practice to use **/dev/null** in its place.

--hole-detection=METHOD

Use *METHOD* to detect holes in sparse files. This option implies **--sparse**. Valid values for *METHOD* are **seek** and **raw**. Default is **seek** with fallback to **raw** when not applicable.

-G, --incremental

Handle old GNU-format incremental backups.

--ignore-failed-read

Do not exit with nonzero on unreadable files.

--level=NUMBER

Set dump level for created listed-incremental archive. Currently only **--level=0** is meaningful: it instructs **tar** to truncate the snapshot file before dumping, thereby forcing a level 0 dump.

-n, --seek

Assume the archive is seekable. Normally **tar** determines automatically whether the archive can be seeked or not. This option is intended for use in cases when such recognition fails. It takes effect only if the archive is open for reading (e.g. with **--list** or **--extract** options).

--no-check-device

Do not check device numbers when creating incremental archives.

--no-seek

Assume the archive is not seekable.

--occurrence[=N]

Process only the *N*th occurrence of each file in the archive. This option is valid only when used with one of the following subcommands: **--delete**, **--diff**, **--extract** or **--list** and when a list of files is given either on the command line or via the **-T** option. The default *N* is **1**.

--restrict

Disable the use of some potentially harmful options.

--sparse-version=MAJOR[.MINOR]

Set version of the sparse format to use (implies **--sparse**). This option implies **--sparse**. Valid argument values are **0.0**, **0.1**, and **1.0**. For a detailed discussion of sparse formats, refer to the **GNU Tar Manual**, appendix **D**, "Sparse Formats". Using **inf o** reader, it can be accessed running the following command: **info tar 'Sparse Formats'**.

-S, --sparse

Handle sparse files efficiently. Some files in the file system may have segments which were actually never written (quite often these are database files created by such systems as **DBM**). When given this option, **tar** attempts to determine if the file is sparse prior to archiving it, and if so, to reduce the resulting archive size by not dumping empty parts of the file.

Overwrite control

These options control **tar** actions when extracting a file over an existing copy on disk.

-k, --keep-old-files

Don't replace existing files when extracting.

--keep-newer-files

Don't replace existing files that are newer than their archive copies.

--keep-directory-symlink

Don't replace existing symlinks to directories when extracting.

--no-overwrite-dir

Preserve metadata of existing directories.

--one-top-level[=DIR]

Extract all files into *DIR*, or, if used without argument, into a subdirectory named by the base name of the archive (minus standard compression suffixes recognizable by **--auto-compress**).

--overwrite

Overwrite existing files when extracting.

--overwrite-dir

Overwrite metadata of existing directories when extracting (default).

--recursive-unlink

Recursively remove all files in the directory prior to extracting it.

--remove-files

Remove files from disk after adding them to the archive.

--skip-old-files

Don't replace existing files when extracting, silently skip over them.

-U, --unlink-first

Remove each file prior to extracting over it.

-W, --verify

Verify the archive after writing it.

Output stream selection**--ignore-command-error**

Ignore subprocess exit codes.

--no-ignore-command-error

Treat non-zero exit codes of children as error (default).

-O, --to-stdout

Extract files to standard output.

--to-command=COMMAND

Pipe extracted files to *COMMAND*. The argument is the pathname of an external program, optionally with command line arguments. The program will be invoked and the contents of the file being extracted supplied to it on its standard input. Additional data will be supplied via the following environment variables:

TAR_FILETYPE

Type of the file. It is a single letter with the following meaning:

f	Regular file
d	Directory
l	Symbolic link
h	Hard link
b	Block device
c	Character device

Currently only regular files are supported.

TAR_MODE

File mode, an octal number.

TAR_FILENAME

The name of the file.

TAR_REALNAME

Name of the file as stored in the archive.

TAR_UNAME

Name of the file owner.

TAR_GNAME

Name of the file owner group.

TAR_ATIME

Time of last access. It is a decimal number, representing seconds since the Epoch. If the archive provides times with nanosecond precision, the nanoseconds are appended to the timestamp after a decimal point.

TAR_MTIME

Time of last modification.

TAR_CTIME

Time of last status change.

TAR_SIZE

Size of the file.

TAR_UID

UID of the file owner.

TAR_GID

GID of the file owner.

Additionally, the following variables contain information about **tar** operation mode and the archive being processed:

TAR_VERSION

GNU **tar** version number.

TAR_ARCHIVE

The name of the archive **tar** is processing.

TAR_BLOCKING_FACTOR

Current blocking factor, i.e. number of 512-byte blocks in a record.

TAR_VOLUME

Ordinal number of the volume **tar** is processing (set if reading a multi-volume archive).

TAR_FORMAT

Format of the archive being processed. One of: **gnu**, **oldgnu**, **posix**, **ustar**, **v7**.

TAR_SUBCOMMAND

A short option (with a leading dash) describing the operation **tar** is executing.

Handling of file attributes**--atime-preserve[=METHOD]**

Preserve access times on dumped files, either by restoring the times after reading (*METHOD=replace*, this is the default) or by not setting the times in the first place (*METHOD=system*)

--delay-directory-restore

Delay setting modification times and permissions of extracted directories until the end of extraction. Use this option when extracting from an archive which has unusual member ordering.

--group=NAME[:GID]

Force *NAME* as group for added files. If *GID* is not supplied, *NAME* can be either a user name or numeric GID. In this case the missing part (GID or name) will be inferred from the current host's group database.

When used with **--group-map=FILE**, affects only those files whose owner group is not listed in

FILE.

--group-map=FILE

Read group translation map from *FILE*. Empty lines are ignored. Comments are introduced with # sign and extend to the end of line. Each non-empty line in *FILE* defines translation for a single group. It must consist of two fields, delimited by any amount of whitespace:

OLDGRP NEWGRP[:NEWGID]

OLDGRP is either a valid group name or a GID prefixed with +. Unless *NEWGID* is supplied, *NEWGRP* must also be either a valid group name or a +*GID*. Otherwise, both *NEWGRP* and *NEWGID* need not be listed in the system group database.

As a result, each input file with owner group *OLDGRP* will be stored in archive with owner group *NEWGRP* and GID *NEWGID*.

--mode=CHANGES

Force symbolic mode *CHANGES* for added files.

--mtime=DATE-OR-FILE

Set mtime for added files. *DATE-OR-FILE* is either a date/time in almost arbitrary format, or the name of an existing file. In the latter case the mtime of that file will be used.

-m, --touch

Don't extract file modified time.

--no-delay-directory-restore

Cancel the effect of the prior **--delay-directory-restore** option.

--no-same-owner

Extract files as yourself (default for ordinary users).

--no-same-permissions

Apply the user's umask when extracting permissions from the archive (default for ordinary users).

--numeric-owner

Always use numbers for user/group names.

--owner=NAME[:UID]

Force *NAME* as owner for added files. If *UID* is not supplied, *NAME* can be either a user name or numeric UID. In this case the missing part (UID or name) will be inferred from the current host's user database.

When used with **--owner-map=FILE**, affects only those files whose owner is not listed in *FILE*.

--owner-map=FILE

Read owner translation map from *FILE*. Empty lines are ignored. Comments are introduced with # sign and extend to the end of line. Each non-empty line in *FILE* defines translation for a single UID. It must consist of two fields, delimited by any amount of whitespace:

OLDUSR NEWUSR[:NEWUID]

OLDUSR is either a valid user name or a UID prefixed with +. Unless *NEWUID* is supplied, *NEWUSR* must also be either a valid user name or a +*UID*. Otherwise, both *NEWUSR* and *NEWUID* need not be listed in the system user database.

As a result, each input file owned by *OLDUSR* will be stored in archive with owner name *NEWUSR* and UID *NEWUID*.

-p, --preserve-permissions, --same-permissions

extract information about file permissions (default for superuser)

--same-owner

Try extracting files with the same ownership as exists in the archive (default for superuser).

-s, --preserve-order, --same-order

Sort names to extract to match archive

--sort=ORDER

When creating an archive, sort directory entries according to *ORDER*, which is one of **none**, **name**, or **inode**.

The default is **--sort=none**, which stores archive members in the same order as returned by the operating system.

Using **--sort=name** ensures the member ordering in the created archive is uniform and reproducible.

Using **--sort=inode** reduces the number of disk seeks made when creating the archive and thus can considerably speed up archivation. This sorting order is supported only if the underlying system provides the necessary information.

Extended file attributes

--acls Enable POSIX ACLs support.

--no-acls

Disable POSIX ACLs support.

--selinux

Enable SELinux context support.

--no-selinux

Disable SELinux context support.

--xattrs

Enable extended attributes support.

--no-xattrs

Disable extended attributes support.

--xattrs-exclude=PATTERN

Specify the exclude pattern for xattr keys. *PATTERN* is a POSIX regular expression, e.g. **--xattrs-exclude='^user.'**, to exclude attributes from the user namespace.

--xattrs-include=PATTERN

Specify the include pattern for xattr keys. *PATTERN* is a POSIX regular expression.

Device selection and switching**-f, --file=ARCHIVE**

Use archive file or device *ARCHIVE*. If this option is not given, **tar** will first examine the environment variable ‘TAPE’. If it is set, its value will be used as the archive name. Otherwise, **tar** will assume the compiled-in default. The default value can be inspected either using the **--show-defaults** option, or at the end of the **tar --help** output.

An archive name that has a colon in it specifies a file or device on a remote machine. The part before the colon is taken as the machine name or IP address, and the part after it as the file or device pathname, e.g.:

```
--file=remotehost:/dev/sr0
```

An optional username can be prefixed to the hostname, placing a @ sign between them.

By default, the remote host is accessed via the **rsh(1)** command. Nowadays it is common to use **ssh(1)** instead. You can do so by giving the following command line option:

```
--rsh-command=/usr/bin/ssh
```

The remote machine should have the **rmt(8)** command installed. If its pathname does not match **tar**'s default, you can inform **tar** about the correct pathname using the **--rmt-command** option.

--force-local

Archive file is local even if it has a colon.

-F, --info-script=COMMAND, --new-volume-script=COMMAND

Run *COMMAND* at the end of each tape (implies **-M**). The command can include arguments. When started, it will inherit **tar**'s environment plus the following variables:

TAR_VERSION

GNU **tar** version number.

TAR_ARCHIVE

The name of the archive **tar** is processing.

TAR_BLOCKING_FACTOR

Current blocking factor, i.e. number of 512-byte blocks in a record.

TAR_VOLUME

Ordinal number of the volume **tar** is processing (set if reading a multi-volume archive).

TAR_FORMAT

Format of the archive being processed. One of: **gnu**, **oldgnu**, **posix**, **ustar**, **v7**.

TAR_SUBCOMMAND

A short option (with a leading dash) describing the operation **tar** is executing.

TAR_FD

File descriptor which can be used to communicate the new volume name to **tar**.

If the info script fails, **tar** exits; otherwise, it begins writing the next volume.

-L, --tape-length=N

Change tape after writing *N*×1024 bytes. If *N* is followed by a size suffix (see the subsection **Size suffixes** below), the suffix specifies the multiplicative factor to be used instead of 1024.

This option implies **-M**.

-M, --multi-volume

Create/list/extract multi-volume archive.

--rmt-command=COMMAND

Use *COMMAND* instead of **rmt** when accessing remote archives. See the description of the **-f** option, above.

--rsh-command=COMMAND

Use *COMMAND* instead of **rsh** when accessing remote archives. See the description of the **-f** option, above.

--volno-file=FILE

When this option is used in conjunction with **--multi-volume**, **tar** will keep track of which volume of a multi-volume archive it is working in *FILE*.

Device blocking

-b, --blocking-factor=BLOCKS

Set record size to *BLOCKS*×512 bytes.

-B, --read-full-records

When listing or extracting, accept incomplete input records after end-of-file marker.

-i, --ignore-zeros

Ignore zeroed blocks in archive. Normally two consecutive 512-blocks filled with zeroes mean EOF and tar stops reading after encountering them. This option instructs it to read further and is useful when reading archives created with the **-A** option.

--record-size=NUMBER

Set record size. *NUMBER* is the number of bytes per record. It must be multiple of **512**. It can be suffixed with a **size suffix**, e.g. **--record-size=10K**, for 10 Kilobytes. See the subsection **Size suffixes**, for a list of valid suffixes.

Archive format selection**-H, --format=FORMAT**

Create archive of the given format. Valid formats are:

gnu GNU tar 1.13.x format

oldgnu GNU format as per tar <= 1.12.

pax, posix

POSIX 1003.1-2001 (pax) format.

ustar POSIX 1003.1-1988 (ustar) format.

v7 Old V7 tar format.

--old-archive, --portability

Same as **--format=v7**.

--pax-option=keyword[[[:]=value][,[keyword[[[:]=value]]...]

Control pax keywords when creating **PAX** archives (**-H pax**). This option is equivalent to the **-o** option of the **pax(1)** utility.

--posix

Same as **--format=posix**.

-V, --label=TEXT

Create archive with volume name *TEXT*. If listing or extracting, use *TEXT* as a globbing pattern for volume name.

Compression options**-a, --auto-compress**

Use archive suffix to determine the compression program.

-I, --use-compress-program=COMMAND

Filter data through *COMMAND*. It must accept the **-d** option, for decompression. The argument can contain command line options.

-j, --bzip2

Filter the archive through **bzip2(1)**.

-J, --xz

Filter the archive through **xz(1)**.

--lzip Filter the archive through **lzip(1)**.**--lzma**

Filter the archive through **lzma(1)**.

--lzop Filter the archive through **lzop(1)**.**--no-auto-compress**

Do not use archive suffix to determine the compression program.

-z, --gzip, --gunzip, --ungzip
 Filter the archive through **gzip(1)**.

-Z, --compress, --uncompress
 Filter the archive through **compress(1)**.
--zstd Filter the archive through **zstd(1)**.

Local file selection

--add-file=FILE
 Add *FILE* to the archive (useful if its name starts with a dash).

--backup[=CONTROL]
 Backup before removal. The *CONTROL* argument, if supplied, controls the backup policy. Its valid values are:

none, off
 Never make backups.

t, numbered
 Make numbered backups.

nil, existing
 Make numbered backups if numbered backups exist, simple backups otherwise.

never, simple
 Always make simple backups

If *CONTROL* is not given, the value is taken from the **VERSION_CONTROL** environment variable. If it is not set, **existing** is assumed.

-C, --directory=DIR

Change to *DIR* before performing any operations. This option is order-sensitive, i.e. it affects all options that follow.

--exclude=PATTERN

Exclude files matching *PATTERN*, a **glob(3)**-style wildcard pattern.

--exclude-backups

Exclude backup and lock files.

--exclude-caches

Exclude contents of directories containing file **CACHEDIR.TAG**, except for the tag file itself.

--exclude-caches-all

Exclude directories containing file **CACHEDIR.TAG** and the file itself.

--exclude-caches-under

Exclude everything under directories containing **CACHEDIR.TAG**

--exclude-ignore=FILE

Before dumping a directory, see if it contains *FILE*. If so, read exclusion patterns from this file. The patterns affect only the directory itself.

--exclude-ignore-recursive=FILE

Same as **--exclude-ignore**, except that patterns from *FILE* affect both the directory and all its subdirectories.

--exclude-tag=FILE

Exclude contents of directories containing *FILE*, except for *FILE* itself.

--exclude-tag-all=FILE

Exclude directories containing *FILE*.

- exclude-tag-under=FILE**
Exclude everything under directories containing *FILE*.
- exclude-vcs**
Exclude version control system directories.
- exclude-vcs-ignores**
Exclude files that match patterns read from VCS-specific ignore files. Supported files are: **.cvsignore**, **.gitignore**, **.bzrignore**, and **.hgignore**.
- h, --dereference**
Follow symlinks; archive and dump the files they point to.
- hard-dereference**
Follow hard links; archive and dump the files they refer to.
- K, --starting-file=MEMBER**
Begin at the given member in the archive.
- newer-mtime=DATE**
Work on files whose data changed after the *DATE*. If *D ATE* starts with / or . it is taken to be a file name; the mtime of that file is used as the date.
- no-null**
Disable the effect of the previous **--null** option.
- no-recursion**
Avoid descending automatically in directories.
- no-unquote**
Do not unquote input file or member names.
- no-verbatim-files-from**
Treat each line read from a file list as if it were supplied in the command line. I.e., leading and trailing whitespace is removed and, if the resulting string begins with a dash, it is treated as **tar** command line option.

This is the default behavior. The **--no-verbatim-files-from** option is provided as a way to restore it after **--verbatim-files-from** option.

This option is positional: it affects all **--files-from** options that occur after it in, until **--verbatim-files-from** option or end of line, whichever occurs first.

It is implied by the **--no-null** option.
--null Instruct subsequent **-T** options to read null-terminated names verbatim (disables special handling of names that start with a dash).

See also **--verbatim-files-from**.
- N, --newer=DATE, --after-date=DATE**
Only store files newer than *DATE*. If *D ATE* starts with / or . it is taken to be a file name; the mtime of that file is used as the date.
- one-file-system**
Stay in local file system when creating archive.
- P, --absolute-names**
Don't strip leading slashes from file names when creating archives.
- recursion**
Recurse into directories (default).

--suffix=STRING

Backup before removal, override usual suffix. Default suffix is `~`, unless overridden by environment variable `SIMPLE_BACKUP_SUFFIX`.

-T, --files-from=FILE

Get names to extract or create from *FILE*.

Unless specified otherwise, the *FILE* must contain a list of names separated by ASCII **LF** (i.e. one name per line). The names read are handled the same way as command line arguments. They undergo quote removal and word splitting, and any string that starts with a `-` is handled as **tar** command line option.

If this behavior is undesirable, it can be turned off using the **--verbatim-files-from** option.

The **--null** option instructs **tar** that the names in *FILE* are separated by ASCII **NUL** character, instead of **LF**. It is useful if the list is generated by **find(1) -print0** predicate.

--unquote

Unquote file or member names (default).

--verbatim-files-from

Treat each line obtained from a file list as a file name, even if it starts with a dash. File lists are supplied with the **--files-from** (**-T**) option. The default behavior is to handle names supplied in file lists as if they were typed in the command line, i.e. any names starting with a dash are treated as **tar** options. The **--verbatim-files-from** option disables this behavior.

This option affects all **--files-from** options that occur after it in the command line. Its effect is reverted by the **--no-verbatim-files-from** option.

This option is implied by the --null option.

See also **--add-file**.

-X, --exclude-from=FILE

Exclude files matching patterns listed in *FILE*.

File name transformations**--strip-components=NUMBER**

Strip *NUMBER* leading components from file names on extraction.

--transform=EXPRESSION, --xform=EXPRESSION

Use sed replace *EXPRESSION* to transform file names.

File name matching options

These options affect both exclude and include patterns.

--anchored

Patterns match file name start.

--ignore-case

Ignore case.

--no-anchored

Patterns match after any `/` (default for exclusion).

--no-ignore-case

Case sensitive matching (default).

--no-wildcards

Verbatim string matching.

--no-wildcards-match-slash

Wildcards do not match /.

--wildcards

Use wildcards (default for exclusion).

--wildcards-match-slash

Wildcards match / (default for exclusion).

Informative output**--checkpoint[=N]**

Display progress messages every *N*th record (default 10).

--checkpoint-action=ACTION

Run *ACTION* on each checkpoint.

--clamp-mtime

Only set time when the file is more recent than what was given with --mtime.

--full-time

Print file time to its full resolution.

--index-file=FILE

Send verbose output to *FILE*.

-l, --check-links

Print a message if not all links are dumped.

--no-quote-chars=STRING

Disable quoting for characters from *STRING*.

--quote-chars=STRING

Additionally quote characters from *STRING*.

--quoting-style=STYLE

Set quoting style for file and member names. Valid values for *STYLE* are **literal**, **shell**, **shell-always**, **c**, **c-maybe**, **escape**, **locale**, **clocale**.

-R, --block-number

Show block number within archive with each message.

--show-omitted-dirs

When listing or extracting, list each directory that does not match search criteria.

--show-transformed-names, --show-stored-names

Show file or archive names after transformation by --strip and --transform options.

--totals[=SIGNAL]

Print total bytes after processing the archive. If *SIGNAL* is given, print total bytes when this signal is delivered. Allowed signals are: **SIGHUP**, **SIGQUIT**, **SIGINT**, **SIGUSR1**, and **SIGUSR2**. The **SIG** prefix can be omitted.

--utc

Print file modification times in UTC.

-v, --verbose

Verbosely list files processed. Each instance of this option on the command line increases the verbosity level by one. The maximum verbosity level is 3. For a detailed discussion of how various verbosity levels affect tar's output, please refer to **GNU Tar Manual**, subsection 2.5.1 "The --verbose Option".

--warning=KEYWORD

Enable or disable warning messages identified by *KEYWORD*. The messages are suppressed if *KEYWORD* is prefixed with **no-** and enabled otherwise.

Multiple --warning messages accumulate.

Keywords controlling general **tar** operation:

all Enable all warning messages. This is the default.

none Disable all warning messages.

filename-with-nuls

"%s: file name read contains nul character"

alone-zero-block

"A lone zero block at %s"

Keywords applicable for **tar --create**:

cachedir

"%s: contains a cache directory tag %s; %s"

file-shrank

"%s: File shrank by %s bytes; padding with zeros"

xdev "%s: file is on a different filesystem; not dumped"

file-ignored

"%s: Unknown file type; file ignored"

"%s: socket ignored"

"%s: door ignored"

file-unchanged

"%s: file is unchanged; not dumped"

ignore-archive

"%s: file is the archive; not dumped"

file-removed

"%s: File removed before we read it"

file-changed

"%s: file changed as we read it"

failed-read

Suppresses warnings about unreadable files or directories. This keyword applies only if used together with the **--ignore-failed-read** option.

Keywords applicable for **tar --extract**:

existing-file

"%s: skipping existing file"

timestamp

"%s: implausibly old time stamp %s"

"%s: time stamp %s is %s s in the future"

contiguous-cast

"Extracting contiguous files as regular files"

symlink-cast

"Attempting extraction of symbolic links as hard links"

unknown-cast

"%s: Unknown file type '%c', extracted as normal file"

ignore-newer

"Current %s is newer or same age"

unknown-keyword

"Ignoring unknown extended header keyword '%s'"

decompress-program

Controls verbose description of failures occurring when trying to run alternative decompressor programs. This warning is disabled by default (unless **--verbose** is used). A common example of what you can get when using this warning is:

```
$ tar --warning=decompress-program -x -f archive.Z
tar (child): cannot run compress: No such file or directory
tar (child): trying gzip
```

This means that **tar** first tried to decompress **archive.Z** using **compress**, and, when that failed, switched to **gzip**.

record-size

"Record size = %lu blocks"

Keywords controlling incremental extraction:

rename-directory

"%s: Directory has been renamed from %s"
"%s: Directory has been renamed"

new-directory

"%s: Directory is new"

xdev

"%s: directory is on a different device: not purging"

bad-dumpdir

"Malformed dumpdir: 'X' never used"

-w, --interactive, --confirmation

Ask for confirmation for every action.

Compatibility options

-o When creating, same as **--old-archive**. When extracting, same as **--no-same-owner**.

Size suffixes

<i>Suffix</i>	<i>Units</i>	<i>Byte Equivalent</i>
b	Blocks	<i>SIZE</i> x 512
B	Kilobytes	<i>SIZE</i> x 1024
c	Bytes	<i>SIZE</i>
G	Gigabytes	<i>SIZE</i> x 1024^3
K	Kilobytes	<i>SIZE</i> x 1024
k	Kilobytes	<i>SIZE</i> x 1024
M	Megabytes	<i>SIZE</i> x 1024^2
P	Petabytes	<i>SIZE</i> x 1024^5
T	Terabytes	<i>SIZE</i> x 1024^4
w	Words	<i>SIZE</i> x 2

RETURN VALUE

Tar exit code indicates whether it was able to successfully perform the requested operation, and if not, what kind of error occurred.

- 0** Successful termination.
- 1** *Some files differ*: If tar was invoked with the **--compare** (**--diff**, **-d**) command line option, this means that some files in the archive differ from their disk counterparts. If tar was given one of the **--create**, **--append** or **--update** options, this exit code means that some files were changed while being archived and so the resulting archive does not contain the exact copy of the file set.
- 2** *Fatal error*: This means that some fatal, unrecoverable error occurred.

If a subprocess that had been invoked by **tar** exited with a nonzero exit code, **tar** itself exits with that code as well. This can happen, for example, if a compression option (e.g. **-z**) was used and the external

compressor program failed. Another example is **rmt** failure during backup to a remote device.

NAME

tee – read from standard input and write to standard output and files

SYNOPSIS

tee [*OPTION*]... [*FILE*]...

DESCRIPTION

Copy standard input to each FILE, and also to standard output.

-a, --append

append to the given FILES, do not overwrite

-i, --ignore-interrupts

ignore interrupt signals

-p diagnose errors writing to non pipes

--output-error[=*MODE*]

set behavior on write error. See MODE below

--help display this help and exit

--version

output version information and exit

MODE determines behavior with write errors on the outputs:

'warn' diagnose errors writing to any output

'warn-nopipe'

diagnose errors writing to any output not a pipe

'exit' exit on error writing to any output

'exit-nopipe'

exit on error writing to any output not a pipe

The default MODE for the **-p** option is 'warn-nopipe'. The default operation when **--output-error** is not specified, is to exit immediately on error writing to a pipe, and diagnose errors writing to non pipe outputs.

NAME

tee – duplicating pipe content

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#define _GNU_SOURCE      /* See feature_test_macros(7) */
#include <fcntl.h>
ssize_t tee(int fd_in, int fd_out, size_t len, unsigned int flags);
```

DESCRIPTION

tee() duplicates up to *len* bytes of data from the pipe referred to by the file descriptor *fd_in* to the pipe referred to by the file descriptor *fd_out*. It does not consume the data that is duplicated from *fd_in*; therefore, that data can be copied by a subsequent **splice(2)**.

flags is a bit mask that is composed by ORing together zero or more of the following values:

SPLICE_F_MOVE	Currently has no effect for tee() ; see splice(2) .
SPLICE_F_NONBLOCK	Do not block on I/O; see splice(2) for further details.
SPLICE_F_MORE	Currently has no effect for tee() , but may be implemented in the future; see splice(2) .
SPLICE_F_GIFT	Unused for tee() ; see vmsplice(2) .

RETURN VALUE

Upon successful completion, **tee()** returns the number of bytes that were duplicated between the input and output. A return value of 0 means that there was no data to transfer, and it would not make sense to block, because there are no writers connected to the write end of the pipe referred to by *fd_in*.

On error, **tee()** returns -1 and *errno* is set to indicate the error.

ERRORS

EAGAIN

SPLICE_F_NONBLOCK was specified in *flags* or one of the file descriptors had been marked as nonblocking (**O_NONBLOCK**), and the operation would block.

EINVAL

fd_in or *fd_out* does not refer to a pipe; or *fd_in* and *fd_out* refer to the same pipe.

ENOMEM

Out of memory.

VERSIONS

The **tee()** system call first appeared in Linux 2.6.17; library support was added in glibc 2.5.

STANDARDS

This system call is Linux-specific.

NOTES

Conceptually, **tee()** copies the data between the two pipes. In reality no real data copying takes place though: under the covers, **tee()** assigns data to the output by merely grabbing a reference to the input.

EXAMPLES

The example below implements a basic **tee(1)** program using the **tee()** system call. Here is an example of its use:

```
$ date | ./a.out out.log | cat
Tue Oct 28 10:06:00 CET 2014
$ cat out.log
Tue Oct 28 10:06:00 CET 2014
```

Program source

```

#define _GNU_SOURCE
#include <errno.h>
#include <fcntl.h>
#include <limits.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int      fd;
    ssize_t  len, slen;

    if (argc != 2) {
        fprintf(stderr, "Usage: %s <file>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fd = open(argv[1], O_WRONLY | O_CREAT | O_TRUNC, 0644);
    if (fd == -1) {
        perror("open");
        exit(EXIT_FAILURE);
    }

    for (;;) {
        /*
         * tee stdin to stdout.
         */
        len = tee(STDIN_FILENO, STDOUT_FILENO,
                  INT_MAX, SPLICE_F_NONBLOCK);
        if (len < 0) {
            if (errno == EAGAIN)
                continue;
            perror("tee");
            exit(EXIT_FAILURE);
        }
        if (len == 0)
            break;

        /*
         * Consume stdin by splicing it to a file.
         */
        while (len > 0) {
            slen = splice(STDIN_FILENO, NULL, fd, NULL,
                          len, SPLICE_F_MOVE);
            if (slen < 0) {
                perror("splice");
                exit(EXIT_FAILURE);
            }
            len -= slen;
        }
    }
}

```

```
    }  
  
    close(fd);  
    exit(EXIT_SUCCESS);  
}
```

SEE ALSO

[splice\(2\)](#), [vmsplice\(2\)](#), [pipe\(7\)](#)

NAME

tkill, **tkill** – send a signal to a thread

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <signal.h>      /* Definition of SIG* constants */
#include <sys/syscall.h>   /* Definition of SYS_* constants */
#include <unistd.h>

[[deprecated]] int syscall(SYS_tkill, pid_t tid, int sig);

#include <signal.h>

int tkill(pid_t tgid, pid_t tid, int sig);
```

Note: glibc provides no wrapper for **tkill()**, necessitating the use of **syscall(2)**.

DESCRIPTION

tgkill() sends the signal *sig* to the thread with the thread ID *tid* in the thread group *tgid*. (By contrast, **kill(2)** can be used to send a signal only to a process (i.e., thread group) as a whole, and the signal will be delivered to an arbitrary thread within that process.)

tkill() is an obsolete predecessor to **tgkill()**. It allows only the target thread ID to be specified, which may result in the wrong thread being signaled if a thread terminates and its thread ID is recycled. Avoid using this system call.

These are the raw system call interfaces, meant for internal thread library use.

RETURN VALUE

On success, zero is returned. On error, **-1** is returned, and *errno* is set to indicate the error.

ERRORS

EAGAIN

The **RLIMIT_SIGPENDING** resource limit was reached and *sig* is a real-time signal.

EAGAIN

Insufficient kernel memory was available and *sig* is a real-time signal.

EINVAL

An invalid thread ID, thread group ID, or signal was specified.

EPERM

Permission denied. For the required permissions, see **kill(2)**.

ESRCH

No process with the specified thread ID (and thread group ID) exists.

VERSIONS

tkill() is supported since Linux 2.4.19 / 2.5.4. **tgkill()** was added in Linux 2.5.75.

Library support for **tgkill()** was added in glibc 2.30.

STANDARDS

tkill() and **tgkill()** are Linux-specific and should not be used in programs that are intended to be portable.

NOTES

See the description of **CLONE_THREAD** in **clone(2)** for an explanation of thread groups.

Before glibc 2.30, there was also no wrapper function for **tgkill()**.

SEE ALSO

clone(2), **gettid(2)**, **kill(2)**, **rt_sigqueueinfo(2)**

NAME

time – time a simple command or give resource usage

SYNOPSIS

time [*options*] *command* [*arguments...*]

DESCRIPTION

The **time** command runs the specified program *command* with the given arguments. When *command* finishes, **time** writes a message to standard error giving timing statistics about this program run. These statistics consist of (i) the elapsed real time between invocation and termination, (ii) the user CPU time (the sum of the *tms_utime* and *tms_cutime* values in a *struct tms* as returned by **times(2)**), and (iii) the system CPU time (the sum of the *tms_stime* and *tms_cstime* values in a *struct tms* as returned by **times(2)**).

Note: some shells (e.g., **bash(1)**) have a built-in **time** command that provides similar information on the usage of time and possibly other resources. To access the real command, you may need to specify its pathname (something like */usr/bin/time*).

OPTIONS

-p When in the POSIX locale, use the precise traditional format

```
"real %f\nuser %f\nsys %f\n"
```

(with numbers in seconds) where the number of decimals in the output for %f is unspecified but is sufficient to express the clock tick accuracy, and at least one.

EXIT STATUS

If *command* was invoked, the exit status is that of *command*. Otherwise, it is 127 if *command* could not be found, 126 if it could be found but could not be invoked, and some other nonzero value (1–125) if something else went wrong.

ENVIRONMENT

The variables **LANG**, **LC_ALL**, **LC_CTYPE**, **LC_MESSAGES**, **LC_NUMERIC**, and **NLSPATH** are used for the text and formatting of the output. **PATH** is used to search for *command*.

GNU VERSION

Below a description of the GNU 1.7 version of **time**. Disregarding the name of the utility, GNU makes it output lots of useful information, not only about time used, but also on other resources like memory, I/O and IPC calls (where available). The output is formatted using a format string that can be specified using the **-f** option or the **TIME** environment variable.

The default format string is:

```
%User %Ssystem %Eelapsed %PCPU (%Xtext+%Ddata %Mmax)k
%Iinputs+%Ooutputs (%Fmajor+%Rminor)pagefaults %Wswaps
```

When the **-p** option is given, the (portable) output format is used:

```
real %e
user %U
sys %S
```

The format string

The format is interpreted in the usual printf-like way. Ordinary characters are directly copied, tab, newline, and backslash are escaped using \t, \n, and \\, a percent sign is represented by %% , and otherwise % indicates a conversion. The program **time** will always add a trailing newline itself. The conversions follow. All of those used by **tcsh(1)** are supported.

Time

%E Elapsed real time (in [hours:]minutes:seconds).

%e (Not in **tcsh(1)**.) Elapsed real time (in seconds).

%S Total number of CPU-seconds that the process spent in kernel mode.

- %U** Total number of CPU-seconds that the process spent in user mode.
%P Percentage of the CPU that this job got, computed as $(\%U + \%S) / \%E$.

Memory

- %M** Maximum resident set size of the process during its lifetime, in Kbytes.
%t (Not in **tcsesh(1)**.) Average resident set size of the process, in Kbytes.
%K Average total (data+stack+text) memory use of the process, in Kbytes.
%D Average size of the process's unshared data area, in Kbytes.
%p (Not in **tcsesh(1)**.) Average size of the process's unshared stack space, in Kbytes.
%X Average size of the process's shared text space, in Kbytes.
%Z (Not in **tcsesh(1)**.) System's page size, in bytes. This is a per-system constant, but varies between systems.
%F Number of major page faults that occurred while the process was running. These are faults where the page has to be read in from disk.
%R Number of minor, or recoverable, page faults. These are faults for pages that are not valid but which have not yet been claimed by other virtual pages. Thus the data in the page is still valid but the system tables must be updated.
%W Number of times the process was swapped out of main memory.
%c Number of times the process was context-switched involuntarily (because the time slice expired).
%w Number of waits: times that the program was context-switched voluntarily, for instance while waiting for an I/O operation to complete.

I/O

- %I** Number of filesystem inputs by the process.
%O Number of filesystem outputs by the process.
%r Number of socket messages received by the process.
%s Number of socket messages sent by the process.
%k Number of signals delivered to the process.
%C (Not in **tcsesh(1)**.) Name and command-line arguments of the command being timed.
%x (Not in **tcsesh(1)**.) Exit status of the command.

GNU options

- f** *format*, **--format**=*format*
 Specify output format, possibly overriding the format specified in the environment variable TIME.
- p**, **--portability**
 Use the portable output format.
- o** *file*, **--output**=*file*
 Do not send the results to *stderr*, but overwrite the specified file.
- a**, **--append**
 (Used together with -o.) Do not overwrite but append.
- v**, **--verbose**
 Give very verbose output about all the program knows about.
- q**, **--quiet**
 Don't report abnormal program termination (where *command* is terminated by a signal) or non-zero exit status.

GNU standard options

--help Print a usage message on standard output and exit successfully.

-V, --version

Print version information on standard output, then exit successfully.

-- Terminate option list.

BUGS

Not all resources are measured by all versions of UNIX, so some of the values might be reported as zero. The present selection was mostly inspired by the data provided by 4.2 or 4.3BSD.

GNU time version 1.7 is not yet localized. Thus, it does not implement the POSIX requirements.

The environment variable **TIME** was badly chosen. It is not unusual for systems like **autoconf(1)** or **make(1)** to use environment variables with the name of a utility to override the utility to be used. Uses like MORE or TIME for options to programs (instead of program pathnames) tend to lead to difficulties.

It seems unfortunate that **-o** overwrites instead of appends. (That is, the **-a** option should be the default.)

Mail suggestions and bug reports for GNU **time** to bug-time@gnu.org. Please include the version of **time**, which you can get by running

```
time --version
```

and the operating system and C compiler you used.

NAME

`time` – get time in seconds

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <time.h>
time_t time(time_t *_Nullable tloc);
```

DESCRIPTION

`time()` returns the time as the number of seconds since the Epoch, 1970-01-01 00:00:00 +0000 (UTC).

If *tloc* is non-NULL, the return value is also stored in the memory pointed to by *tloc*.

RETURN VALUE

On success, the value of time in seconds since the Epoch is returned. On error, $((\text{time_t}) - 1)$ is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT

tloc points outside your accessible address space (but see BUGS).

On systems where the C library `time()` wrapper function invokes an implementation provided by the `vdso(7)` (so that there is no trap into the kernel), an invalid address may instead trigger a `SIGSEGV` signal.

STANDARDS

SVr4, 4.3BSD, C99, POSIX.1-2001. POSIX does not specify any error conditions.

NOTES

POSIX.1 defines *seconds since the Epoch* using a formula that approximates the number of seconds between a specified time and the Epoch. This formula takes account of the facts that all years that are evenly divisible by 4 are leap years, but years that are evenly divisible by 100 are not leap years unless they are also evenly divisible by 400, in which case they are leap years. This value is not the same as the actual number of seconds between the time and the Epoch, because of leap seconds and because system clocks are not required to be synchronized to a standard reference. The intention is that the interpretation of seconds since the Epoch values be consistent; see POSIX.1-2008 Rationale A.4.15 for further rationale.

On Linux, a call to `time()` with *tloc* specified as NULL cannot fail with the error `EOVERFLOW`, even on ABIs where *time_t* is a signed 32-bit integer and the clock reaches or exceeds 2**31 seconds (2038-01-19 03:14:08 UTC, ignoring leap seconds). (POSIX.1 permits, but does not require, the `EOVERFLOW` error in the case where the seconds since the Epoch will not fit in *time_t*.) Instead, the behavior on Linux is undefined when the system time is out of the *time_t* range. Applications intended to run after 2038 should use ABIs with *time_t* wider than 32 bits.

BUGS

Error returns from this system call are indistinguishable from successful reports that the time is a few seconds *before* the Epoch, so the C library wrapper function never sets *errno* as a result of this call.

The *tloc* argument is obsolescent and should always be NULL in new code. When *tloc* is NULL, the call cannot fail.

C library/kernel differences

On some architectures, an implementation of `time()` is provided in the `vdso(7)`.

NAME

`time` – time functions for gawk

SYNOPSIS

```
@load "time"

time = gettimeofday()
ret = sleep(amount)
```

CAUTION

This extension is deprecated in favor of the **timex** extension in the *gawkextlib* project. In the next major release of *gawk*, loading it will issue a warning. It will be removed from the *gawk* distribution in the major release after the next one.

DESCRIPTION

The *time* extension adds two functions named **gettimeofday()** and **sleep()**, as follows.

gettimeofday()

This function returns the number of seconds since the Epoch as a floating-point value. It should have subsecond precision. It returns `-1` upon error and sets **ERRNO** to indicate the problem.

sleep(seconds)

This function attempts to sleep for the given amount of seconds, which may include a fractional portion. If *seconds* is negative, or the attempt to sleep fails, then it returns `-1` and sets **ERRNO**. Otherwise, the function should return `0` after sleeping for the indicated amount of time.

EXAMPLE

```
@load "time"
...
printf "It is now %g seconds since the Epoch\n", gettimeofday()
printf "Pausing for a while... " ; sleep(2.5) ; print "done"
```

NAME

time – overview of time and timers

DESCRIPTION

Real time and process time

Real time is defined as time measured from some fixed point, either from a standard point in the past (see the description of the Epoch and calendar time below), or from some point (e.g., the start) in the life of a process (*elapsed time*).

Process time is defined as the amount of CPU time used by a process. This is sometimes divided into *user* and *system* components. User CPU time is the time spent executing code in user mode. System CPU time is the time spent by the kernel executing in system mode on behalf of the process (e.g., executing system calls). The **time**(1) command can be used to determine the amount of CPU time consumed during the execution of a program. A program can determine the amount of CPU time it has consumed using **times**(2), **getrusage**(2), or **clock**(3).

The hardware clock

Most computers have a (battery-powered) hardware clock which the kernel reads at boot time in order to initialize the software clock. For further details, see **rtc**(4) and **hwclock**(8).

The software clock, HZ, and jiffies

The accuracy of various system calls that set timeouts, (e.g., **select**(2), **sigtimedwait**(2)) and measure CPU time (e.g., **getrusage**(2)) is limited by the resolution of the *software clock*, a clock maintained by the kernel which measures time in *jiffies*. The size of a jiffy is determined by the value of the kernel constant **HZ**.

The value of **HZ** varies across kernel versions and hardware platforms. On i386 the situation is as follows: on kernels up to and including Linux 2.4.x, **HZ** was 100, giving a jiffy value of 0.01 seconds; starting with Linux 2.6.0, **HZ** was raised to 1000, giving a jiffy of 0.001 seconds. Since Linux 2.6.13, the **HZ** value is a kernel configuration parameter and can be 100, 250 (the default) or 1000, yielding a jiffies value of, respectively, 0.01, 0.004, or 0.001 seconds. Since Linux 2.6.20, a further frequency is available: 300, a number that divides evenly for the common video frame rates (PAL, 25 Hz; NTSC, 30 Hz).

The **times**(2) system call is a special case. It reports times with a granularity defined by the kernel constant **USER_HZ**. User-space applications can determine the value of this constant using **sysconf(_SC_CLK_TCK)**.

System and process clocks; time namespaces

The kernel supports a range of clocks that measure various kinds of elapsed and virtual (i.e., consumed CPU) time. These clocks are described in **clock_gettime**(2). A few of the clocks are settable using **clock_settime**(2). The values of certain clocks are virtualized by time namespaces; see **time_namespaces**(7).

High-resolution timers

Before Linux 2.6.21, the accuracy of timer and sleep system calls (see below) was also limited by the size of the jiffy.

Since Linux 2.6.21, Linux supports high-resolution timers (HRTs), optionally configurable via **CONFIG_HIGH_RES_TIMERS**. On a system that supports HRTs, the accuracy of sleep and timer system calls is no longer constrained by the jiffy, but instead can be as accurate as the hardware allows (microsecond accuracy is typical of modern hardware). You can determine whether high-resolution timers are supported by checking the resolution returned by a call to **clock_getres**(2) or looking at the "resolution" entries in **/proc/timer_list**.

HRTs are not supported on all hardware architectures. (Support is provided on x86, ARM, and PowerPC, among others.)

The Epoch

UNIX systems represent time in seconds since the *Epoch*, 1970-01-01 00:00:00 +0000 (UTC).

A program can determine the *calendar time* via the **clock_gettime**(2) **CLOCK_REALTIME** clock, which returns time (in seconds and nanoseconds) that have elapsed since the Epoch; **time**(2) provides similar information, but only with accuracy to the nearest second. The system time can be changed using

clock_settime(2).

Broken-down time

Certain library functions use a structure of type *tm* to represent *broken-down time*, which stores time value separated out into distinct components (year, month, day, hour, minute, second, etc.). This structure is described in **tm(3type)**, which also describes functions that convert between calendar time and broken-down time. Functions for converting between broken-down time and printable string representations of the time are described in **ctime(3)**, **strftime(3)**, and **strptime(3)**.

Sleeping and setting timers

Various system calls and functions allow a program to sleep (suspend execution) for a specified period of time; see **nanosleep(2)**, **clock_nanosleep(2)**, and **sleep(3)**.

Various system calls allow a process to set a timer that expires at some point in the future, and optionally at repeated intervals; see **alarm(2)**, **getitimer(2)**, **timerfd_create(2)**, and **timer_create(2)**.

Timer slack

Since Linux 2.6.28, it is possible to control the "timer slack" value for a thread. The timer slack is the length of time by which the kernel may delay the wake-up of certain system calls that block with a timeout. Permitting this delay allows the kernel to coalesce wake-up events, thus possibly reducing the number of system wake-ups and saving power. For more details, see the description of **PR_SET_TIMERSLACK** in **prctl(2)**.

NAME

`time.conf` – configuration file for the pam_time module

DESCRIPTION

The pam_time PAM module does not authenticate the user, but instead it restricts access to a system and/or specific applications at various times of the day and on specific days or over various terminal lines. This module can be configured to deny access to (individual) users based on their name, the time of day, the day of week, the service they are applying for and their terminal from which they are making their request.

For this module to function correctly there must be a correctly formatted /etc/security/time.conf file present. White spaces are ignored and lines maybe extended with '\' (escaped newlines). Text following a '#' is ignored to the end of the line.

The syntax of the lines is as follows:

services;ttys;users;times

In words, each rule occupies a line, terminated with a newline or the beginning of a comment; a '#'. It contains four fields separated with semicolons, ';':

The first field, the *services* field, is a logic list of PAM service names that the rule applies to.

The second field, the *tty* field, is a logic list of terminal names that this rule applies to.

The third field, the *users* field, is a logic list of users or a netgroup of users to whom this rule applies.

A logic list namely means individual tokens that are optionally prefixed with '!' (logical not) and separated with '&' (logical and) and '|' (logical or).

For these items the simple wildcard '*' may be used only once. With netgroups no wildcards or logic operators are allowed.

The *times* field is used to indicate the times at which this rule applies. The format here is a logic list of day/time-range entries. The days are specified by a sequence of two character entries, MoTuSa for example is Monday Tuesday and Saturday. Note that repeated days are unset MoMo = no day, and MoWk = all weekdays bar Monday. The two character combinations accepted are Mo Tu We Th Fr Sa Su Wk Wd Al, the last two being week-end days and all 7 days of the week respectively. As a final example, AlFr means all days except Friday.

Each day/time-range can be prefixed with a '!' to indicate "anything but". The time-range part is two 24-hour times HHMM, separated by a hyphen, indicating the start and finish time (if the finish time is smaller than the start time it is deemed to apply on the following day).

For a rule to be active, ALL of service+ttys+users must be satisfied by the applying process.

Note, currently there is no daemon enforcing the end of a session. This needs to be remedied.

Poorly formatted rules are logged as errors using `syslog(3)`.

EXAMPLES

These are some example lines which might be specified in /etc/security/time.conf.

All users except for *root* are denied access to console-login at all times:

```
login ; tty* & !typ* ; !root ; !Al0000-2400
```

Games (configured to use PAM) are only to be accessed out of working hours. This rule does not apply to the user *waster*:

```
games ; * ; !waster ; Wd0000-2400 | Wk1800-0800
```

pam_time was written by Andrew G. Morgan <morgan@kernel.org>.

NAME

`system_data_types` – overview of system data types

DESCRIPTION

aiocb

Include: `<aio.h>`.

```
struct aiocb {
    int             aio_fildes;      /* File descriptor */
    off_t           aio_offset;     /* File offset */
    volatile void * aio_buf;        /* Location of buffer */
    size_t          aio_nbytes;     /* Length of transfer */
    int             aio_reqprio;    /* Request priority offset */
    struct sigevent aio_sigevent;  /* Signal number and value */
    int             aio_lio_opcode; /* Operation to be performed */
};
```

For further information about this structure, see [aio\(7\)](#).

Conforming to: POSIX.1-2001 and later.

See also: [aio_cancel\(3\)](#), [aio_error\(3\)](#), [aio_fsync\(3\)](#), [aio_read\(3\)](#), [aio_return\(3\)](#), [aio_suspend\(3\)](#), [aio_write\(3\)](#), [lio_listio\(3\)](#)

clock_t

Include: `<time.h>` or `<sys/types.h>`. Alternatively, `<sys/time.h>`.

Used for system time in clock ticks or **CLOCKS_PER_SEC** (defined in `<time.h>`). According to POSIX, it shall be an integer type or a real-floating type.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: [times\(2\)](#), [clock\(3\)](#)

clockid_t

Include: `<sys/types.h>`. Alternatively, `<time.h>`.

Used for clock ID type in the clock and timer functions. According to POSIX, it shall be defined as an arithmetic type.

Conforming to: POSIX.1-2001 and later.

See also: [clock_adjtime\(2\)](#), [clock_getres\(2\)](#), [clock_nanosleep\(2\)](#), [timer_create\(2\)](#), [clock_getcpuclockid\(3\)](#)

dev_t

Include: `<sys/types.h>`. Alternatively, `<sys/stat.h>`.

Used for device IDs. According to POSIX, it shall be an integer type. For further details of this type, see [makedev\(3\)](#).

Conforming to: POSIX.1-2001 and later.

See also: [mknod\(2\)](#), [stat\(2\)](#)

div_t

Include: `<stdlib.h>`.

```
typedef struct {
    int quot; /* Quotient */
    int rem; /* Remainder */
} div_t;
```

It is the type of the value returned by the [div\(3\)](#) function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: [div\(3\)](#)

double_t

Include: <math.h>.

The implementation's most efficient floating type at least as wide as *double*. Its type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <float.h>):

- 0 *double_t* is *double*.
- 1 *double_t* is *double*.
- 2 *double_t* is *long double*.

For other values of **FLT_EVAL_METHOD**, the type of *double_t* is implementation-defined.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *float_t* type in this page.

fd_set

Include: <sys/select.h>. Alternatively, <sys/time.h>.

A structure type that can represent a set of file descriptors. According to POSIX, the maximum number of file descriptors in an *fd_set* structure is the value of the macro **FD_SETSIZE**.

Conforming to: POSIX.1-2001 and later.

See also: **select**(2)

fenv_t

Include: <fenv.h>.

This type represents the entire floating-point environment, including control modes and status flags; for further details, see **fenv**(3).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fenv**(3)

fexcept_t

Include: <fenv.h>.

This type represents the floating-point status flags collectively; for further details see **fenv**(3).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fenv**(3)

FILE

Include: <stdio.h>. Alternatively, <wchar.h>.

An object type used for streams.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fclose**(3), **flockfile**(3), **fopen**(3), **fprintf**(3), **fread**(3), **fscanf**(3), **stdin**(3), **stdio**(3)

float_t

Include: <math.h>.

The implementation's most efficient floating type at least as wide as *float*. Its type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <float.h>):

- 0 *float_t* is *float*.
- 1 *float_t* is *double*.
- 2 *float_t* is *long double*.

For other values of **FLT_EVAL_METHOD**, the type of *float_t* is implementation-defined.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *double_t* type in this page.

gid_t

Include: <sys/types.h>. Alternatively, <grp.h>, <pwd.h>, <signal.h>, <stropts.h>, <sys/ipc.h>, <sys/stat.h>, or <unistd.h>.

A type used to hold group IDs. According to POSIX, this shall be an integer type.

Conforming to: POSIX.1-2001 and later.

See also: chown(2), getgid(2), getegid(2), getgroups(2), getresgid(2), getgrnam(2), credentials(7)

id_t

Include: <sys/types.h>. Alternatively, <sys/resource.h>.

A type used to hold a general identifier. According to POSIX, this shall be an integer type that can be used to contain a *pid_t*, *uid_t*, or *gid_t*.

Conforming to: POSIX.1-2001 and later.

See also: getpriority(2), waitid(2)

imaxdiv_t

Include: <inttypes.h>.

```
typedef struct {
    intmax_t      quot; /* Quotient */
    intmax_t      rem;   /* Remainder */
} imaxdiv_t;
```

It is the type of the value returned by the imaxdiv(3) function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: imaxdiv(3)

intmax_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

A signed integer type capable of representing any value of any signed integer type supported by the implementation. According to the C language standard, it shall be capable of storing values in the range [INTMAX_MIN, INTMAX_MAX].

The macro INTMAX_C() expands its argument to an integer constant of type *intmax_t*.

The length modifier for *intmax_t* for the printf(3) and the scanf(3) families of functions is **j**; resulting commonly in %**jd** or %**ji** for printing *intmax_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

Bugs: *intmax_t* is not large enough to represent values of type __int128 in implementations where __int128 is defined and long long is less than 128 bits wide.

See also: the *uintmax_t* type in this page.

intN_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

int8_t, *int16_t*, *int32_t*, *int64_t*

A signed integer type of a fixed width of exactly N bits, N being the value specified in its type name. According to the C language standard, they shall be capable of storing values in the range [INTN_MIN, INTN_MAX], substituting N by the appropriate number.

According to POSIX, *int8_t*, *int16_t*, and *int32_t* are required; *int64_t* is only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The length modifiers for the *intN_t* types for the printf(3) family of functions are expanded by macros of the forms **PRIIdN** and **PRIiN** (defined in <inttypes.h>); resulting for example in %"**PRI64**" or %"**PRIi64**" for printing *int64_t* values. The length modifiers for the *intN_t*

types for the **scanf**(3) family of functions are expanded by macros of the forms **SCNdN** and **SCNiN**, (defined in *<inttypes.h>*); resulting for example in **%"SCNd8"** or **%"SCNi8"** for scanning *int8_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intmax_t*, *uintN_t*, and *uintmax_t* types in this page.

intptr_t

Include: *<stdint.h>*. Alternatively, *<inttypes.h>*.

A signed integer type such that any valid (*void **) value can be converted to this type and back. According to the C language standard, it shall be capable of storing values in the range [**INTPTR_MIN**, **INTPTR_MAX**].

The length modifier for *intptr_t* for the **printf**(3) family of functions is expanded by the macros **PRIIdPTR** and **PRIiPTR** (defined in *<inttypes.h>*); resulting commonly in **%"PRIIdPTR"** or **%"PRIiPTR"** for printing *intptr_t* values. The length modifier for *intptr_t* for the **scanf**(3) family of functions is expanded by the macros **SCNdPTR** and **SCNiPTR**, (defined in *<inttypes.h>*); resulting commonly in **%"SCNdPTR"** or **%"SCNiPTR"** for scanning *intptr_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *uintptr_t* and *void ** types in this page.

lconv

Include: *<locale.h>*.

```
struct lconv {                                /* Values in the "C" locale: */
    char    *decimal_point;                  /* ". " */
    char    *thousands_sep;                 /* " " */
    char    *grouping;                      /* " " */
    char    *mon_decimal_point;             /* " " */
    char    *mon_thousands_sep;             /* " " */
    char    *mon_grouping;                 /* " " */
    char    *positive_sign;                /* " " */
    char    *negative_sign;                /* " " */
    char    *currency_symbol;              /* " " */
    char    frac_digits;                   /* CHAR_MAX */
    char    p_cs_precedes;                /* CHAR_MAX */
    char    n_cs_precedes;                /* CHAR_MAX */
    char    p_sep_by_space;                /* CHAR_MAX */
    char    n_sep_by_space;                /* CHAR_MAX */
    char    p_sign_posn;                  /* CHAR_MAX */
    char    n_sign_posn;                  /* CHAR_MAX */
    char    *int_curr_symbol;              /* " " */
    char    int_frac_digits;               /* CHAR_MAX */
    char    int_p_cs_precedes;             /* CHAR_MAX */
    char    int_n_cs_precedes;             /* CHAR_MAX */
    char    int_p_sep_by_space;             /* CHAR_MAX */
    char    int_n_sep_by_space;             /* CHAR_MAX */
    char    int_p_sign_posn;               /* CHAR_MAX */
    char    int_n_sign_posn;               /* CHAR_MAX */
};
```

Contains members related to the formatting of numeric values. In the "C" locale, its members have the values shown in the comments above.

Conforming to: C11 and later; POSIX.1-2001 and later.

See also: **setlocale**(3), **localeconv**(3), **charsets**(5), **locale**(7)

ldiv_t

Include: <stdlib.h>.

```
typedef struct {
    long      quot; /* Quotient */
    long      rem;   /* Remainder */
} ldiv_t;
```

It is the type of the value returned by the **ldiv(3)** function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **ldiv(3)**

lldiv_t

Include: <stdlib.h>.

```
typedef struct {
    long long  quot; /* Quotient */
    long long  rem;  /* Remainder */
} lldiv_t;
```

It is the type of the value returned by the **lldiv(3)** function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **lldiv(3)**

off_t

Include: <sys/types.h>. Alternatively, <aio.h>, <fcntl.h>, <stdio.h>, <sys/mman.h>, <sys/stat.h>, or <unistd.h>.

Used for file sizes. According to POSIX, this shall be a signed integer type.

Versions: <aio.h> and <stdio.h> define *off_t* since POSIX.1-2008.

Conforming to: POSIX.1-2001 and later.

Notes: On some architectures, the width of this type can be controlled with the feature test macro **_FILE_OFFSET_BITS**.

See also: **lseek(2)**, **mmap(2)**, **posix_fadvise(2)**, **pread(2)**, **truncate(2)**, **fseeko(3)**, **lockf(3)**, **posix_fallocate(3)**, **feature_test_macros(7)**

pid_t

Include: <sys/types.h>. Alternatively, <fcntl.h>, <sched.h>, <signal.h>, <spawn.h>, <sys/msg.h>, <sys/sem.h>, <sys/shm.h>, <sys/wait.h>, <termios.h>, <time.h>, <unistd.h>, or <utmpx.h>.

This type is used for storing process IDs, process group IDs, and session IDs. According to POSIX, it shall be a signed integer type, and the implementation shall support one or more programming environments where the width of *pid_t* is no greater than the width of the type *long*.

Conforming to: POSIX.1-2001 and later.

See also: **fork(2)**, **getpid(2)**, **getppid(2)**, **getsid(2)**, **gettid(2)**, **getpgid(2)**, **kill(2)**, **pidfd_open(2)**, **sched_setscheduler(2)**, **waitpid(2)**, **sigqueue(3)**, **credentials(7)**,

ptrdiff_t

Include: <stddef.h>.

Used for a count of elements, and array indices. It is the result of subtracting two pointers. According to the C language standard, it shall be a signed integer type capable of storing values in the range [**PTRDIFF_MIN**, **PTRDIFF_MAX**].

The length modifier for *ptrdiff_t* for the **printf(3)** and the **scanf(3)** families of functions is **t**; resulting commonly in **%td** or **%ti** for printing *ptrdiff_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the `size_t` and `ssize_t` types in this page.

`regex_t`

Include: `<regex.h>`.

```
typedef struct {
    size_t re_nsub; /* Number of parenthesized subexpressions. */
} regex_t;
```

This is a structure type used in regular expression matching. It holds a compiled regular expression, compiled with `regcomp(3)`.

Conforming to: POSIX.1-2001 and later.

See also: `regex(3)`

`regmatch_t`

Include: `<regex.h>`.

```
typedef struct {
    regoff_t rm_so; /* Byte offset from start of string
                      to start of substring */
    regoff_t rm_eo; /* Byte offset from start of string of
                      the first character after the end of
                      substring */
} regmatch_t;
```

This is a structure type used in regular expression matching.

Conforming to: POSIX.1-2001 and later.

See also: `regexec(3)`

`regoff_t`

Include: `<regex.h>`.

According to POSIX, it shall be a signed integer type capable of storing the largest value that can be stored in either a `ptrdiff_t` type or a `ssize_t` type.

Versions: Prior to POSIX.1-2008, the type was capable of storing the largest value that can be stored in either an `off_t` type or a `ssize_t` type.

Conforming to: POSIX.1-2001 and later.

See also: the `regmatch_t` structure and the `ptrdiff_t` and `ssize_t` types in this page.

`sigevent`

Include: `<signal.h>`. Alternatively, `<aio.h>`, `<mqueue.h>`, or `<time.h>`.

```
struct sigevent {
    int           sigev_notify; /* Notification type */
    int           sigev_signo;  /* Signal number */
    union sigval  sigev_value; /* Signal value */
    void         (*sigev_notify_function)(union sigval);
                 /* Notification function */
    pthread_attr_t *sigev_notify_attributes;
                 /* Notification attributes */
};
```

For further details about this type, see `sigevent(7)`.

Versions: `<aio.h>` and `<time.h>` define `sigevent` since POSIX.1-2008.

Conforming to: POSIX.1-2001 and later.

See also: `timer_create(2)`, `getaddrinfo_a(3)`, `lio_listio(3)`, `mq_notify(3)`

See also the *aiocb* structure in this page.

siginfo_t

Include: <signal.h>. Alternatively, <sys/wait.h>.

```
typedef struct {
    int      si_signo; /* Signal number */
    int      si_code;  /* Signal code */
    pid_t   si_pid;   /* Sending process ID */
    uid_t   si_uid;   /* Real user ID of sending process */
    void    *si_addr; /* Address of faulting instruction */
    int     si_status; /* Exit value or signal */
    union sigval si_value; /* Signal value */
} siginfo_t;
```

Information associated with a signal. For further details on this structure (including additional, Linux-specific fields), see **sigaction**(2).

Conforming to: POSIX.1-2001 and later.

See also: **pidfd_send_signal**(2), **rt_sigqueueinfo**(2), **sigaction**(2), **sigwaitinfo**(2), **psiginfo**(3)

sigset_t

Include: <signal.h>. Alternatively, <spawn.h>, or <sys/select.h>.

This is a type that represents a set of signals. According to POSIX, this shall be an integer or structure type.

Conforming to: POSIX.1-2001 and later.

See also: **epoll_pwait**(2), **ppoll**(2), **pselect**(2), **sigaction**(2), **signalfd**(2), **sigpending**(2), **sigprocmask**(2), **sigsuspend**(2), **sigwaitinfo**(2), **signal**(7)

sigval

Include: <signal.h>.

```
union sigval {
    int     sigval_int; /* Integer value */
    void   *sigval_ptr; /* Pointer value */
};
```

Data passed with a signal.

Conforming to: POSIX.1-2001 and later.

See also: **pthread_sigqueue**(3), **sigqueue**(3), **sigevent**(7)

See also the *sigevent* structure and the *siginfo_t* type in this page.

size_t

Include: <stddef.h> or <sys/types.h>. Alternatively, <aio.h>, <glob.h>, <grp.h>, <iconv.h>, <monetary.h>, <mqueue.h>, <ndbm.h>, <pwd.h>, <regex.h>, <search.h>, <signal.h>, <stdio.h>, <stdlib.h>, <string.h>, <strings.h>, <sys/mman.h>, <sys/msg.h>, <sys/sem.h>, <sys/shm.h>, <sys/socket.h>, <sys/uio.h>, <time.h>, <unistd.h>, <wchar.h>, or <wctype.h>.

Used for a count of bytes. It is the result of the *sizeof* operator. According to the C language standard, it shall be an unsigned integer type capable of storing values in the range [0, **SIZE_MAX**]. According to POSIX, the implementation shall support one or more programming environments where the width of *size_t* is no greater than the width of the type *long*.

The length modifier for *size_t* for the **printf**(3) and the **scanf**(3) families of functions is **z**; resulting commonly in **%zu** or **%zx** for printing *size_t* values.

Versions: <aio.h>, <glob.h>, <grp.h>, <iconv.h>, <mqueue.h>, <pwd.h>, <signal.h>, and <sys/socket.h> define *size_t* since POSIX.1-2008.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **read(2)**, **write(2)**, **fread(3)**, **fwrite(3)**, **memcmp(3)**, **memcpy(3)**, **memset(3)**, **off-setof(3)**

See also the *ptrdiff_t* and *ssize_t* types in this page.

ssize_t

Include: <sys/types.h>. Alternatively, <aio.h>, <monetary.h>, <mqueue.h>, <stdio.h>, <sys/msg.h>, <sys/socket.h>, <sys/uio.h>, or <unistd.h>.

Used for a count of bytes or an error indication. According to POSIX, it shall be a signed integer type capable of storing values at least in the range [-1, **SSIZE_MAX**], and the implementation shall support one or more programming environments where the width of *ssize_t* is no greater than the width of the type *long*.

Glibc and most other implementations provide a length modifier for *ssize_t* for the **printf(3)** and the **scanf(3)** families of functions, which is **z**; resulting commonly in **%zd** or **%zi** for printing *ssize_t* values. Although **z** works for *ssize_t* on most implementations, portable POSIX programs should avoid using it—for example, by converting the value to *intmax_t* and using its length modifier (**j**).

Conforming to: POSIX.1-2001 and later.

See also: **read(2)**, **readlink(2)**, **readv(2)**, **recv(2)**, **send(2)**, **write(2)**

See also the *ptrdiff_t* and *size_t* types in this page.

suseconds_t

Include: <sys/types.h>. Alternatively, <sys/select.h>, or <sys/time.h>.

Used for time in microseconds. According to POSIX, it shall be a signed integer type capable of storing values at least in the range [-1, 1000000], and the implementation shall support one or more programming environments where the width of *suseconds_t* is no greater than the width of the type *long*.

Conforming to: POSIX.1-2001 and later.

See also: the *timeval* structure in this page.

time_t

Include: <time.h> or <sys/types.h>. Alternatively, <sched.h>, <sys/msg.h>, <sys/select.h>, <sys/sem.h>, <sys/shm.h>, <sys/stat.h>, <sys/time.h>, or <utime.h>.

Used for time in seconds. According to POSIX, it shall be an integer type.

Versions: <sched.h> defines *time_t* since POSIX.1-2008.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **stime(2)**, **time(2)**, **ctime(3)**, **difftime(3)**

timer_t

Include: <sys/types.h>. Alternatively, <time.h>.

Used for timer ID returned by **timer_create(2)**. According to POSIX, there are no defined comparison or assignment operators for this type.

Conforming to: POSIX.1-2001 and later.

See also: **timer_create(2)**, **timer_delete(2)**, **timer_getoverrun(2)**, **timer_settime(2)**

timespec

Include: <time.h>. Alternatively, <aio.h>, <mqueue.h>, <sched.h>, <signal.h>, <sys/select.h>, or <sys/stat.h>.

```
struct timespec {
    time_t tv_sec; /* Seconds */
```

```
    long      tv_nsec; /* Nanoseconds */
}
```

Describes times in seconds and nanoseconds.

Conforming to: C11 and later; POSIX.1-2001 and later.

See also: **clock_gettime(2)**, **clock_nanosleep(2)**, **nanosleep(2)**, **timerfd_gettime(2)**, **timer_gettime(2)**

timeval

Include: <sys/time.h>. Alternatively, <sys/resource.h>, <sys/select.h>, or <utmpx.h>.

```
struct timeval {
    time_t      tv_sec;   /* Seconds */
    suseconds_t tv_usec; /* Microseconds */
};
```

Describes times in seconds and microseconds.

Conforming to: POSIX.1-2001 and later.

See also: **gettimeofday(2)**, **select(2)**, **utimes(2)**, **adjtime(3)**, **futimes(3)**, **timeradd(3)**

uid_t

Include: <sys/types.h>. Alternatively, <pwd.h>, <signal.h>, <stropts.h>, <sys/ipc.h>, <sys/stat.h>, or <unistd.h>.

A type used to hold user IDs. According to POSIX, this shall be an integer type.

Conforming to: POSIX.1-2001 and later.

See also: **chown(2)**, **getuid(2)**, **geteuid(2)**, **getresuid(2)**, **getpwnam(2)**, **credentials(7)**

uintmax_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

An unsigned integer type capable of representing any value of any unsigned integer type supported by the implementation. According to the C language standard, it shall be capable of storing values in the range [0, **UINTMAX_MAX**].

The macro **UINTMAX_C()** expands its argument to an integer constant of type *uintmax_t*.

The length modifier for *uintmax_t* for the **printf(3)** and the **scanf(3)** families of functions is **j**; resulting commonly in **%ju** or **%jx** for printing *uintmax_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

Bugs: *uintmax_t* is not large enough to represent values of type *unsigned __int128* in implementations where *unsigned __int128* is defined and *unsigned long long* is less than 128 bits wide.

See also: the *intmax_t* type in this page.

uintN_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

uint8_t, *uint16_t*, *uint32_t*, *uint64_t*

An unsigned integer type of a fixed width of exactly N bits, N being the value specified in its type name. According to the C language standard, they shall be capable of storing values in the range [0, **UINTN_MAX**], substituting N by the appropriate number.

According to POSIX, *uint8_t*, *uint16_t*, and *uint32_t* are required; *uint64_t* is only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The length modifiers for the *uintN_t* types for the **printf(3)** family of functions are expanded by macros of the forms **PRIuN**, **PRIoN**, **PRIxN**, and **PRIXN** (defined in <inttypes.h>); resulting for example in **%"PRIu32"** or **%"PRIx32"** for printing *uint32_t* values. The length modifiers for

the *uintN_t* types for the **scanf**(3) family of functions are expanded by macros of the forms **SCNuN**, **SCNoN**, **SCNxN**, and **SCNXN** (defined in *<inttypes.h>*); resulting for example in **%"SCNu16"** or **%"SCNx16"** for scanning *uint16_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intmax_t*, *intN_t*, and *uintmax_t* types in this page.

uintptr_t

Include: *<stdint.h>*. Alternatively, *<inttypes.h>*.

An unsigned integer type such that any valid (*void **) value can be converted to this type and back. According to the C language standard, it shall be capable of storing values in the range [0, **UINTPTR_MAX**].

The length modifier for *uintptr_t* for the **printf**(3) family of functions is expanded by the macros **PRIupTR**, **PRIoPTR**, **PRIxPTR**, and **PRIxPTR** (defined in *<inttypes.h>*); resulting commonly in **%"PRIupTR"** or **%"PRIxPTR"** for printing *uintptr_t* values. The length modifier for *uintptr_t* for the **scanf**(3) family of functions is expanded by the macros **SCNuPTR**, **SCNoPTR**, **SCNxPTR**, and **SCNXPTR** (defined in *<inttypes.h>*); resulting commonly in **%"SCNuPTR"** or **%"SCNxPTR"** for scanning *uintptr_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intptr_t* and *void ** types in this page.

va_list

Include: *<stdarg.h>*. Alternatively, *<stdio.h>*, or *<wchar.h>*.

Used by functions with a varying number of arguments of varying types. The function must declare an object of type *va_list* which is used by the macros **va_start**(3), **va_arg**(3), **va_copy**(3), and **va_end**(3) to traverse the list of arguments.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **va_start**(3), **va_arg**(3), **va_copy**(3), **va_end**(3)

*void **

According to the C language standard, a pointer to any object type may be converted to a pointer to *void* and back. POSIX further requires that any pointer, including pointers to functions, may be converted to a pointer to *void* and back.

Conversions from and to any other pointer type are done implicitly, not requiring casts at all. Note that this feature prevents any kind of type checking: the programmer should be careful not to convert a *void ** value to a type incompatible to that of the underlying data, because that would result in undefined behavior.

This type is useful in function parameters and return value to allow passing values of any type. The function will typically use some mechanism to know the real type of the data being passed via a pointer to *void*.

A value of this type can't be dereferenced, as it would give a value of type *void*, which is not possible. Likewise, pointer arithmetic is not possible with this type. However, in GNU C, pointer arithmetic is allowed as an extension to the standard; this is done by treating the size of a *void* or of a function as 1. A consequence of this is that *sizeof* is also allowed on *void* and on function types, and returns 1.

The conversion specifier for *void ** for the **printf**(3) and the **scanf**(3) families of functions is **p**.

Versions: The POSIX requirement about compatibility between *void ** and function pointers was added in POSIX.1-2008 Technical Corrigendum 1 (2013).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **malloc**(3), **memcmp**(3), **memcpy**(3), **memset**(3)

See also the *intptr_t* and *uintptr_t* types in this page.

NOTES

The structures described in this manual page shall contain, at least, the members shown in their definition, in no particular order.

Most of the integer types described in this page don't have a corresponding length modifier for the `printf(3)` and the `scanf(3)` families of functions. To print a value of an integer type that doesn't have a length modifier, it should be converted to `intmax_t` or `uintmax_t` by an explicit cast. To scan into a variable of an integer type that doesn't have a length modifier, an intermediate temporary variable of type `intmax_t` or `uintmax_t` should be used. When copying from the temporary variable to the destination variable, the value could overflow. If the type has upper and lower limits, the user should check that the value is within those limits, before actually copying the value. The example below shows how these conversions should be done.

Conventions used in this page

In "Conforming to" we only concern ourselves with C99 and later and POSIX.1-2001 and later. Some types may be specified in earlier versions of one of these standards, but in the interests of simplicity we omit details from earlier standards.

In "Include", we first note the "primary" header(s) that define the type according to either the C or POSIX.1 standards. Under "Alternatively", we note additional headers that the standards specify shall define the type.

EXAMPLES

The program shown below scans from a string and prints a value stored in a variable of an integer type that doesn't have a length modifier. The appropriate conversions from and to `intmax_t`, and the appropriate range checks, are used as explained in the notes section above.

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>

int
main (void)
{
    static const char *const str = "500000 us in half a second";
    suseconds_t us;
    intmax_t tmp;

    /* Scan the number from the string into the temporary variable */

    sscanf(str, "%jd", &tmp);

    /* Check that the value is within the valid range of suseconds_t */

    if (tmp < -1 || tmp > 1000000) {
        fprintf(stderr, "Scanned value outside valid range!\n");
        exit(EXIT_FAILURE);
    }

    /* Copy the value to the suseconds_t variable 'us' */

    us = tmp;

    /* Even though suseconds_t can hold the value -1, this isn't
       a sensible number of microseconds */
}
```

```
if (us < 0) {
    fprintf(stderr, "Scanned value shouldn't be negative!\n");
    exit(EXIT_FAILURE);
}

/* Print the value */

printf("There are %jd microseconds in half a second.\n",
       (intmax_t) us);

exit(EXIT_SUCCESS);
}
```

NAME

timedatectl – Control the system time and date

SYNOPSIS

timedatectl [OPTIONS...] {COMMAND}

DESCRIPTION

timedatectl may be used to query and change the system clock and its settings, and enable or disable time synchronization services.

Use **systemd-firstboot(1)** to initialize the system time zone for mounted (but not booted) system images.

timedatectl may be used to show the current status of time synchronization services, for example **systemd-timesyncd.service(8)**.

COMMANDS

The following commands are understood:

status

Show current settings of the system clock and RTC, including whether network time synchronization is active. If no command is specified, this is the implied default.

show

Show the same information as **status**, but in machine readable form. This command is intended to be used whenever computer-parsable output is required. Use **status** if you are looking for formatted human-readable output.

By default, empty properties are suppressed. Use **--all** to show those too. To select specific properties to show, use **--property=**.

set-time [TIME]

Set the system clock to the specified time. This will also update the RTC time accordingly. The time may be specified in the format "2012-10-30 18:17:16".

set-timezone [TIMEZONE]

Set the system time zone to the specified value. Available timezones can be listed with **list-timezones**. If the RTC is configured to be in the local time, this will also update the RTC time. This call will alter the /etc/localtime symlink. See **localtime(5)** for more information.

list-timezones

List available time zones, one per line. Entries from the list can be set as the system timezone with **set-timezone**.

set-local-rtc [BOOL]

Takes a boolean argument. If "0", the system is configured to maintain the RTC in universal time. If "1", it will maintain the RTC in local time instead. Note that maintaining the RTC in the local timezone is not fully supported and will create various problems with time zone changes and daylight saving adjustments. If at all possible, keep the RTC in UTC mode. Note that invoking this will also synchronize the RTC from the system clock, unless **--adjust-system-clock** is passed (see above). This command will change the 3rd line of /etc/adjtime, as documented in **hwclock(8)**.

set-ntp [BOOL]

Takes a boolean argument. Controls whether network time synchronization is active and enabled (if available). If the argument is true, this enables and starts the first existing network synchronization service. If the argument is false, then this disables and stops the known network synchronization services. The way that the list of services is built is described in **systemd-timedated.service(8)**.

systemd-timesyncd Commands

The following commands are specific to **systemd-timesyncd.service(8)**.

timesync-status

Show current status of **systemd-timesyncd.service(8)**. If **--monitor** is specified, then this will monitor the status updates.

show-timesync

Show the same information as **timesync-status**, but in machine readable form. This command is intended to be used whenever computer-parsable output is required. Use **timesync-status** if you are looking for formatted human-readable output.

By default, empty properties are suppressed. Use **--all** to show those too. To select specific properties to show, use **--property=**.

ntp-servers INTERFACE SERVER...

Set the interface specific NTP servers. This command can be used only when the interface is managed by **systemd-networkd**.

revert INTERFACE

Revert the interface specific NTP servers. This command can be used only when the interface is managed by **systemd-networkd**.

OPTIONS

The following options are understood:

--no-ask-password

Do not query the user for authentication for privileged operations.

--adjust-system-clock

If **set-local-rtc** is invoked and this option is passed, the system clock is synchronized from the RTC again, taking the new setting into account. Otherwise, the RTC is synchronized from the system clock.

--monitor

If **timesync-status** is invoked and this option is passed, then **timedatectl** monitors the status of **systemd-timesyncd.service(8)** and updates the outputs. Use Ctrl+C to terminate the monitoring.

-a, --all

When showing properties of **systemd-timesyncd.service(8)**, show all properties regardless of whether they are set or not.

-p, --property=

When showing properties of **systemd-timesyncd.service(8)**, limit display to certain properties as specified as argument. If not specified, all set properties are shown. The argument should be a property name, such as "ServerName". If specified more than once, all properties with the specified names are shown.

--value

When printing properties with **show-timesync**, only print the value, and skip the property name and "**=**".

-H, --host=

Execute the operation remotely. Specify a hostname, or a username and hostname separated by "@", to connect to. The hostname may optionally be suffixed by a port ssh is listening on, separated by ":"; and then a container name, separated by "/", which connects directly to a specific container on the specified host. This will use SSH to talk to the remote machine manager instance. Container names may be enumerated with **machinectl -H HOST**. Put IPv6 addresses in brackets.

-M, --machine=

Execute operation on a local container. Specify a container name to connect to, optionally prefixed by a user name to connect as and a separating "@" character. If the special string ".host" is used in place of the container name, a connection to the local system is made (which is useful to connect to a specific user's user bus: "--user --machine=lennart@.host"). If the "@" syntax is not used, the connection is made as root user. If the "@" syntax is used either the left hand side or the right hand side may be omitted (but not both) in which case the local user name and ".host" are implied.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

--no-pager

Do not pipe output into a pager.

EXIT STATUS

On success, 0 is returned, a non-zero failure code otherwise.

ENVIRONMENT***\$SYSTEMD_LOG_LEVEL***

The maximum log level of emitted messages (messages with a higher log level, i.e. less important ones, will be suppressed). Either one of (in order of decreasing importance) **emerg**, **alert**, **crit**, **err**, **warning**, **notice**, **info**, **debug**, or an integer in the range 0...7. See **syslog(3)** for more information.

\$SYSTEMD_LOG_COLOR

A boolean. If true, messages written to the tty will be colored according to priority.

This setting is only useful when messages are written directly to the terminal, because **journalctl(1)** and other tools that display logs will color messages based on the log level on their own.

\$SYSTEMD_LOG_TIME

A boolean. If true, console log messages will be prefixed with a timestamp.

This setting is only useful when messages are written directly to the terminal or a file, because **journalctl(1)** and other tools that display logs will attach timestamps based on the entry metadata on their own.

\$SYSTEMD_LOG_LOCATION

A boolean. If true, messages will be prefixed with a filename and line number in the source code where the message originates.

Note that the log location is often attached as metadata to journal entries anyway. Including it directly in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TID

A boolean. If true, messages will be prefixed with the current numerical thread ID (TID).

Note that this information is attached as metadata to journal entries anyway. Including it directly in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TARGET

The destination for log messages. One of **console** (log to the attached tty), **console-prefixed** (log to the attached tty but with prefixes encoding the log level and "facility", see **syslog(3)**), **kmsg** (log to the kernel circular log buffer), **journal** (log to the journal), **journal-or-kmsg** (log to the journal if available, and to kmsg otherwise), **auto** (determine the appropriate log target automatically, the default), **null** (disable log output).

\$SYSTEMD_PAGER

Pager to use when **--no-pager** is not given; overrides **\$PAGER**. If neither **\$SYSTEMD_PAGER** nor **\$PAGER** are set, a set of well-known pager implementations are tried in turn, including **less(1)** and **more(1)**, until one is found. If no pager implementation is discovered no pager is invoked. Setting this environment variable to an empty string or the value "cat" is equivalent to passing **--no-pager**.

\$SYSTEMD_LESS

Override the options passed to **less** (by default "FRSXMK").

Users might want to change two options in particular:

K

This option instructs the pager to exit immediately when Ctrl+C is pressed. To allow **less** to

handle Ctrl+C itself to switch back to the pager command prompt, unset this option.

If the value of `$SYSTEMD_LESS` does not include "K", and the pager that is invoked is `less`, Ctrl+C will be ignored by the executable, and needs to be handled by the pager.

X

This option instructs the pager to not send termcap initialization and deinitialization strings to the terminal. It is set by default to allow command output to remain visible in the terminal even after the pager exits. Nevertheless, this prevents some pager functionality from working, in particular paged output cannot be scrolled with the mouse.

See `less(1)` for more discussion.

`$SYSTEMD_LESSCHARSET`

Override the charset passed to `less` (by default "utf-8", if the invoking terminal is determined to be UTF-8 compatible).

`$SYSTEMD_PAGERSECURE`

Takes a boolean argument. When true, the "secure" mode of the pager is enabled; if false, disabled. If `$SYSTEMD_PAGERSECURE` is not set at all, secure mode is enabled if the effective UID is not the same as the owner of the login session, see `geteuid(2)` and `sd_pid_get_owner_uid(3)`. In secure mode, `LESSSECURE=1` will be set when invoking the pager, and the pager shall disable commands that open or create new files or start new subprocesses. When `$SYSTEMD_PAGERSECURE` is not set at all, pagers which are not known to implement secure mode will not be used. (Currently only `less(1)` implements secure mode.)

Note: when commands are invoked with elevated privileges, for example under `sudo(8)` or `pkexec(1)`, care must be taken to ensure that unintended interactive features are not enabled. "Secure" mode for the pager may be enabled automatically as described above. Setting `SYSTEMD_PAGERSECURE=0` or not removing it from the inherited environment allows the user to invoke arbitrary commands. Note that if the `$SYSTEMD_PAGER` or `$PAGER` variables are to be honoured, `$SYSTEMD_PAGERSECURE` must be set too. It might be reasonable to completely disable the pager using `--no-pager` instead.

`$SYSTEMD_COLORS`

Takes a boolean argument. When true, `systemd` and related utilities will use colors in their output, otherwise the output will be monochrome. Additionally, the variable can take one of the following special values: "16", "256" to restrict the use of colors to the base 16 or 256 ANSI colors, respectively. This can be specified to override the automatic decision based on `$TERM` and what the console is connected to.

`$SYSTEMD_URLIFY`

The value must be a boolean. Controls whether clickable links should be generated in the output for terminal emulators supporting this. This can be specified to override the decision that `systemd` makes based on `$TERM` and other conditions.

EXAMPLES

Show current settings:

```
$ timedatectl
  Local time: Thu 2017-09-21 16:08:56 CEST
  Universal time: Thu 2017-09-21 14:08:56 UTC
    RTC time: Thu 2017-09-21 14:08:56
    Time zone: Europe/Warsaw (CEST, +0200)
System clock synchronized: yes
      NTP service: active
      RTC in local TZ: no
```

Enable network time synchronization:

```
$ timedatectl set-ntp true
===== AUTHENTICATING FOR org.freedesktop.timedate1.set-ntp ====
Authentication is required to control whether network time synchronization shall be enabled.
Authenticating as: user
Password: *****
===== AUTHENTICATION COMPLETE ===
```

```
$ systemctl status systemd-timesyncd.service
systemd-timesyncd.service – Network Time Synchronization
   Loaded: loaded (/lib/systemd/system/systemd-timesyncd.service; enabled)
   Active: active (running) since Mo 2015-03-30 14:20:38 CEST; 5s ago
     Docs: man:systemd-timesyncd.service(8)
 Main PID: 595 (systemd-timesyn)
    Status: "Using Time Server 216.239.38.15:123 (time4.google.com)."
   CGroup: /system.slice/systemd-timesyncd.service
          595 /lib/systemd/systemd-timesyncd
...

```

Show current status of **systemd-timesyncd.service(8)**:

```
$ timedatectl timesync-status
  Server: 216.239.38.15 (time4.google.com)
  Poll interval: 1min 4s (min: 32s; max 34min 8s)
    Leap: normal
    Version: 4
    Stratum: 1
    Reference: GPS
    Precision: 1us (-20)
  Root distance: 335us (max: 5s)
    Offset: +316us
    Delay: 349us
    Jitter: 0
  Packet count: 1
    Frequency: -8.802ppm
```

NAME

times – get process times

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/times.h>
clock_t times(struct tms *buf);
```

DESCRIPTION

times() stores the current process times in the *struct tms* that *buf* points to. The *struct tms* is as defined in *<sys/times.h>*:

```
struct tms {
    clock_t tms_utime; /* user time */
    clock_t tms_stime; /* system time */
    clock_t tms_cutime; /* user time of children */
    clock_t tms_cstime; /* system time of children */
};
```

The *tms_utime* field contains the CPU time spent executing instructions of the calling process. The *tms_stime* field contains the CPU time spent executing inside the kernel while performing tasks on behalf of the calling process.

The *tms_cutime* field contains the sum of the *tms_utime* and *tms_cutime* values for all waited-for terminated children. The *tms_cstime* field contains the sum of the *tms_stime* and *tms_cstime* values for all waited-for terminated children.

Times for terminated children (and their descendants) are added in at the moment **wait(2)** or **waitpid(2)** returns their process ID. In particular, times of grandchildren that the children did not wait for are never seen.

All times reported are in clock ticks.

RETURN VALUE

times() returns the number of clock ticks that have elapsed since an arbitrary point in the past. The return value may overflow the possible range of type *clock_t*. On error, *(clock_t) -1* is returned, and *errno* is set to indicate the error.

ERRORS**EFAULT**

tms points outside the process's address space.

STANDARDS

POSIX.1-2001, POSIX.1-2008, SVr4, 4.3BSD.

NOTES

The number of clock ticks per second can be obtained using:

```
sysconf(_SC_CLK_TCK);
```

In POSIX.1-1996 the symbol **CLK_TCK** (defined in *<time.h>*) is mentioned as obsolescent. It is obsolete now.

Before Linux 2.6.9, if the disposition of **SIGCHLD** is set to **SIG_IGN**, then the times of terminated children are automatically included in the *tms_cstime* and *tms_cutime* fields, although POSIX.1-2001 says that this should happen only if the calling process **wait(2)**s on its children. This nonconformance is rectified in Linux 2.6.9 and later.

On Linux, the *buf* argument can be specified as NULL, with the result that **times()** just returns a function result. However, POSIX does not specify this behavior, and most other UNIX implementations require a non-NULL value for *buf*.

Note that **clock(3)** also returns a value of type *clock_t*, but this value is measured in units of

CLOCKS_PER_SEC, not the clock ticks used by **times()**.

On Linux, the “arbitrary point in the past” from which the return value of **times()** is measured has varied across kernel versions. On Linux 2.4 and earlier, this point is the moment the system was booted. Since Linux 2.6, this point is $(2^{32}/HZ) - 300$ seconds before system boot time. This variability across kernel versions (and across UNIX implementations), combined with the fact that the returned value may overflow the range of *clock_t*, means that a portable application would be wise to avoid using this value. To measure changes in elapsed time, use **clock_gettime(2)** instead.

Historical

SVr1-3 returns *long* and the struct members are of type *time_t* although they store clock ticks, not seconds since the Epoch. V7 used *long* for the struct members, because it had no type *time_t* yet.

BUGS

A limitation of the Linux system call conventions on some architectures (notably i386) means that on Linux 2.6 there is a small time window (41 seconds) soon after boot when **times()** can return -1, falsely indicating that an error occurred. The same problem can occur when the return value wraps past the maximum value that can be stored in **clock_t**.

NAME

timesyncd.conf, timesyncd.conf.d – Network Time Synchronization configuration files

SYNOPSIS

```
/etc/systemd/timesyncd.conf
/etc/systemd/timesyncd.conf.d/*.conf
/run/systemd/timesyncd.conf.d/*.conf
/usr/lib/systemd/timesyncd.conf.d/*.conf
```

DESCRIPTION

These configuration files control NTP network time synchronization. See **systemd.syntax(7)** for a general description of the syntax.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in /etc/systemd/ contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from /usr/lib/systemd/*.conf.d/, /usr/local/lib/systemd/*.conf.d/, and /etc/systemd/*.conf.d/. Those drop-ins have higher precedence and override the main configuration file. Files in the *.conf.d/ configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under /usr/. Files in /etc/ are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to /dev/null in the configuration directory in /etc/, with the same filename as the vendor configuration file.

OPTIONS

The following settings are configured in the [Time] section:

NTP=

A space-separated list of NTP server host names or IP addresses. During runtime this list is combined with any per-interface NTP servers acquired from **systemd-networkd.service(8)**.

systemd-timesyncd will contact all configured system or per-interface servers in turn, until one responds. When the empty string is assigned, the list of NTP servers is reset, and all prior assignments will have no effect. This setting defaults to an empty list.

FallbackNTP=

A space-separated list of NTP server host names or IP addresses to be used as the fallback NTP servers. Any per-interface NTP servers obtained from **systemd-networkd.service(8)** take precedence over this setting, as do any servers set via *NTP=* above. This setting is hence only relevant if no other NTP server information is known. When the empty string is assigned, the list of NTP servers is reset, and all prior assignments will have no effect. If this option is not given, a compiled-in list of NTP servers is used.

RootDistanceMaxSec=

Maximum acceptable root distance, i.e. the maximum estimated time required for a packet to travel to the server we are connected to from the server with the reference clock. If the current server does not satisfy this limit, **systemd-timesyncd** will switch to a different server.

Takes a time span value. The default unit is seconds, but other units may be specified, see **systemd.time(5)**. Defaults to 5 seconds.

PollIntervalMinSec=, *PollIntervalMaxSec=*

The minimum and maximum poll intervals for NTP messages. Polling starts at the minimum poll interval, and is adjusted within the specified limits in response to received packets.

Each setting takes a time span value. The default unit is seconds, but other units may be specified, see **systemd.time(5)**. *PollIntervalMinSec=* defaults to 32 seconds and must not be smaller than 16 seconds. *PollIntervalMaxSec=* defaults to 34 min 8 s (2048 seconds) and must be larger than *PollIntervalMinSec=*.

ConnectionRetrySec=

Specifies the minimum delay before subsequent attempts to contact a new NTP server are made.

Takes a time span value. The default unit is seconds, but other units may be specified, see **systemd.time(5)**. Defaults to 30 seconds and must not be smaller than 1 second.

NAME

timesyncd.conf, timesyncd.conf.d – Network Time Synchronization configuration files

SYNOPSIS

```
/etc/systemd/timesyncd.conf
/etc/systemd/timesyncd.conf.d/*.conf
/run/systemd/timesyncd.conf.d/*.conf
/usr/lib/systemd/timesyncd.conf.d/*.conf
```

DESCRIPTION

These configuration files control NTP network time synchronization. See **systemd.syntax(7)** for a general description of the syntax.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in /etc/systemd/ contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from /usr/lib/systemd/*.conf.d/, /usr/local/lib/systemd/*.conf.d/, and /etc/systemd/*.conf.d/. Those drop-ins have higher precedence and override the main configuration file. Files in the *.conf.d/ configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under /usr/. Files in /etc/ are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to /dev/null in the configuration directory in /etc/, with the same filename as the vendor configuration file.

OPTIONS

The following settings are configured in the [Time] section:

NTP=

A space-separated list of NTP server host names or IP addresses. During runtime this list is combined with any per-interface NTP servers acquired from **systemd-networkd.service(8)**.

systemd-timesyncd will contact all configured system or per-interface servers in turn, until one responds. When the empty string is assigned, the list of NTP servers is reset, and all prior assignments will have no effect. This setting defaults to an empty list.

FallbackNTP=

A space-separated list of NTP server host names or IP addresses to be used as the fallback NTP servers. Any per-interface NTP servers obtained from **systemd-networkd.service(8)** take precedence over this setting, as do any servers set via *NTP=* above. This setting is hence only relevant if no other NTP server information is known. When the empty string is assigned, the list of NTP servers is reset, and all prior assignments will have no effect. If this option is not given, a compiled-in list of NTP servers is used.

RootDistanceMaxSec=

Maximum acceptable root distance, i.e. the maximum estimated time required for a packet to travel to the server we are connected to from the server with the reference clock. If the current server does not satisfy this limit, **systemd-timesyncd** will switch to a different server.

Takes a time span value. The default unit is seconds, but other units may be specified, see **systemd.time(5)**. Defaults to 5 seconds.

PollIntervalMinSec=, *PollIntervalMaxSec=*

The minimum and maximum poll intervals for NTP messages. Polling starts at the minimum poll interval, and is adjusted within the specified limits in response to received packets.

Each setting takes a time span value. The default unit is seconds, but other units may be specified, see **systemd.time(5)**. *PollIntervalMinSec=* defaults to 32 seconds and must not be smaller than 16 seconds. *PollIntervalMaxSec=* defaults to 34 min 8 s (2048 seconds) and must be larger than *PollIntervalMinSec=*.

ConnectionRetrySec=

Specifies the minimum delay before subsequent attempts to contact a new NTP server are made.

Takes a time span value. The default unit is seconds, but other units may be specified, see **systemd.time(5)**. Defaults to 30 seconds and must not be smaller than 1 second.

systemd(1), **systemd-timesyncd.service(8)**, **systemd-networkd.service(8)**

NAME

tkill, **tkill** – send a signal to a thread

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <signal.h>      /* Definition of SIG* constants */
#include <sys/syscall.h>   /* Definition of SYS_* constants */
#include <unistd.h>

[[deprecated]] int syscall(SYS_tkill, pid_t tid, int sig);

#include <signal.h>

int tkill(pid_t tgid, pid_t tid, int sig);
```

Note: glibc provides no wrapper for **tkill()**, necessitating the use of **syscall(2)**.

DESCRIPTION

tgkill() sends the signal *sig* to the thread with the thread ID *tid* in the thread group *tgid*. (By contrast, **kill(2)** can be used to send a signal only to a process (i.e., thread group) as a whole, and the signal will be delivered to an arbitrary thread within that process.)

tkill() is an obsolete predecessor to **tgkill()**. It allows only the target thread ID to be specified, which may result in the wrong thread being signaled if a thread terminates and its thread ID is recycled. Avoid using this system call.

These are the raw system call interfaces, meant for internal thread library use.

RETURN VALUE

On success, zero is returned. On error, **-1** is returned, and *errno* is set to indicate the error.

ERRORS

EAGAIN

The **RLIMIT_SIGPENDING** resource limit was reached and *sig* is a real-time signal.

EAGAIN

Insufficient kernel memory was available and *sig* is a real-time signal.

EINVAL

An invalid thread ID, thread group ID, or signal was specified.

EPERM

Permission denied. For the required permissions, see **kill(2)**.

ESRCH

No process with the specified thread ID (and thread group ID) exists.

VERSIONS

tkill() is supported since Linux 2.4.19 / 2.5.4. **tgkill()** was added in Linux 2.5.75.

Library support for **tgkill()** was added in glibc 2.30.

STANDARDS

tkill() and **tgkill()** are Linux-specific and should not be used in programs that are intended to be portable.

NOTES

See the description of **CLONE_THREAD** in **clone(2)** for an explanation of thread groups.

Before glibc 2.30, there was also no wrapper function for **tgkill()**.

SEE ALSO

clone(2), **gettid(2)**, **kill(2)**, **rt_sigqueueinfo(2)**

NAME

top – display Linux processes

SYNOPSIS

```
top [-hv|bcEeHiOSs1] [-d secs] [-n max] [-u|U user] [-p pids] [-o field] [-w [cols]]
```

The traditional switches ‘–’ and whitespace are optional.

DESCRIPTION

The **top** program provides a dynamic real-time view of a running system. It can display **system** summary information as well as a list of **processes** or **threads** currently being managed by the Linux kernel. The types of system summary information shown and the types, order and size of information displayed for processes are all user configurable and that configuration can be made persistent across restarts.

The program provides a limited interactive interface for process manipulation as well as a much more extensive interface for personal configuration — encompassing every aspect of its operation. And while **top** is referred to throughout this document, you are free to name the program anything you wish. That new name, possibly an alias, will then be reflected on top’s display and used when reading and writing a configuration file.

Operation

When operating top, the two most important keys are the help (h or ?) key and quit ('q') key. Alternatively, you could simply use the traditional interrupt key (^C) when you're done.

When started for the first time, you'll be presented with these traditional elements on the main top screen: 1) Summary Area; 2) Fields/Columns Header; 3) Task Area. Each of these will be explored in the sections that follow. There is also an Input/Message line between the Summary Area and Columns Header which needs no further explanation.

The main top screen is *generally* quite adaptive to changes in terminal dimensions under X-Windows. Other top screens may be less so, especially those with static text. It ultimately depends, however, on your particular window manager and terminal emulator. There may be occasions when their view of terminal size and current contents differs from top's view, which is always based on operating system calls.

Following any re-size operation, if a top screen is corrupted, appears incomplete or disordered, simply typing something innocuous like a punctuation character or cursor motion key will usually restore it. In extreme cases, the following sequence almost certainly will:

```
key/cmd objective
^Z    suspend top
fg    resume top
<Left> force a screenr edraw (if necessary)
```

But if the display is still corrupted, there is one more step you could try. Insert this command after top has been suspended but before resuming it.

```
key/cmd objective
reset restore yourterminal settings
```

Note: the width of top's display will be limited to 512 positions. Displaying all fields requires approximately 250 characters. Remaining screen width is usually allocated to any variable width columns currently visible. The variable width columns, such as COMMAND, are noted in topic 3a. DESCRIPTIONS of Fields. Actual output width may also be influenced by the -w switch, which is discussed in topic 1. COMMAND-LINE Options.

Lastly, some of top's screens or functions require the use of cursor motion keys like the standard arrow keys plus the Home, End, PgUp and PgDn keys. If your terminal or emulator does not provide those keys, the following combinations are accepted as alternatives:

key	equivalent-keys
Left	alt +h
Down	alt +j
Up	alt +k
Right	alt +l
Home	alt + ctrl +h
PgDn	alt + ctrl +j
PgUp	alt + ctrl +k
End	alt + ctrl +l

The **Up** and **Down** arrow keys have special significance when prompted for line input terminated with the <Enter> key. Those keys, or their aliases, can be used to retrieve previous input lines which can then be edited and re-input. And there are four additional keys available with line oriented input.

<i>key</i>	<i>special-significance</i>
Up	recall older strings for re-editing
Down	recall newer strings or erase entire line
Insert	toggle between insert and o vertype modes
Delete	character removed at cursor, moving others left
Home	jump to beginning of input line
End	jump to end of input line

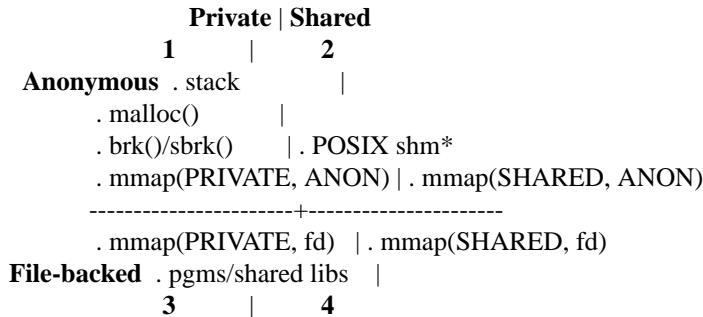

Linux Memory Types

For our purposes there are three types of memory, and one is optional. First is physical memory, a limited resource where code and data must reside when executed or referenced. Next is the optional swap file, where modified (dirty) memory can be saved and later retrieved if too many demands are made on physical memory. Lastly we have virtual memory, a nearly unlimited resource serving the following goals:

1. abstraction, free from physical memory addresses/limits
2. isolation, every process in a separate address space
3. sharing, a single mapping can serve multiple needs
4. flexibility, assign a virtual address to a file

Regardless of which of these forms memory may take, all are managed as pages (typically 4096 bytes) but expressed by default in top as KiB (kibibyte). The memory discussed under topic ‘2c. MEMORY Usage’ deals with physical memory and the swap file for the system as a whole. The memory reviewed in topic ‘3. FIELDS / Columns Display’ embraces all three memory types, but for individual processes.

For each such process, every memory page is restricted to a single quadrant from the table below. Both physical memory and virtual memory can include any of the four, while the swap file only includes #1 through #3. The memory in quadrant #4, when modified, acts as its own dedicated swap file.

The following may help in interpreting process level memory values displayed as scalable columns and discussed under topic ‘3a. DESCRIPTIONS of Fields’.

- %MEM – simply RES divided by total physical memory
- CODE – the ‘pgms’ portion of quadrant **3**
- DATA – the entire quadrant **1** portion of VIRT plus all explicit mmap file-backed pages of quadrant **3**
- RES – anything occupying physical memory which, beginning with Linux-4.5, is the sum of the following three fields:
 - RSan – quadrant **1** pages, which include any former quadrant **3** pages if modified
 - RSfd – quadrant **3** and quadrant **4** pages

RSsh – quadrant **2** pages
 RSlk – subset of RES which cannot be swapped out (any quadrant)
 SHR – subset of RES (excludes **1**, includes all **2 & 4**, some **3**)
 SWAP – potentially any quadrant except **4**
 USED – simply the sum of RES and SWAP
 VIRT – everything in-use and/or reserved (all quadrants)

Note: Even though program images and shared libraries are considered *private* to a process, they will be accounted for as *shared* (SHR) by the kernel.

1. COMMAND-LINE Options

The command-line syntax for top consists of:

-hv|bcEeHiOSs1 -d secs -n max -u|U user -p pids -o field -w [cols]

The typically mandatory switch ('-') and even whitespace are completely optional.

-h | -v :Help/Version

Show library version and the usage prompt, then quit.

-b :Batch-mode operation

Starts top in Batch mode, which could be useful for sending output from top to other programs or to a file. In this mode, top will not accept input and runs until the iterations limit you've set with the '-n' command-line option or until killed.

-c :Command-line/Program-name toggle

Starts top with the last remembered 'c' state reversed. Thus, if top was displaying command lines, now that field will show program names, and vice versa. See the 'c' interactive command for additional information.

-d :Delay-time interval as: **-d ss.t (secs.tenths)**

Specifies the delay between screen updates, and overrides the corresponding value in one's personal configuration file or the startup default. Later this can be changed with the 'd' or 's' interactive commands.

Fractional seconds are honored, but a negative number is not allowed. In all cases, however, such changes are prohibited if top is running in Secure mode, except for root (unless the 's' command-line option was used). For additional information on Secure mode see topic 6d. SYSTEM Restrictions File.

-e :Enforce-Task-Memory-Scaling as: **-e k|m|g|t|p**

Instructs top to force task area memory to be scaled as:

k – kibibytes

m – mebibytes

g – gibibytes

t – tebibytes

p – pebibytes

Later this can be changed with the 'e' command toggle.

-E :Enforce-Summary-Memory-Scaling as: -E k|m|g|t|p|e

Instructs top to force summary area memory to be scaled as:

- k – kibibytes
- m – mebibytes
- g – gibibytes
- t – tebibytes
- p – pebibytes
- e – exbibytes

Later this can be changed with the ‘E’ command toggle.

-H :Threads-mode operation

Instructs top to display individual threads. Without this command-line option a summation of all threads in each process is shown. Later this can be changed with the ‘H’ interactive command.

-i :Idle-process toggle

Starts top with the last remembered ‘i’ state reversed. When this toggle is *Off*, tasks that have not used any CPU since the last update will not be displayed. For additional information regarding this toggle see topic 4c. TASK AREA Commands, SIZE.

-n :Number-of-iterations limit as: -n number

Specifies the maximum number of iterations, or frames, top should produce before ending.

-o :Override-sort-field as: -o fieldname

Specifies the name of the field on which tasks will be sorted, independent of what is reflected in the configuration file. You can prepend a ‘+’ or ‘-’ to the field name to also override the sort direction. A leading ‘+’ will force sorting high to low, whereas a ‘-’ will ensure a low to high ordering.

This option exists primarily to support automated/scripted batch mode operation.

-O :Output-field-names

This option acts as a form of help for the above –o option. It will cause top to print each of the available field names on a separate line, then quit. Such names are subject to NLS (National Language Support) translation.

-p :Monitor-PIDs mode as: -pN1 -pN2 ... or -pN1,N2,N3 ...

Monitor only processes with specified process IDs. This option can be given up to 20 times, or you can provide a comma delimited list with up to 20 pids. Co-mingling both approaches is permitted.

A pid value of zero will be treated as the process id of the top program itself once it is running.

This is a command-line option only and should you wish to return to normal operation, it is not necessary to quit and restart top — just issue any of these interactive commands: ‘=’, ‘u’ or ‘U’.

The ‘p’, ‘u’ and ‘U’ command-line options are mutually exclusive.

-s :Secure-mode operation

Starts top with secure mode forced, even for root. This mode is far better controlled through a system configuration file (see topic 6. FILES).

-S :*Cumulative-time toggle*

Starts top with the last remembered ‘S’ state reversed. When Cumulative time mode is *On*, each process is listed with the cpu time that it and its dead children have used. See the ‘S’ interactive command for additional information regarding this mode.

-u | -U :*User-filter-mode* as: **-u | -U number or name**

Display only processes with a user id or user name matching that given. The ‘-u’ option matches on *effective* user whereas the ‘-U’ option matches on *any* user (real, effective, saved, or filesystem).

Prepending an exclamation point (!) to the user id or name instructs top to display only processes with users not matching the one provided.

The ‘p’, ‘u’ and ‘U’ command-line options are mutually exclusive.

-w :*Output-width-override* as: **-w [number]**

In Batch mode, when used without an argument top will format output using the COLUMNS= and LINES= environment variables, if set. Otherwise, width will be fixed at the maximum 512 columns. With an argument, output width can be decreased or increased (up to 512) but the number of rows is considered unlimited.

In normal display mode, when used without an argument top will *attempt* to format output using the COLUMNS= and LINES= environment variables, if set. With an argument, output width can only be decreased, not increased. Whether using environment variables or an argument with –w, when *not* in Batch mode actual terminal dimensions can never be exceeded.

Note: Without the use of this command-line option, output width is always based on the terminal at which top was invoked whether or not in Batch mode.

-1 :*Single/Separate-Cpu-States toggle*

Starts top with the last remembered Cpu States portion of the summary area reversed. Either all cpu information will be displayed in a single line or each cpu will be displayed separately, depending on the state of the NUMA Node command toggle (‘2’).

See the ‘1’ and ‘2’ interactive commands for additional information.

2. SUMMARY Display

Each of the following three areas are individually controlled through one or more interactive commands. See topic 4b. SUMMARY AREA Commands for additional information regarding these provisions.

2a. UPTIME and LOAD Averages

This portion consists of a single line containing:

- program** or **window** name, depending on display mode
- current time and length of time since last boot
- total number of users
- system load avg over the last 1, 5 and 15 minutes

2b. TASK and CPU States

This portion consists of a minimum of two lines. In an SMP environment, additional lines can reflect individual CPU state percentages.

Line 1 shows total **tasks** or **threads**, depending on the state of the Threads-mode toggle. That total is further classified as:

running; sleeping; stopped; zombie

Line 2 shows CPU state percentages based on the interval since the last refresh.

As a default, percentages for these individual categories are displayed. Where two labels are shown below, those for more recent kernel versions are shown first.

- us, user** : time running un-niced user processes
- sy, system** : time running kernel processes
- ni, nice** : time running niced user processes
- id, idle** : time spent in the kernel idle handler
- wa, IO-wait** : time waiting for I/O completion
- hi** : time spent servicing hardware interrupts
- si** : time spent servicing software interrupts
- st** : time stolen from this vm by the hypervisor

In the alternate cpu states display modes, beyond the first tasks/threads line, an abbreviated summary is shown consisting of these elements:

```
a b c d
%Cpu(s): 75.0/25.0 100[ ...]
```

Where: a) is the ‘user’ (us + ni) percentage; b) is the ‘system’ (sy + hi + si) percentage; c) is the total; and d) is one of two visual graphs of those representations. See topic 4b. SUMMARY AREA Commands and the ‘t’ command for additional information on that special 4-way toggle.

2c. MEMORY Usage

This portion consists of two lines which may express values in kibibytes (KiB) through exbibytes (EiB) depending on the scaling factor enforced with the ‘E’ interactive command.

As a default, Line 1 reflects physical memory, classified as:
total, free, used and buff/cache

Line 2 reflects mostly virtual memory, classified as:
total, free, used and avail (which is physical memory)

The **avail** number on line 2 is an estimation of physical memory available for starting new applications, without swapping. Unlike the **free** field, it attempts to account for readily reclaimable page cache and memory slabs. It is available on kernels 3.14, emulated on kernels 2.6.27+, otherwise the same as **free**.

In the alternate memory display modes, two abbreviated summary lines are shown consisting of these elements:

```
a b c
GiB Mem : 18.7/15.738 [ ...
GiB Swap: 0.0/7.999 [ ...]
```

Where: a) is the percentage used; b) is the total available; and c) is one of two visual graphs of those representations.

In the case of physical memory, the percentage represents the **total** minus the estimated **avail** noted above. The ‘Mem’ graph itself is divided between **used** and any remaining memory not otherwise accounted for by **avail**. See topic 4b. SUMMARY AREA Commands and the ‘m’ command for additional information on that special 4-way toggle.

This table may help in interpreting the scaled values displayed:

KiB = kibibyte = 1024 bytes
 MiB = mebibyte = 1024 KiB = 1,048,576 bytes
 GiB = gibibyte = 1024 MiB = 1,073,741,824 bytes
 TiB = tebibyte = 1024 GiB = 1,099,511,627,776 bytes
 PiB = pebibyte = 1024 TiB = 1,125,899,906,842,624 bytes
 EiB = exbibyte = 1024 PiB = 1,152,921,504,606,846,976 bytes

3. FIELDS / Columns

3a. DESCRIPTIONS of Fields

Listed below are top's available process fields (columns). They are shown in strict ascii alphabetical order. You may customize their position and whether or not they are displayable with the 'f' or 'F' (Fields Management) interactive commands.

Any field is selectable as the sort field, and you control whether they are sorted high-to-low or low-to-high. For additional information on sort provisions see topic 4c. TASK AREA Commands, SORTING.

The fields related to physical memory or virtual memory reference '(KiB)' which is the unsuffixed display mode. Such fields may, however, be scaled from KiB through PiB. That scaling is influenced via the 'e' interactive command or established for startup through a build option.

1. %CPU — CPU Usage

The task's share of the elapsed CPU time since the last screen update, expressed as a percentage of total CPU time.

In a true SMP environment, if a process is multi-threaded and top is *not* operating in Threads mode, amounts greater than 100% may be reported. You toggle Threads mode with the 'H' interactive command.

Also for multi-processor environments, if Irix mode is *Off*, top will operate in Solaris mode where a task's cpu usage will be divided by the total number of CPUs. You toggle Irix/Solaris modes with the 'T' interactive command.

Note: When running in forest view mode ('V') with children collapsed ('v'), this field will also include the CPU time of those unseen children. See topic 4c. TASK AREA Commands, CONTENT for more information regarding the 'V' and 'v' toggles.

2. %MEM — Memory Usage (RES)

A task's currently resident share of available physical memory.

See 'OVERVIEW, Linux Memory Types' for additional details.

3. CGNAME — Control Group Name

The name of the control group to which a process belongs, or '-' if not applicable for that process.

This will typically be the last entry in the full list of control groups as shown under the next heading (CGROUPS). And as is true there, this field is also variable width.

4. CGROUPS — Control Groups

The names of the control group(s) to which a process belongs, or '-' if not applicable for that process.

Control Groups provide for allocating resources (cpu, memory, network bandwidth, etc.) among installation-defined groups of processes. They enable fine-grained control over allocating, denying,

prioritizing, managing and monitoring those resources.

Many different hierarchies of cgroups can exist simultaneously on a system and each hierarchy is attached to one or more subsystems. A subsystem represents a single resource.

Note: The CGROUPS field, unlike most columns, is not fixed-width. When displayed, it plus any other variable width columns will be allocated all remaining screen width (up to the maximum 512 characters). Even so, such variable width fields could still suffer truncation. See topic 5c. SCROLLING a Window for additional information on accessing any truncated data.

5. CODE -- Code Size (KiB)

The amount of physical memory currently devoted to executable code, also known as the Text Resident Set size or TRS.

See ‘OVERVIEW, Linux Memory Types’ for additional details.

6. COMMAND -- Command Name or Command Line

Display the command line used to start a task or the name of the associated program. You toggle between command *line* and *name* with ‘c’, which is both a command-line option and an interactive command.

When you’ve chosen to display command lines, processes without a command line (like kernel threads) will be shown with only the program name in brackets, as in this example:

[kthreadd]

This field may also be impacted by the forest view display mode. See the ‘V’ interactive command for additional information regarding that mode.

Note: The COMMAND field, unlike most columns, is not fixed-width. When displayed, it plus any other variable width columns will be allocated all remaining screen width (up to the maximum 512 characters). Even so, such variable width fields could still suffer truncation. This is especially true for this field when command lines are being displayed (the ‘c’ interactive command.) See topic 5c. SCROLLING a Window for additional information on accessing any truncated data.

7. DATA -- Data + Stack Size (KiB)

The amount of private memory *reserved* by a process. It is also known as the Data Resident Set or DRS. Such memory may not yet be mapped to physical memory (RES) but will always be included in the virtual memory (VIRT) amount.

See ‘OVERVIEW, Linux Memory Types’ for additional details.

8. ENVIRON -- Environment variables

Display all of the environment variables, if any, as seen by the respective processes. These variables will be displayed in their raw native order, not the sorted order you are accustomed to seeing with an unqualified ‘set’.

Note: The ENVIRON field, unlike most columns, is not fixed-width. When displayed, it plus any other variable width columns will be allocated all remaining screen width (up to the maximum 512 characters). Even so, such variable width fields could still suffer truncation. This is especially true for this field. See topic 5c. SCROLLING a Window for additional information on accessing any truncated data.

9. Flags -- Task Flags

This column represents the task's current scheduling flags which are expressed in hexadecimal notation and with zeros suppressed. These flags are officially documented in <linux/sched.h>.

10. GID -- Group Id

The *effective* group ID.

11. GROUP -- Group Name

The *effective* group name.

12. LXC -- Lxc Container Name

The name of the lxc container within which a task is running. If a process is not running inside a container, a dash ('-') will be shown.

13. NI -- Nice Value

The nice value of the task. A negative nice value means higher priority, whereas a positive nice value means lower priority. Zero in this field simply means priority will not be adjusted in determining a task's dispatch-ability.

14. NU -- Last known NUMA node

A number representing the NUMA node associated with the last used processor ('P'). When -1 is displayed it means that NUMA information is not available.

See the '2' and '3' interactive commands for additional NUMA provisions affecting the summary area.

15. OOMa -- Out of Memory Adjustment Factor

The value, ranging from -1000 to +1000, added to the current out of memory score (OOMs) which is then used to determine which task to kill when memory is exhausted.

16. OOMs -- Out of Memory Score

The value, ranging from 0 to +1000, used to select task(s) to kill when memory is exhausted. Zero translates to 'never kill' whereas 1000 means 'always kill'.

17. P -- Last used CPU (SMP)

A number representing the last used processor. In a true SMP environment this will likely change frequently since the kernel intentionally uses weak affinity. Also, the very act of running top may break this weak affinity and cause more processes to change CPUs more often (because of the extra demand for cpu time).

18. PGRP -- Process Group Id

Every process is member of a unique process group which is used for distribution of signals and by terminals to arbitrate requests for their input and output. When a process is created (forked), it becomes a member of the process group of its parent. By convention, this value equals the process ID (see PID) of the first member of a process group, called the process group leader.

19. PID -- Process Id

The task's unique process ID, which periodically wraps, though never restarting at zero. In kernel terms, it is a dispatchable entity defined by a task_struct.

This value may also be used as: a process group ID (see PGRP); a session ID for the session leader (see SID); a thread group ID for the thread group leader (see Tgid); and a TTY process group ID for the process group leader (see TPGID).

20. PPID -- Parent Process Id

The process ID (pid) of a task's parent.

21. PR -- Priority

The scheduling priority of the task. If you see 'rt' in this field, it means the task is running under real time scheduling priority.

Under linux, real time priority is somewhat misleading since traditionally the operating itself was not preemptible. And while the 2.6 kernel can be made mostly preemptible, it is not always so.

22. RES -- Resident Memory Size (KiB)

A subset of the virtual address space (VIRT) representing the non-swapped physical memory a task is currently using. It is also the sum of the RSan, RSfd and RSsh fields.

It can include private anonymous pages, private pages mapped to files (including program images and shared libraries) plus shared anonymous pages. All such memory is backed by the swap file represented separately under SWAP.

Lastly, this field may also include shared file-backed pages which, when modified, act as a dedicated swap file and thus will never impact SWAP.

See 'OVERVIEW, Linux Memory Types' for additional details.

23. RSan -- Resident Anonymous Memory Size (KiB)

A subset of resident memory (RES) representing private pages not mapped to a file.

24. RSfd -- Resident File-Backed Memory Size (KiB)

A subset of resident memory (RES) representing the implicitly shared pages supporting program images and shared libraries. It also includes explicit file mappings, both private and shared.

25. RSlk -- Resident Locked Memory Size (KiB)

A subset of resident memory (RES) which cannot be swapped out.

26. RSsh -- Resident Shared Memory Size (KiB)

A subset of resident memory (RES) representing the explicitly shared anonymous shm*/mmap pages.

27. RUID -- Real User Id

The *real* user ID.

28. RUSER -- Real User Name

The *real* user name.

29. S -- Process Status

The status of the task which can be one of:

D = uninterruptible sleep

I = idle

R = running
S = sleeping
T = stopped by job control signal
t = stopped by debugger during trace
Z = zombie

Tasks shown as running should be more properly thought of as ready to run -- their task_struct is simply represented on the Linux run-queue. Even without a true SMP machine, you may see numerous tasks in this state depending on top's delay interval and nice value.

30. **SHR** — Shared Memory Size (KiB)

A subset of resident memory (RES) that may be used by other processes. It will include shared anonymous pages and shared file-backed pages. It also includes private pages mapped to files representing program images and shared libraries.

See ‘OVERVIEW, Linux Memory Types’ for additional details.

31. **SID** — Session Id

A session is a collection of process groups (see PGRP), usually established by the login shell. A newly forked process joins the session of its creator. By convention, this value equals the process ID (see PID) of the first member of the session, called the session leader, which is usually the login shell.

32. **SUID** — Saved User Id

The *saved* user ID.

33. **SUPGIDS** — Supplementary Group IDs

The IDs of any supplementary group(s) established at login or inherited from a task’s parent. They are displayed in a comma delimited list.

Note: The SUPGIDS field, unlike most columns, is not fixed-width. When displayed, it plus any other variable width columns will be allocated all remaining screen width (up to the maximum 512 characters). Even so, such variable width fields could still suffer truncation. See topic 5c. SCROLLING a Window for additional information on accessing any truncated data.

34. **SUPGRPS** — Supplementary Group Names

The names of any supplementary group(s) established at login or inherited from a task’s parent. They are displayed in a comma delimited list.

Note: The SUPGRPS field, unlike most columns, is not fixed-width. When displayed, it plus any other variable width columns will be allocated all remaining screen width (up to the maximum 512 characters). Even so, such variable width fields could still suffer truncation. See topic 5c. SCROLLING a Window for additional information on accessing any truncated data.

35. **SUSER** — Saved User Name

The *saved* user name.

36. **SWAP** — Swapped Size (KiB)

The formerly resident portion of a task’s address space written to the swap file when physical memory becomes over committed.

See ‘OVERVIEW, Linux Memory Types’ for additional details.

37. TGID — Thread Group Id

The ID of the thread group to which a task belongs. It is the PID of the thread group leader. In kernel terms, it represents those tasks that share an mm_struct.

38. TIME — CPU Time

Total CPU time the task has used since it started. When Cumulative mode is *On*, each process is listed with the cpu time that it and its dead children have used. You toggle Cumulative mode with ‘S’, which is both a command-line option and an interactive command. See the ‘S’ interactive command for additional information regarding this mode.

39. TIME+ — CPU Time, hundredths

The same as TIME, but reflecting more granularity through hundredths of a second.

40. TPGID — Tty Process Group Id

The process group ID of the foreground process for the connected tty, or -1 if a process is not connected to a terminal. By convention, this value equals the process ID (see PID) of the process group leader (see PGRP).

41. TTY — Controlling Tty

The name of the controlling terminal. This is usually the device (serial port, pty, etc.) from which the process was started, and which it uses for input or output. However, a task need not be associated with a terminal, in which case you’ll see ‘?’ displayed.

42. UID — User Id

The *effective* user ID of the task’s owner.

43. USED — Memory in Use (KiB)

This field represents the non-swapped physical memory a task is using (RES) plus the swapped out portion of its address space (SWAP).

See ‘OVERVIEW, Linux Memory Types’ for additional details.

44. USER — User Name

The *effective* user name of the task’s owner.

45. VIRT — Virtual Memory Size (KiB)

The total amount of virtual memory used by the task. It includes all code, data and shared libraries plus pages that have been swapped out and pages that have been mapped but not used.

See ‘OVERVIEW, Linux Memory Types’ for additional details.

46. WCHAN — Sleeping in Function

This field will show the name of the kernel function in which the task is currently sleeping. Running tasks will display a dash (‘-’) in this column.

47. nDRT — Dirty Pages Count

The number of pages that have been modified since they were last written to auxiliary storage. Dirty pages must be written to auxiliary storage before the corresponding physical memory location can be used for some other virtual page.

This field was deprecated with linux 2.6 and is always zero.

48. **nMaj** — Major Page Fault Count

The number of **major** page faults that have occurred for a task. A page fault occurs when a process attempts to read from or write to a virtual page that is not currently present in its address space. A major page fault is when auxiliary storage access is involved in making that page available.

49. **nMin** — Minor Page Fault count

The number of **minor** page faults that have occurred for a task. A page fault occurs when a process attempts to read from or write to a virtual page that is not currently present in its address space. A minor page fault does not involve auxiliary storage access in making that page available.

50. **nTH** — Number of Threads

The number of threads associated with a process.

51. **nsIPC** — IPC namespace

The Inode of the namespace used to isolate interprocess communication (IPC) resources such as System V IPC objects and POSIX message queues.

52. **nsMNT** — MNT namespace

The Inode of the namespace used to isolate filesystem mount points thus offering different views of the filesystem hierarchy.

53. **nsNET** — NET namespace

The Inode of the namespace used to isolate resources such as network devices, IP addresses, IP routing, port numbers, etc.

54. **nsPID** — PID namespace

The Inode of the namespace used to isolate process ID numbers meaning they need not remain unique. Thus, each such namespace could have its own ‘init/systemd’ (PID #1) to manage various initialization tasks and reap orphaned child processes.

55. **nsUSER** — USER namespace

The Inode of the namespace used to isolate the user and group ID numbers. Thus, a process could have a normal unprivileged user ID outside a user namespace while having a user ID of 0, with full root privileges, inside that namespace.

56. **nsUTS** — UTS namespace

The Inode of the namespace used to isolate hostname and NIS domain name. UTS simply means “UNIX Time-sharing System”.

57. **vMj** — Major Page Fault Count Delta

The number of **major** page faults that have occurred since the last update (see nMaj).

58. **vMn** — Minor Page Fault Count Delta

The number of **minor** page faults that have occurred since the last update (see nMin).

3b. MANAGING Fields

After pressing the interactive command ‘f’ or ‘F’ (Fields Management) you will be presented with a screen showing: 1) the ‘current’ window name; 2) the designated sort field; 3) all fields in their current order along

with descriptions. Entries marked with an asterisk are the currently displayed fields, screen width permitting.

- As the on screen instructions indicate, you navigate among the fields with the **Up** and **Down** arrow keys. The PgUp, PgDn, Home and End keys can also be used to quickly reach the first or last available field.
- The **Right** arrow key selects a field for repositioning and the **Left** arrow key or the <**Enter**> key commits that field's placement.
- The 'd' key or the <**Space**> bar toggles a field's display status, and thus the presence or absence of the asterisk.
- The 's' key designates a field as the sort field. See topic 4c. TASK AREA Commands, SORTING for additional information regarding your selection of a sort field.
- The 'a' and 'w' keys can be used to cycle through all available windows and the 'q' or <**Esc**> keys exit Fields Management.

The Fields Management screen can also be used to change the 'current' window/field group in either full-screen mode or alternate-display mode. Whatever was targeted when 'q' or <**Esc**> was pressed will be made current as you return to the top display. See topic 5. ALTERNATE-DISPLAY Provisions and the 'g' interactive command for insight into 'current' windows and field groups.

Note: Any window that has been scrolled *horizontally* will be reset if any field changes are made via the Fields Management screen. Any *vertical* scrolled position, however, will not be affected. See topic 5c. SCROLLING a Window for additional information regarding vertical and horizontal scrolling.

4. INTERACTIVE Commands

Listed below is a brief index of commands within categories. Some commands appear more than once -- their meaning or scope may vary depending on the context in which they are issued.

4a. Global-Commands

<**Ent/Sp**> ?, =, 0,
A, B, d, E, e, g, h, H, I, k, q, r, s, W, X, Y, Z

4b. Summary-Area-Commands

C, l, t, m, 1, 2, 3, 4, !

4c. Task-Area-Commands

Appearance: b, J, j, x, y, z
Content: c, f, F, o, O, S, u, U, V, v
Size: #, i, n
Sorting: <, >, f, F, R

4d. Color-Mapping

<**Ret**>, a, B, b, H, M, q, S, T, w, z, 0 – 7

5b. Commands-for-Windows

–, _, =, +, A, a, g, G, w

5c. Scrolling-a-Window

C, Up, Dn, Left, Right, PgUp, PgDn, Home, End

5d. Searching-in-a-Window

L, &

4a. GLOBAL Commands

The global interactive commands are **always** available in both full–screen mode and alternate–display mode. However, some of these interactive commands are **not available** when running in Secure mode.

If you wish to know in advance whether or not your top has been secured, simply ask for help and view the system summary on the second line.

<Enter> or <Space> :Refresh-Display

These commands awaken top and following receipt of any input the entire display will be repainted. They also force an update of any hotplugged cpu or physical memory changes.

Use either of these keys if you have a large delay interval and wish to see current status,

? | h :Help

There are two help levels available. The first will provide a reminder of all the basic interactive commands. If top is secured, that screen will be abbreviated.

Typing ‘h’ or ‘?’ on that help screen will take you to help for those interactive commands applicable to alternate–display mode.

= :Exit-Display-Limits

Removes restrictions on what is shown. This command will reverse any ‘i’ (idle tasks), ‘n’ (max tasks) and ‘v’ (hide children) commands that might be active. It also provides for an exit from PID monitoring, User filtering, Other filtering, Locate processing and Combine Cpus mode.

Additionally, if the window has been scrolled it will be reset with this command.

0 :Zero-Suppress toggle

This command determines whether zeros are shown or suppressed for many of the fields in a task window. Fields like UID, GID, NI, PR or P are not affected by this toggle.

A :Alternate-Display-Mode toggle

This command will switch between full–screen mode and alternate–display mode. See topic 5. ALTERNATE–DISPLAY Provisions and the ‘g’ interactive command for insight into ‘current’ windows and field groups.

B :Bold-Disable/Enable toggle

This command will influence use of the bold terminfo capability and alters **both** the summary area and task area for the ‘current’ window. While it is intended primarily for use with dumb terminals, it can be applied anytime.

Note: When this toggle is *On* and top is operating in monochrome mode, the **entire display** will appear as normal text. Thus, unless the ‘x’ and/or ‘y’ toggles are using reverse for emphasis, there will be no visual confirmation that they are even on.

*** d | s :Change-Delay-Time-interval**

You will be prompted to enter the delay time, in seconds, between display updates.

Fractional seconds are honored, but a negative number is not allowed. Entering 0 causes (nearly) continuous updates, with an unsatisfactory display as the system and tty driver try to keep up with top’s demands. The delay value is inversely proportional to system loading, so set it with care.

If at any time you wish to know the current delay time, simply ask for help and view the system summary on the second line.

E :Enforce-Summary-Memory-Scale in Summary Area

With this command you can cycle through the available summary area memory scaling which ranges from KiB (kilobytes or 1,024 bytes) through EiB (exabytes or 1,152,921,504,606,846,976 bytes).

If you see a ‘+’ between a displayed number and the following label, it means that top was forced to truncate some portion of that number. By raising the scaling factor, such truncation can be avoided.

e :Enforce-Task-Memory-Scale in Task Area

With this command you can cycle through the available task area memory scaling which ranges from KiB (kilobytes or 1,024 bytes) through PiB (pebibytes or 1,125,899,906,842,624 bytes).

While top will try to honor the selected target range, additional scaling might still be necessary in order to accommodate current values. If you wish to see a more homogeneous result in the memory columns, raising the scaling range will usually accomplish that goal. Raising it too high, however, is likely to produce an all zero result which cannot be suppressed with the ‘0’ interactive command.

g :Choose-Another-Window/Field-Group

You will be prompted to enter a number between 1 and 4 designating the field group which should be made the ‘current’ window. You will soon grow comfortable with these 4 windows, especially after experimenting with alternate-display mode.

H :Threads-mode toggle

When this toggle is *On*, individual threads will be displayed for all processes in all visible task windows. Otherwise, top displays a summation of all threads in each process.

I :Irix/Solaris-Mode toggle

When operating in Solaris mode (‘I’ toggled *Off*), a task’s cpu usage will be divided by the total number of CPUs. After issuing this command, you’ll be told the new state of this toggle.

* **k** :Kill-a-task

You will be prompted for a PID and then the signal to send.

Entering no PID or a negative number will be interpreted as the default shown in the prompt (the first task displayed). A PID value of zero means the top program itself.

The default signal, as reflected in the prompt, is SIGTERM. However, you can send any signal, via number or name.

If you wish to abort the kill process, do one of the following depending on your progress:

- 1) at the pid prompt, type an invalid number
- 2) at the signal prompt, type 0 (or any invalid signal)
- 3) at any prompt, type <Esc>

q :Quit

*** r :Renice-a-Task**

You will be prompted for a PID and then the value to nice it to.

Entering no PID or a negative number will be interpreted as the default shown in the prompt (the first task displayed). A PID value of zero means the top program itself.

A positive nice value will cause a process to lose priority. Conversely, a negative nice value will cause a process to be viewed more favorably by the kernel. As a general rule, ordinary users can only increase the nice value and are prevented from lowering it.

If you wish to abort the renice process, do one of the following depending on your progress:

- 1) at the pid prompt, type an invalid number
- 2) at the nice prompt, type <Enter> with no input
- 3) at any prompt, type <Esc>

W :Write-the-Configuration-File

This will save all of your options and toggles plus the current display mode and delay time. By issuing this command just before quitting top, you will be able restart later in exactly that same state.

X :Extra-Fixed-Width

Some fields are fixed width and not scalable. As such, they are subject to truncation which would be indicated by a '+' in the last position.

This interactive command can be used to alter the widths of the following fields:

<i>field</i>	<i>default</i>	<i>field</i>	<i>default</i>	<i>field</i>	<i>default</i>
GID	5	GROUP	8	WCHAN	10
RUID	5	LXC	8	nsIPC	10
SUID	5	RUSER	8	nsMNT	10
UID	5	SUSER	8	nsNET	10
		TTY	8	nsPID	10
		USER	8	nsUSER	10
				nsUTS	10

You will be prompted for the amount to be added to the default widths shown above. Entering zero forces a return to those defaults.

If you enter a negative number, top will automatically increase the column size as needed until there is no more truncated data. You can accelerate this process by reducing the delay interval or holding down the <Space> bar.

Note: Whether explicitly or automatically increased, the widths for these fields are never decreased by top. To narrow them you must specify a smaller number or restore the defaults.

Y :Inspect-Other-Output

After issuing the 'Y' interactive command, you will be prompted for a target PID. Typing a value or accepting the default results in a separate screen. That screen can be used to view a variety of files or piped command output while the normal top iterative display is paused.

Note: This interactive command is only fully realized when supporting entries have been manually added to the end of the top configuration file. For details on creating those entries, see topic 6b. ADDING INSPECT Entries.

Most of the keys used to navigate the Inspect feature are reflected in its header prologue. There are, however, additional keys available once you have selected a particular file or command. They are familiar to anyone who has used the pager ‘less’ and are summarized here for future reference.

<i>key</i>	<i>function</i>
=	alternate status-line, file or pipeline
/	find, equivalent to ‘L’ locate
n	find next, equivalent to ‘&’ locate next
<Space>	scroll down, equivalent to <PgDn>
b	scroll up, equivalent to <PgUp>
g	first line, equivalent to <Home>
G	last line, equivalent to <End>

Z :Change-Color-Mapping

This key will take you to a separate screen where you can change the colors for the ‘current’ window, or for all windows. For details regarding this interactive command see topic 4d. COLOR Mapping.

- * The commands shown with an asterisk (“*”) are not available in Secure mode, nor will they be shown on the level-1 help screen.

4b. SUMMARY AREA Commands

The summary area interactive commands are **always available** in both full-screen mode and alternate-display mode. They affect the beginning lines of your display and will determine the position of messages and prompts.

These commands always impact just the ‘current’ window/field group. See topic 5. ALTERNATE-DISPLAY Provisions and the ‘g’ interactive command for insight into ‘current’ windows and field groups.

C :Show-scroll-coordinates toggle

Toggle an informational message which is displayed whenever the message line is not otherwise being used. For additional information see topic 5c. SCROLLING a Window.

I :Load-Average/Uptime toggle

This is also the line containing the program name (possibly an alias) when operating in full-screen mode or the ‘current’ window name when operating in alternate-display mode.

t :Task/Cpu-States toggle

This command affects from 2 to many summary area lines, depending on the state of the ‘1’, ‘2’ or ‘3’ command toggles and whether or not top is running under true SMP.

This portion of the summary area is also influenced by the ‘H’ interactive command toggle, as reflected in the total label which shows either Tasks or Threads.

This command serves as a 4-way toggle, cycling through these modes:

1. detailed percentages by category
2. abbreviated user/system and total % + bar graph
3. abbreviated user/system and total % + block graph
4. turn off task and cpu states display

When operating in either of the graphic modes, the display becomes much more meaningful when

individual CPUs or NUMA nodes are also displayed. See the the ‘1’, ‘2’ and ‘3’ commands below for additional information.

m :Memory/Swap-Usage toggle

This command affects the two summary area lines dealing with physical and virtual memory.

This command serves as a 4-way toggle, cycling through these modes:

1. detailed percentages by memory type
2. abbreviated % used/total available + bar graph
3. abbreviated % used/total available + block graph
4. turn off memory display

1 :Single/Separate-Cpu-States toggle

This command affects how the ‘t’ command’s Cpu States portion is shown. Although this toggle exists primarily to serve massively-parallel SMP machines, it is not restricted to solely SMP environments.

When you see ‘%Cpu(s):’ in the summary area, the ‘1’ toggle is *On* and all cpu information is gathered in a single line. Otherwise, each cpu is displayed separately as: ‘%Cpu0, %Cpu1, ...’ up to available screen height.

2 :NUMA-Nodes/Cpu-Summary toggle

This command toggles between the ‘1’ command cpu summary display (only) or a summary display plus the cpu usage statistics for each NUMA Node. It is only available if a system has the requisite NUMA support.

3 :Expand-NUMA-Node

You will be invited to enter a number representing a NUMA Node. Thereafter, a node summary plus the statistics for each cpu in that node will be shown until the ‘1’, ‘2’ or ‘4’ command toggle is pressed. This interactive command is only available if a system has the requisite NUMA support.

4 :Display-Cpus-Two-Abreast

This command turns the ‘1’ toggle *Off* for individual cpu display but prints the results two abreast. It requires a terminal with a minimum width of 80 columns. If a terminal’s width is decreased below the minimum while top is running, top reverts to the normal ‘1’ toggle *Off* state.

To avoid truncation when displaying detailed cpu statiscts, as opposed to the graphic representations, a minimum width of 165 columns would be required.

! :Combine-Cpus-Mode

This command toggle is intended for massively parallel SMP environments where, even with the ‘4’ command toggle, not all processors can be displayed. With each press of ‘!’ the number of additional cpu’s combined is doubled thus reducing the total number of cpu lines displayed.

For example, with the first press of ‘!’ one additional cpu will be combined and displayed as ‘0-1, 2-3, ...’ instead of the normal ‘%Cpu0, %Cpu1, %Cpu2, %Cpu3, ...’. With a second ‘!’ command toggle two additional cpus are combined and shown as ‘0-2, 3-5, ...’. Then the third ‘!’ press, combining four additional cpus, shows as ‘0-4, 5-9, ...’, etc.

Such progression continues until individual cpus are again displayed and impacts both the ‘1’ and ‘4’ toggles (one or two columns). Use the ‘=’ command to exit **Combine Cpus** mode.

Note: If the entire summary area has been toggled *Off* for any window, you would be left with just the **message line**. In that way, you will have maximized available task rows but (temporarily) sacrificed the program name in full-screen mode or the ‘current’ window name when in alternate-display mode.

4c. TASK AREA Commands

The task area interactive commands are **always** available in full-screen mode.

The task area interactive commands are **never available** in alternate-display mode *if* the ‘current’ window’s task display has been toggled *Off* (see topic 5. ALTERNATE-DISPLAY Provisions).

APPEARANCE of task window

J :*Justify-Numeric-Columns* toggle

Alternates between right-justified (the default) and left-justified numeric data. If the numeric data completely fills the available column, this command toggle may impact the column header only.

j :*Justify-Character-Columns* toggle

Alternates between left-justified (the default) and right-justified character data. If the character data completely fills the available column, this command toggle may impact the column header only.

The following commands will also be influenced by the state of the global ‘B’ (bold enable) toggle.

b :*Bold/Reverse* toggle

This command will impact how the ‘x’ and ‘y’ toggles are displayed. It may also impact the summary area when a bar graph has been selected for cpu states or memory usage via the ‘t’ or ‘m’ toggles.

x :*Column-Highlight* toggle

Changes highlighting for the current sort field. If you forget which field is being sorted this command can serve as a quick visual reminder, providing the sort field is being displayed. The sort field might *not* be visible because:

- 1) there is insufficient *Screen Width*
- 2) the ‘f’ interactive command turned it *Off*

Note: Whenever Searching and/or Other Filtering is active in a window, column highlighting is temporarily disabled. See the notes at the end of topics 5d. SEARCHING and 5e. FILTERING for an explanation why.

y :*Row-Highlight* toggle

Changes highlighting for “running” tasks. For additional insight into this task state, see topic 3a. DESCRIPTIONS of Fields, the ‘S’ field (Process Status).

Use of this provision provides important insight into your system’s health. The only costs will be a few additional tty escape sequences.

z :*Color/Monochrome* toggle

Switches the ‘current’ window between your last used color scheme and the older form of black-on-white or white-on-black. This command will alter **both** the summary area and task area but does not affect the state of the ‘x’, ‘y’ or ‘b’ toggles.

CONTENT of task window**c** :*Command-Line/Program-Name* toggle

This command will be honored whether or not the COMMAND column is currently visible. Later, should that field come into view, the change you applied will be seen.

f | F :*Fields-Management*

These keys display a separate screen where you can change which fields are displayed, their order and also designate the sort field. For additional information on these interactive commands see topic 3b. MANAGING Fields.

o | O :*Other-Filtering*

You will be prompted for the selection criteria which then determines which tasks will be shown in the ‘current’ window. Your criteria can be made case sensitive or case can be ignored. And you determine if top should include or exclude matching tasks.

See topic 5e. FILTERING in a window for details on these and additional related interactive commands.

S :*Cumulative-Time-Mode* toggle

When Cumulative mode is *On*, each process is listed with the cpu time that it and its dead children have used.

When *Off*, programs that fork into many separate tasks will appear less demanding. For programs like ‘init’ or a shell this is appropriate but for others, like compilers, perhaps not. Experiment with two task windows sharing the same sort field but with different ‘S’ states and see which representation you prefer.

After issuing this command, you’ll be informed of the new state of this toggle. If you wish to know in advance whether or not Cumulative mode is in effect, simply ask for help and view the window summary on the second line.

u | U :*Show-Specific-User-Only*

You will be prompted for the **uid** or **name** of the user to display. The –u option matches on **effective** user whereas the –U option matches on **any** user (real, effective, saved, or filesystem).

Thereafter, in that task window only matching users will be shown, or possibly no processes will be shown. Prepending an exclamation point (!) to the user id or name instructs top to display only processes with users not matching the one provided.

Different task windows can be used to filter different users. Later, if you wish to monitor all users again in the ‘current’ window, re-issue this command but just press <Enter> at the prompt.

V :*Forest-View-Mode* toggle

In this mode, processes are reordered according to their parents and the layout of the COMMAND column resembles that of a tree. In forest view mode it is still possible to toggle between program name and command line (see the ‘c’ interactive command) or between processes and threads (see the ‘H’ interactive command).

Note: Typing any key affecting the sort order will exit forest view mode in the ‘current’ window. See topic 4c. TASK AREA Commands, SORTING for information on those keys.

v :Hide/Show-Children toggle

When in forest view mode, this key serves as a toggle to collapse or expand the children of a parent.

The toggle is applied against the first (topmost) process in the ‘current’ window. See topic 5c. SCROLLING a Window for additional information regarding vertical scrolling.

If the target process has not forked any children, this key has no effect. It also has no effect when not in forest view mode.

SIZE of task window**i :Idle-Process toggle**

Displays all tasks or just active tasks. When this toggle is *Off*, tasks that have not used any CPU since the last update will not be displayed. However, due to the granularity of the %CPU and TIME+ fields, some processes may still be displayed that *appear* to have used *no* CPU.

If this command is applied to the last task display when in alternate–display mode, then it will not affect the window’s size, as all prior task displays will have already been painted.

n | # :Set-Maximum-Tasks

You will be prompted to enter the number of tasks to display. The lesser of your number and available screen rows will be used.

When used in alternate–display mode, this is the command that gives you precise control over the size of each currently visible task display, except for the very last. It will not affect the last window’s size, as all prior task displays will have already been painted.

Note: If you wish to increase the size of the last visible task display when in alternate–display mode, simply decrease the size of the task display(s) above it.

SORTING of task window

For compatibility, this top supports most of the former top sort keys. Since this is primarily a service to former top users, these commands do not appear on any help screen.

command	sorted-field	supported
A	start time (non-display)	No
M	%MEM	Yes
N	PID	Yes
P	%CPU	Yes
T	TIME+	Yes

Before using any of the following sort provisions, top suggests that you temporarily turn on column highlighting using the ‘x’ interactive command. That will help ensure that the actual sort environment matches your intent.

The following interactive commands will **only** be honored when the current sort field is **visible**. The sort field might *not* be visible because:

- 1) there is insufficient *Screen Width*
- 2) the ‘f’ interactive command turned it *Off*

< :Move-Sort-Field-Left

Moves the sort column to the left unless the current sort field is the first field being displayed.

> :Move-Sort-Field-Right

Moves the sort column to the right unless the current sort field is the last field being displayed.

The following interactive commands will **always** be honored whether or not the current sort field is visible.

f | F :Fields-Management

These keys display a separate screen where you can change which field is used as the sort column, among other functions. This can be a convenient way to simply verify the current sort field, when running top with column highlighting turned *Off*.

R :Reverse/Normal-Sort-Field toggle

Using this interactive command you can alternate between high-to-low and low-to-high sorts.

Note: Field sorting uses internal values, not those in column display. Thus, the TTY and WCHAN fields will violate strict ASCII collating sequence.

4d. COLOR Mapping

When you issue the ‘Z’ interactive command, you will be presented with a separate screen. That screen can be used to change the colors in just the ‘current’ window or in all four windows before returning to the top display.

The following interactive commands are available.

4 upper case letters to select a **target**

8 numbers to select a **color**

normal toggles available

B :bold disable/enable

b :running tasks "bold"/reverse

z :color/mono

other commands available

a/w :apply, then go to next/prior

<Enter> :apply and exit

q :abandon current changes and exit

If you use ‘a’ or ‘w’ to cycle the targeted window, you will have applied the color scheme that was displayed when you left that window. You can, of course, easily return to any window and reapply different colors or turn colors *Off* completely with the ‘z’ toggle.

The Color Mapping screen can also be used to change the ‘current’ window/field group in either full-screen mode or alternate-display mode. Whatever was targeted when ‘q’ or <Enter> was pressed will be made current as you return to the top display.

5. ALTERNATE-DISPLAY Provisions

5a. WINDOWS Overview

Field Groups/Windows:

In full-screen mode there is a single window represented by the entire screen. That single window can still be changed to display 1 of 4 different **field groups** (see the ‘g’ interactive command, repeated below). Each of the 4 field groups has a unique separately configurablesummary ar ea and its own

configurable **task area**.

In alternate–display mode, those 4 underlying field groups can now be made visible simultaneously, or can be turned *Off* individually at your command.

The summary area will always exist, even if it's only the message line. At any given time only *one* summary area can be displayed. However, depending on your commands, there could be from *zero* to *four* separate task displays currently showing on the screen.

Current Window:

The ‘current’ window is the window associated with the summary area and the window to which task related commands are always directed. Since in alternate–display mode you can toggle the task display *Off*, some commands might be restricted for the ‘current’ window.

A further complication arises when you have toggled the first summary area line *Off*. With the loss of the window name (the ‘l’ toggled line), you’ll not easily know what window is the ‘current’ window.

5b. COMMANDS for Windows

- | _ :Show/Hide-Window(s) toggles

The ‘-’ key turns the ‘current’ window’s task display *On* and *Off*. When *On*, that task area will show a minimum of the columns header you’ve established with the ‘f’ interactive command. It will also reflect any other task area options/toggles you’ve applied yielding zero or more tasks.

The ‘_’ key does the same for all task displays. In other words, it switches between the currently visible task display(s) and any task display(s) you had toggled *Off*. If all 4 task displays are currently visible, this interactive command will leave the summary area as the only display element.

* = | + :Equalize/Reset-Window(s)

The ‘=’ key forces the ‘current’ window’s task display to be visible. It also reverses any active ‘i’ (idle tasks), ‘n’ (max tasks), ‘u/U’ (user filter), ‘o/O’ (other filter), ‘v’ (hide children), ‘L’ (locate) and ‘!’ (combine cpus) commands. Also, if the window had been scrolled, it will be reset with this command. See topic 5c. SCROLLING a Window for additional information regarding vertical and horizontal scrolling.

The ‘+’ key does the same for all windows. The four task displays will reappear, evenly balanced, while retaining any customizations previously applied beyond those noted for the ‘=’ command toggle.

* **A** :Alternate-Display-Mode toggle

This command will switch between full–screen mode and alternate–display mode.

The first time you issue this command, all four task displays will be shown. Thereafter when you switch modes, you will see only the task display(s) you’ve chosen to make visible.

* **a** | **w** :Next-Window-Forward/Backward

This will change the ‘current’ window, which in turn changes the window to which commands are directed. These keys act in a circular fashion so you can reach any desired window using either key.

Assuming the window name is visible (you have not toggled ‘l’ *Off*), whenever the ‘current’ window name loses its emphasis/color, that’s a reminder the task display is *Off* and many

commands will be restricted.

*** g :Choose-Another-Window/Field-Group**

You will be prompted to enter a number between 1 and 4 designating the field group which should be made the ‘current’ window.

In full–screen mode, this command is necessary to alter the ‘current’ window. In alternate–display mode, it is simply a less convenient alternative to the ‘a’ and ‘w’ commands.

G :Change-Window/Field-Group-Name

You will be prompted for a new name to be applied to the ‘current’ window. It does not require that the window name be visible (the ‘l’ toggle to be *On*).

- * The interactive commands shown with an asterisk (“*”) have use beyond alternate–display mode.
- =, A, g are always available
- a, w act the same with color mapping
and fields management

5c. SCROLLING a Window

Typically a task window is a partial view into a system’s total tasks/threads which shows only some of the available fields/columns. With these scrolling keys, you can move that view vertically or horizontally to reveal any desired task or column.

Up,PgUp :Scroll-Tasks

Move the view up toward the first task row, until the first task is displayed at the top of the ‘current’ window. The *Up* arrow key moves a single line while *PgUp* scrolls the entire window.

Down,PgDn :Scroll-Tasks

Move the view down toward the last task row, until the last task is the only task displayed at the top of the ‘current’ window. The *Down* arrow key moves a single line while *PgDn* scrolls the entire window.

Left,Right :Scroll-Columns

Move the view of displayable fields horizontally one column at a time.

Note: As a reminder, some fields/columns are not fixed-width but allocated all remaining screen width when visible. When scrolling right or left, that feature may produce some unexpected results initially.

Additionally, there are special provisions for any variable width field when positioned as the last displayed field. Once that field is reached via the right arrow key, and is thus the only column shown, you can continue scrolling horizontally within such a field. See the ‘C’ interactive command below for additional information.

Home :Jump-to-Home-Position

Reposition the display to the un-scrolled coordinates.

End :Jump-to-End-Position

Reposition the display so that the rightmost column reflects the last displayable field and the bottom task row represents the last task.

Note: From this position it is still possible to scroll *down* and *right* using the arrow keys. This is true until a single column and a single task is left as the only display element.

C :Show-scroll-coordinates toggle

Toggle an informational message which is displayed whenever the message line is not otherwise being used. That message will take one of two forms depending on whether or not a variable width column has also been scrolled.

scroll coordinates: y = n/n (tasks), x = n/n (fields)

scroll coordinates: y = n/n (tasks), x = n/n (fields) + nn

The coordinates shown as **n/n** are relative to the upper left corner of the ‘current’ window. The additional ‘+ nn’ represents the displacement into a variable width column when it has been scrolled horizontally. Such displacement occurs in normal 8 character tab stop amounts via the right and left arrow keys.

y = n/n (tasks)

The first **n** represents the topmost visible task and is controlled by scrolling keys. The second **n** is updated automatically to reflect total tasks.

x = n/n (fields)

The first **n** represents the leftmost displayed column and is controlled by scrolling keys. The second **n** is the total number of displayable fields and is established with the ‘f’ interactive command.

The above interactive commands are **always** available in full-screen mode but **never** available in alternate-display mode if the ‘current’ window’s task display has been toggled *Off*.

Note: When any form of filtering is active, you can expect some slight aberrations when scrolling since not all tasks will be visible. This is particularly apparent when using the Up/Down arrow keys.

5d. SEARCHING in a Window

You can use these interactive commands to locate a task row containing a particular value.

L :Locate-a-string

You will be prompted for the case-sensitive string to locate starting from the current window coordinates. There are no restrictions on search string content.

Searches are not limited to values from a single field or column. All of the values displayed in a task row are allowed in a search string. You may include spaces, numbers, symbols and even forest view artwork.

Keying <Enter> with no input will effectively disable the ‘&’ key until a new search string is entered.

& :Locate-next

Assuming a search string has been established, top will attempt to locate the next occurrence.

When a match is found, the current window is repositioned vertically so the task row containing that string is first. The scroll coordinates message can provide confirmation of such vertical repositioning (see the ‘C’ interactive command). Horizontal scrolling, however, is never altered via searching.

The availability of a matching string will be influenced by the following factors.

- a. Which fields are displayable from the total available,
see topic 3b. MANAGING Fields.
- b. Scrolling a window vertically and/or horizontally,
see topic 5c. SCROLLING a Window.
- c. The state of the command/command-line toggle,
see the ‘c’ interactive command.
- d. The stability of the chosen sort column,
for example PID is good but %CPU bad.

If a search fails, restoring the ‘current’ window home (unscrolled) position, scrolling horizontally, displaying command-lines or choosing a more stable sort field could yet produce a successful ‘&’ search.

The above interactive commands are **always** available in full-screen mode but **never** available in alternate-display mode if the ‘current’ window’s task display has been toggled *Off*.

Note: Whenever a Search is active in a window, top will turn column highlighting *Off* to prevent false matches on internal non-display escape sequences. Such highlighting will be restored when a window’s search string is empty. See the ‘x’ interactive command for additional information on sort column highlighting.

5e. FILTERING in a Window

You can use this ‘Other Filter’ feature to establish selection criteria which will then determine which tasks are shown in the ‘current’ window. Such filters can be made persistent if preserved in the rfile via the ‘W’ interactive command.

Establishing a filter requires: 1) a field name; 2) an operator; and 3) a selection value, as a minimum. This is the most complex of top’s user input requirements so, when you make a mistake, command recall will be your friend. Remember the Up/Down arrow keys or their aliases when prompted for input.

Filter Basics

1. field names are case sensitive and spelled as in the header
2. selection values need not comprise the full displayed field
3. a selection is either case insensitive or sensitive to case
4. the default is inclusion, prepending ‘!’ denotes exclusions
5. multiple selection criteria can be applied to a task window
6. inclusion and exclusion criteria can be used simultaneously
7. the 1 equality and 2 relational filters can be freely mixed
8. separate unique filters are maintained for each task window

If a field is not turned on or is not currently in view, then your selection criteria will not affect the display. Later, should a filtered field become visible, the selection criteria will then be applied.

Keyboard Summary

o :*Other-Filter* (lower case)

You will be prompted to establish a filter that **ignores case** when matching.

O :*Other-Filter* (upper case)

You will be prompted to establish a **case sensitive** filter.

^O :*Show-Active-Filters* (Ctrl key + ‘o’)

This can serve as a reminder of which filters are active in the ‘current’ window. A summary will be shown on the message line until you press the <Enter> key.

= :*Reset-Filtering* in current window

This clears all of your selection criteria in the ‘current’ window. It also has additional impact so please see topic 4a. GLOBAL Commands.

+ :*Reset-Filtering* in all windows

This clears the selection criteria in all windows, assuming you are in alternate–display mode. As with the ‘=’ interactive command, it too has additional consequences so you might wish to see topic 5b. COMMANDS for Windows.

Input Requirements

When prompted for selection criteria, the data you provide must take one of two forms. There are 3 required pieces of information, with a 4th as optional. These examples use spaces for clarity but your input generally would not.

```
#1      #2 #3      ( required )
Field-Name ? include-if-value
! Field-Name ? exclude-if-value
#4                  ( optional )
```

Items #1, #3 and #4 should be self-explanatory. Item#2 represents both a required *delimiter* and the *operator* which must be one of either equality (‘=’) or relation (‘<’ or ‘>’).

The ‘=’ equality operator requires only a partial match and that can reduce your ‘if–value’ input requirements. The ‘>’ or ‘<’ relational operators always employ string comparisons, even with numeric fields. They are designed to work with a field’s default *justification* and with homogeneous data. When some field’s numeric amounts have been subjected to *scaling* while others have not, that data is no longer homogeneous.

If you establish a relational filter and you **have** changed the default Numeric or Character *justification*, that filter is likely to fail. When a relational filter is applied to a memory field and you **have not** changed the *scaling*, it may produce misleading results. This happens, for example, because ‘100.0m’ (MiB) would appear greater than ‘1.000g’ (GiB) when compared as strings.

If your filtered results appear suspect, simply altering justification or scaling may yet achieve the desired objective. See the ‘j’, ‘J’ and ‘e’ interactive commands for additional information.

Potential Problems

These **GROUP** filters could produce the exact same results or the second one might not display anything at all, just a blank task window.

```
GROUP=root      ( only the same results when )
GROUP=ROOT     ( invoked via lower case 'o' )
```

Either of these **RES** filters might yield inconsistent and/or misleading results, depending on the current memory scaling factor. Or both filters could produce the exact same results.

```
RES>9999      ( only the same results when )
!RES<10000    ( memory scaling is at 'KiB' )
```

This **nMin** filter illustrates a problem unique to scalable fields. This particular field can display a maximum of 4 digits, beyond which values are automatically scaled to KiB or above. So while amounts greater than 9999 exist, they will appear as 2.6m, 197k, etc.

`nMin>9999` (always a blank task window)

Potential Solutions

These examples illustrate how Other Filtering can be creatively applied to achieve almost any desired result. Single quotes are sometimes shown to delimit the spaces which are part of a filter or to represent a request for status (^O) accurately. But if you used them with if-values in real life, no matches would be found.

Assuming field **nTH** is displayed, the first filter will result in only multi-threaded processes being shown. It also reminds us that a trailing space is part of every displayed field. The second filter achieves the exact same results with less typing.

<code>!nTH=' 1'</code>	(' for clarity only)
<code>nTH>1</code>	(same with less i/p)

With Forest View mode active and the **COMMAND** column in view, this filter effectively collapses child processes so that just 3 levels are shown.

`!COMMAND=' -'` (' for clarity only)

The final two filters appear as in response to the status request key (^O). In reality, each filter would have required separate input. The **PR** example shows the two concurrent filters necessary to display tasks with priorities of 20 or more, since some might be negative. Then by exploiting trailing spaces, the **nMin** series of filters could achieve the failed '9999' objective discussed above.

<code>'PR>20' + '!PR=-'</code>	(2 for right result)
<code>'!nMin=0' + '!nMin=1' + '!nMin=2' + '!nMin=3' ...</code>	

Note: Whenever Other Filtering is active in a window, top will turn column highlighting *Off* to prevent false matches on internal non-display escape sequences. Such highlighting will be restored when a window is no longer subject to filtering. See the 'x' interactive command for additional information on sort column highlighting.

6. FILES

6a. PERSONAL Configuration File

This file is created or updated via the 'W' interactive command.

The legacy version is written as '\$HOME/.your-name-4-top' + 'rc' with a leading period.

A newly created configuration file is written as procps/your-name-4-top' + 'rc' without a leading period. The procps directory will be subordinate to either \$XDG_CONFIG_HOME when set as an absolute path or the \$HOME/.config directory.

While not intended to be edited manually, here is the general layout:

```
global # line 1: the program name/alias notation
      # line 2: id,altscr,irixps,delay,curwin
per ea # line a: winname,fieldscur
window # line b: winflags,sortindx,maxtasks,etc
      # line c: summclr,msgsclr,headclr,taskclr
global # line 15: additional miscellaneous settings
      # any remaining lines are devoted to optional
      # active 'other filters' discussed in section 5e above
      # plus 'inspect' entries discussed in section 6b below
```

If a valid absolute path to the rcf file cannot be established, customizations made to a running top will be impossible to preserve.

6b. ADDING INSPECT Entries

To exploit the ‘Y’ interactive command, you must add entries at the **end** of the top personal configuration file. Such entries simply reflect a file to be read or command/pipeline to be executed whose results will then be displayed in a separate scrollable, searchable window.

If you don’t know the location or name of your top rcf file, use the ‘W’ interactive command to rewrite it and note those details.

Inspect entries can be added with a redirected echo or by editing the configuration file. Redirecting an echo risks overwriting the rcf file should it replace (>) rather than append (>>) to that file. Conversely, when using an editor care must be taken not to corrupt existing lines, some of which will contain unprintable data or unusual characters.

Those Inspect entries beginning with a ‘#’ character are ignored, regardless of content. Otherwise they consist of the following 3 elements, each of which *must* be separated by a tab character (thus 2 ‘\t’ total):

- .type: literal ‘file’ or ‘pipe’
- .name: selection shown on the Inspect screen
- .fmts: string representing a path or command

The two types of Inspect entries are *not* interchangeable. Those designated ‘file’ will be accessed using fopen and must reference a single file in the ‘.fmts’ element. Entries specifying ‘pipe’ will employ popen, their ‘.fmts’ element could contain many pipelined commands and, none can be interactive.

If the file or pipeline represented in your ‘.fmts’ deals with the specific PID input or accepted when prompted, then the format string must also contain the ‘%d’ specifier, as these examples illustrate.

```
.fmts= /proc/%d/numa_maps
(fmts= lsof -P -p%d
```

For ‘pipe’ type entries only, you may also wish to redirect stderr to stdout for a more comprehensive result. Thus the format string becomes:

```
.fmts= pmap -x %d2>&1
```

Here are examples of both types of Inspect entries as they might appear in the rcf file. The first entry will be ignored due to the initial ‘#’ character. For clarity, the pseudo tab depictions (‘I’) are surrounded by an extra space but the actual tabs would not be.

```
# pipe ^I Sockets ^I lsof -n -P -i 2>&1
pipe ^I Open Files ^I lsof -P -p %d 2>&1
file ^I NUMA Info ^I /proc/%d/numa_maps
pipe ^I Log ^I tail -n100 /var/log/syslog | sort -Mr
```

Except for the commented entry above, these next examples show what could be echoed to achieve similar results, assuming the rcf file name was ‘.toprc’. However, due to the embedded tab characters, each of these lines should be preceded by ‘**/bin/echo -e**’, not just a simple an ‘echo’, to enable backslash interpretation regardless of which shell you use.

```
"pipe\tOpen Files\tlsof -P -p %d 2>&1" >> ~/.toprc
"file\tNUMA Info\t/proc/%d/numa_maps" >> ~/.toprc
```

```
"pipe\|Log\|tail -n200 /var/log/syslog | sort -Mr" >> ~/.toprc
```

If any inspect entry you create produces output with unprintable characters they will be displayed in either the ^C notation or hexadecimal <FF> form, depending on their value. This applies to tab characters as well, which will show as '^I'. If you want a truer representation, any embedded tabs should be expanded. The following example takes what could have been a 'file' entry but employs a 'pipe' instead so as to expand the embedded tabs.

```
# next would have contained '\t' ...
# file ^I <your_name> ^I /proc/%d/status
# but this will eliminate embedded '\t' ...
pipe ^I <your_name> ^I cat /proc/%d/status | expand -
```

Note: Some programs might rely on *SIGINT* to end. Therefore, if a '**pipe**' such as the following is established, one must use Ctrl-C to terminate it in order to review the results. This is the single occasion where a '^C' will not also terminate top.

```
pipe ^I Trace ^I /usr/bin/strace -p %d 2>&1
```

Lastly, while '**pipe**' type entries have been discussed in terms of pipelines and commands, there is nothing to prevent you from including *shell scripts* as well. Perhaps even newly created scripts designed specifically for the 'Y' interactive command.

For example, as the number of your Inspect entries grows over time, the 'Options:' row will be truncated when screen width is exceeded. That does not affect operation other than to make some selections invisible. However, if some choices are lost to truncation but you want to see more options, there is an easy solution hinted at below.

```
Inspection Pause at pid ...
Use: left/right then <Enter> ...
Options: help 1 2 3 4 5 6 7 8 9 10 11 ...
```

The entries in the top rconfig file would have a number for the '.name' element and the 'help' entry would identify a shell script you've written explaining what those numbered selections actually mean. In that way, many more choices can be made visible.

6c. SYSTEM Configuration File

This configuration file represents defaults for users who have not saved their own configuration file. The format mirrors exactly the personal configuration file and can also include 'inspect' entries as explained above.

Creating it is a simple process.

1. Configure top appropriately for your installation and preserve that configuration with the 'W' interactive command.
2. Add and test any desired 'inspect' entries.
3. Copy that configuration file to the */etc/* directory as '**topdefaultrc**'.

6d. SYSTEM Restrictions File

The presence of this file will influence which version of the help screen is shown to an ordinary user.

More importantly, it will limit what ordinary users are allowed to do when top is running. They will not be

able to issue the following commands.

- k Kill a task
- r Renice a task
- d or s Change delay/sleep interval

This configuration file is not created by top. Rather, it is created manually and placed it in the */etc/* directory as ‘**toprc**’.

It should have exactly two lines, as shown in this example:

- s # line 1: secure mode switch
- 5.0 # line 2: delay interval in seconds

7. STUPID TRICKS Sampler

Many of these tricks work best when you give top a scheduling boost. So plan on starting him with a nice value of **-10**, assuming you’ve got the authority.

7a. Kernel Magic

For these stupid tricks, top needs full-screen mode.

- The user interface, through prompts and help, intentionally implies that the delay interval is limited to tenths of a second. However, you’re free to set any desired delay. If you want to see Linux at his scheduling best, try a delay of .09 seconds or less.

For this experiment, under x-windows open an xterm and maximize it. Then do the following:

- . provide a scheduling boost and tiny delay via:
nice -n -10 top -d.09
- . keep sorted column highlighting *Off* so as to minimize path length
- . turn *On* reverse row highlighting for emphasis
- . try various sort columns (TIME/MEM work well), and normal or reverse sorts to bring the most active processes into view

What you’ll see is a very busy Linux doing what he’s always done for you, but there was no program available to illustrate this.

- Under an xterm using ‘white-on-black’ colors, on top’s Color Mapping screen set the task color to black and be sure that task highlighting is set to bold, not reverse. Then set the delay interval to around .3 seconds.

After bringing the most active processes into view, what you’ll see are the ghostly images of just the currently running tasks.

- Delete the existing rcfile, or create a new symlink. Start this new version then type ‘T’ (a secret key, see topic 4c. Task Area Commands, SORTING) followed by ‘W’ and ‘q’. Finally, restart the program with **-d0** (zero delay).

Your display will be refreshed at three times the rate of the former top, a 300% speed advantage. As top climbs the TIME ladder, be as patient as you can while speculating on whether or not top will ever reach the top.

7b. Bouncing Windows

For these stupid tricks, top needs alternate–display mode.

- With 3 or 4 task displays visible, pick any window other than the last and turn idle processes *Off* using the ‘i’ command toggle. Depending on where you applied ‘i’, sometimes several task displays are bouncing and sometimes it’s like an accordion, as top tries his best to allocate space.
- Set each window’s summary lines differently: one with no memory (‘m’); another with no states (‘t’); maybe one with nothing at all, just the message line. Then hold down ‘a’ or ‘w’ and watch a variation on bouncing windows — hopping windows.
- Display all 4 windows and for each, in turn, set idle processes to *Off* using the ‘i’ command toggle. You’ve just entered the “extreme bounce” zone.

7c. The Big Bird Window

This stupid trick also requires alternate–display mode.

- Display all 4 windows and make sure that 1:Def is the ‘current’ window. Then, keep increasing window size with the ‘n’ interactive command until all the other task displays are “pushed out of the nest”.

When they’ve all been displaced, toggle between all visible/invisible windows using the ‘_’ command toggle. Then ponder this:

is top fibbing or telling honestly your imposed truth?

7d. The Ol’ Switcheroo

This stupid trick works best without alternate–display mode, since justification is active on a per window basis.

- Start top and make COMMAND the last (rightmost) column displayed. If necessary, use the ‘c’ command toggle to display command lines and ensure that forest view mode is active with the ‘V’ command toggle.

Then use the up/down arrow keys to position the display so that some truncated command lines are shown (‘+’ in last position). You may have to resize your xterm to produce truncation.

Lastly, use the ‘j’ command toggle to make the COMMAND column right justified.

Now use the right arrow key to reach the COMMAND column. Continuing with the right arrow key, watch closely the direction of travel for the command lines being shown.

some lines travel left, while others travel right

eventually all lines will Switcheroo, and move right

NAME

touch – change file timestamps

SYNOPSIS

touch [*OPTION*]... *FILE*...

DESCRIPTION

Update the access and modification times of each *FILE* to the current time.

A *FILE* argument that does not exist is created empty, unless **-c** or **-h** is supplied.

A *FILE* argument string of **-** is handled specially and causes touch to change the times of the file associated with standard output.

Mandatory arguments to long options are mandatory for short options too.

-a change only the access time

-c, --no-create
do not create any files

-d, --date=STRING
parse STRING and use it instead of current time

-f (ignored)

-h, --no-dereference

affect each symbolic link instead of any referenced file (useful only on systems that can change the timestamps of a symlink)

-m change only the modification time

-r, --reference=FILE
use this file's times instead of current time

-t STAMP
use [[CC]YY]MMDDhhmm[.ss] instead of current time

--time=WORD
change the specified time: WORD is access, atime, or use: equivalent to **-a** WORD is modify or mtime: equivalent to **-m**

--help display this help and exit

--version
output version information and exit

Note that the **-d** and **-t** options accept different time–date formats.

DATE STRING

The **--date=STRING** is a mostly free format human readable date string such as "Sun, 29 Feb 2004 16:21:42 -0800" or "2004-02-29 16:21:42" or even "next Thursday". A date string may contain items indicating calendar date, time of day, time zone, day of week, relative time, relative date, and numbers. An empty string indicates the beginning of the day. The date string format is more complex than is easily documented here but is fully described in the info documentation.

NAME

tr – translate or delete characters

SYNOPSIS

tr [*OPTION*]... *SET1* [*SET2*]

DESCRIPTION

Translate, squeeze, and/or delete characters from standard input, writing to standard output.

-c, --complement

use the complement of SET1

-d, --delete

delete characters in SET1, do not translate

-s, --squeeze-repeats

replace each sequence of a repeated character that is listed in the last specified SET, with a single occurrence of that character

-t, --truncate-set1

first truncate SET1 to length of SET2

--help display this help and exit

--version

output version information and exit

SETS are specified as strings of characters. Most represent themselves. Interpreted sequences are:

\NNN character with octal value NNN (1 to 3 octal digits)

\\\ backslash

\a audible BEL

\b backspace

\f form feed

\n new line

\r return

\t horizontal tab

\v vertical tab

CHAR1–CHAR2

all characters from CHAR1 to CHAR2 in ascending order

[CHAR*]

in SET2, copies of CHAR until length of SET1

[CHAR*REPEAT]

REPEAT copies of CHAR, REPEAT octal if starting with 0

:alnum:]

all letters and digits

:alpha:]

all letters

:blank:]

all horizontal whitespace

:cntrl:] all control characters

:digit:] all digits

[**:graph:**] all printable characters, not including space
[**:lower:**] all lower case letters
[**:print:**] all printable characters, including space
[**:punct:**] all punctuation characters
[**:space:**] all horizontal or vertical whitespace
[**:upper:**] all upper case letters
[**:xdigit:**] all hexadecimal digits
[=CHAR=] all characters which are equivalent to CHAR

Translation occurs if **-d** is not given and both SET1 and SET2 appear. **-t** may be used only when translating. SET2 is extended to length of SET1 by repeating its last character as necessary. Excess characters of SET2 are ignored. Only [**:lower:**] and [**:upper:**] are guaranteed to expand in ascending order; used in SET2 while translating, they may only be used in pairs to specify case conversion. **-s** uses the last specified SET, and occurs after translation or deletion.

NAME

tty – controlling terminal

DESCRIPTION

The file */dev/tty* is a character file with major number 5 and minor number 0, usually with mode 0666 and ownership root:tty. It is a synonym for the controlling terminal of a process, if any.

In addition to the **ioctl**(2) requests supported by the device that **tty** refers to, the **ioctl**(2) request **TIOCNOTTY** is supported.

TIOCNOTTY

Detach the calling process from its controlling terminal.

If the process is the session leader, then **SIGHUP** and **SIGCONT** signals are sent to the foreground process group and all processes in the current session lose their controlling tty.

This **ioctl**(2) call works only on file descriptors connected to */dev/tty*. It is used by daemon processes when they are invoked by a user at a terminal. The process attempts to open */dev/tty*. If the open succeeds, it detaches itself from the terminal by using **TIOCNOTTY**, while if the open fails, it is obviously not attached to a terminal and does not need to detach itself.

NAME

ttyS – serial terminal lines

DESCRIPTION

ttyS[0–3] are character devices for the serial terminal lines.

They are typically created by:

```
mknod -m 660 /dev/ttys0 c 4 64 # base address 0x3f8
mknod -m 660 /dev/ttys1 c 4 65 # base address 0x2f8
mknod -m 660 /dev/ttys2 c 4 66 # base address 0x3e8
mknod -m 660 /dev/ttys3 c 4 67 # base address 0x2e8
chown root:tty /dev/ttys[0-3]
```

NAME

ioctl_tty – ioctls for terminals and serial lines

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/ioctl.h>
#include <asm/termbits.h> /* Definition of struct termios,
                           struct termios2, and
                           Bnnn, BOTHER, CBAUD, CLOCAL,
                           TC*{FLUSH,ON,OFF} and other constants */

int ioctl(int fd, int cmd, ...);
```

DESCRIPTION

The **ioctl**(2) call for terminals and serial ports accepts many possible command arguments. Most require a third argument, of varying type, here called *argp* or *arg*.

Use of **ioctl()** makes for nonportable programs. Use the POSIX interface described in **termios**(3) whenever possible.

Please note that **struct termios** from *<asm/termbits.h>* is different and incompatible with **struct termios** from *<termios.h>*. These ioctl calls require **struct termios** from *<asm/termbits.h>*.

Get and set terminal attributes**TCGETS**

Argument: **struct termios** **argp*

Equivalent to *tcgetattr(fd, argp)*.

Get the current serial port settings.

TCSETS

Argument: **const struct termios** **argp*

Equivalent to *tcsetattr(fd, TCSANOW, argp)*.

Set the current serial port settings.

TCSETSW

Argument: **const struct termios** **argp*

Equivalent to *tcsetattr(fd, TCSADRAIN, argp)*.

Allow the output buffer to drain, and set the current serial port settings.

TCSETSF

Argument: **const struct termios** **argp*

Equivalent to *tcsetattr(fd, TCSAFLUSH, argp)*.

Allow the output buffer to drain, discard pending input, and set the current serial port settings.

The following four ioctls, added in Linux 2.6.20, are just like **TCGETS**, **TCSETS**, **TCSETSW**, **TCSETSF**, except that they take a *struct termios2* * instead of a *struct termios* *. If the structure member **c_cflag** contains the flag **BOTHER**, then the baud rate is stored in the structure members **c_ispeed** and **c_ospeed** as integer values. These ioctls are not supported on all architectures.

TCGETS2	struct termios2 * <i>argp</i>
TCSETS2	const struct termios2 * <i>argp</i>
TCSETSW2	const struct termios2 * <i>argp</i>
TCSETSF2	const struct termios2 * <i>argp</i>

The following four ioctls are just like **TCGETS**, **TCSETS**, **TCSETSW**, **TCSETSF**, except that they take a *struct termio* * instead of a *struct termios* *.

TCGETA	struct termio *argp
TCSETA	const struct termio *argp
TCSETAW	const struct termio *argp
TCSETAF	const struct termio *argp

Locking the termios structure

The *termios* structure of a terminal can be locked. The lock is itself a *termios* structure, with nonzero bits or fields indicating a locked value.

TIOCGLKTRMIOS

Argument: **struct termios *argp**

Gets the locking status of the *termios* structure of the terminal.

TIOCSLKTRMIOS

Argument: **const struct termios *argp**

Sets the locking status of the *termios* structure of the terminal. Only a process with the **CAP_SYS_ADMIN** capability can do this.

Get and set window size

Window sizes are kept in the kernel, but not used by the kernel (except in the case of virtual consoles, where the kernel will update the window size when the size of the virtual console changes, for example, by loading a new font).

TIOCGWINSZ

Argument: **struct winsize *argp**

Get window size.

TIOCSWINSZ

Argument: **const struct winsize *argp**

Set window size.

The struct used by these ioctls is defined as

```
struct winsize {
    unsigned short ws_row;
    unsigned short ws_col;
    unsigned short ws_xpixel; /* unused */
    unsigned short ws_ypixel; /* unused */
};
```

When the window size changes, a **SIGWINCH** signal is sent to the foreground process group.

Sending a break**TCSBRK**

Argument: **int arg**

Equivalent to *tcsendbreak(fd, arg)*.

If the terminal is using asynchronous serial data transmission, and *arg* is zero, then send a break (a stream of zero bits) for between 0.25 and 0.5 seconds. If the terminal is not using asynchronous serial data transmission, then either a break is sent, or the function returns without doing anything. When *arg* is nonzero, nobody knows what will happen.

(SVr4, UnixWare, Solaris, and Linux treat *tcsendbreak(fd,arg)* with nonzero *arg* like *tcdrain(fd)*. SunOS treats *arg* as a multiplier, and sends a stream of bits *arg* times as long as done for zero *arg*. DG/UX and AIX treat *arg* (when nonzero) as a time interval measured in milliseconds. HP-UX ignores *arg*.)

TCSBRKP

Argument: **int arg**

So-called "POSIX version" of **TCSBRK**. It treats nonzero *arg* as a time interval measured in microseconds, and does nothing when the driver does not support breaks.

TIOCSBRK

Argument: **void**

Turn break on, that is, start sending zero bits.

TIOCCBRK

Argument: **void**

Turn break off, that is, stop sending zero bits.

Software flow control

TCXONC

Argument: **int arg**

Equivalent to *tcflow(fd, arg)*.

See **tcflow(3)** for the argument values **TCOOFF**, **TCOON**, **TCIOFF**, **TCION**.

Buffer count and flushing

FIONREAD

Argument: **int *argp**

Get the number of bytes in the input buffer.

TIOCINQ

Argument: **int *argp**

Same as **FIONREAD**.

TIOCOUTQ

Argument: **int *argp**

Get the number of bytes in the output buffer.

TCFLSH

Argument: **int arg**

Equivalent to *tcflush(fd, arg)*.

See **tcflush(3)** for the argument values **TCIFLUSH**, **TCOFLUSH**, **TCIOFLUSH**.

TIOCSERGETLSR

Argument: **int *argp**

Get line status register. Status register has **TIOCSER_TEMT** bit set when output buffer is empty and also hardware transmitter is physically empty.

Does not have to be supported by all serial tty drivers.

tcdrain(3) does not wait and returns immediately when **TIOCSER_TEMT** bit is set.

Faking input

TIOCSTI

Argument: **const char *argp**

Insert the given byte in the input queue.

Redirecting console output

TIOCCONS

Argument: **void**

Redirect output that would have gone to */dev/console* or */dev/tty0* to the given terminal. If that was a pseudoterminal master, send it to the slave. Before Linux 2.6.10, anybody can do this as long as the output was not redirected yet; since Linux 2.6.10, only a process with the **CAP_SYS_ADMIN** capability may do this. If output was redirected already, then **EBUSY** is returned, but redirection can be stopped by using this ioctl with *fd* pointing at */dev/console* or

/dev/tty0.

Controlling terminal

TIOCSCTTY

Argument: **int** *arg*

Make the given terminal the controlling terminal of the calling process. The calling process must be a session leader and not have a controlling terminal already. For this case, *arg* should be specified as zero.

If this terminal is already the controlling terminal of a different session group, then the ioctl fails with **EPERM**, unless the caller has the **CAP_SYS_ADMIN** capability and *arg* equals 1, in which case the terminal is stolen, and all processes that had it as controlling terminal lose it.

TIOCNOTTY

Argument: **void**

If the given terminal was the controlling terminal of the calling process, give up this controlling terminal. If the process was session leader, then send **SIGHUP** and **SIGCONT** to the foreground process group and all processes in the current session lose their controlling terminal.

Process group and session ID

TIOCGPGRP

Argument: **pid_t** **argp*

When successful, equivalent to **argp = tcgetpgrp(fd)*.

Get the process group ID of the foreground process group on this terminal.

TIOCSPGRP

Argument: **const pid_t** **argp*

Equivalent to *tcsetpgrp(fd, *argp)*.

Set the foreground process group ID of this terminal.

TIOCGSID

Argument: **pid_t** **argp*

When successful, equivalent to **argp = tcgetsid(fd)*.

Get the session ID of the given terminal. This fails with the error **ENOTTY** if the terminal is not a master pseudoterminal and not our controlling terminal. Strange.

Exclusive mode

TIOCEXCL

Argument: **void**

Put the terminal into exclusive mode. No further **open(2)** operations on the terminal are permitted. (They fail with **EBUSY**, except for a process with the **CAP_SYS_ADMIN** capability.)

TIOCGEXCL

Argument: **int** **argp*

(since Linux 3.8) If the terminal is currently in exclusive mode, place a nonzero value in the location pointed to by *argp*; otherwise, place zero in **argp*.

TIOCNXCL

Argument: **void**

Disable exclusive mode.

Line discipline

TIOCGETD

Argument: **int** **argp*

Get the line discipline of the terminal.

TIOCSETD

Argument: **const int *argp**

Set the line discipline of the terminal.

Pseudoterminal ioctls**TIOCPKT**

Argument: **const int *argp**

Enable (when **argp* is nonzero) or disable packet mode. Can be applied to the master side of a pseudoterminal only (and will return **ENOTTY** otherwise). In packet mode, each subsequent **read(2)** will return a packet that either contains a single nonzero control byte, or has a single byte containing zero ('\0') followed by data written on the slave side of the pseudoterminal. If the first byte is not **TIOCPKT_DATA** (0), it is an OR of one or more of the following bits:

TIOCPKT_FLUSHREAD	The read queue for the terminal is flushed.
TIOCPKT_FLUSHWRITE	The write queue for the terminal is flushed.
TIOCPKT_STOP	Output to the terminal is stopped.
TIOCPKT_START	Output to the terminal is restarted.
TIOCPKT_DOSTOP	The start and stop characters are ^S/^Q .
TIOCPKT_NOSTOP	The start and stop characters are not ^S/^Q .

While packet mode is in use, the presence of control status information to be read from the master side may be detected by a **select(2)** for exceptional conditions or a **poll(2)** for the **POLLPRI** event.

This mode is used by **rlogin(1)** and **rlogind(8)** to implement a remote-echoed, locally **^S/^Q** flow-controlled remote login.

TIOCGPkt

Argument: **const int *argp**

(since Linux 3.8) Return the current packet mode setting in the integer pointed to by *argp*.

TIOCSPTLCK

Argument: **int *argp**

Set (if **argp* is nonzero) or remove (if **argp* is zero) the lock on the pseudoterminal slave device. (See also **unlockpt(3)**.)

TIOCGPTLCK

Argument: **int *argp**

(since Linux 3.8) Place the current lock state of the pseudoterminal slave device in the location pointed to by *argp*.

TIOCGPTPEER

Argument: **int flags**

(since Linux 4.13) Given a file descriptor in *fd* that refers to a pseudoterminal master, open (with the given **open(2)**-style *flags*) and return a new file descriptor that refers to the peer pseudoterminal slave device. This operation can be performed regardless of whether the pathname of the slave device is accessible through the calling process's mount namespace.

Security-conscious programs interacting with namespaces may wish to use this operation rather than **open(2)** with the pathname returned by **ptsname(3)**, and similar library functions that have insecure APIs. (For example, confusion can occur in some cases using **ptsname(3)** with a pathname where a devpts filesystem has been mounted in a different mount namespace.)

The BSD ioctls **TIOCSTOP**, **TIOCSTART**, **TIOCUCNTL**, and **TIOCREMOTE** have not been

implemented under Linux.

Modem control

TIOCMGET

Argument: **int *argp**

Get the status of modem bits.

TIOCMSET

Argument: **const int *argp**

Set the status of modem bits.

TIOCMBIC

Argument: **const int *argp**

Clear the indicated modem bits.

TIOCMBIS

Argument: **const int *argp**

Set the indicated modem bits.

The following bits are used by the above ioctl:

TIOCM_LE	DSR (data set ready/line enable)
TIOCM_DTR	DTR (data terminal ready)
TIOCM_RTS	RTS (request to send)
TIOCM_ST	Secondary TxD (transmit)
TIOCM_SR	Secondary RxD (receive)
TIOCM_CTS	CTS (clear to send)
TIOCM_CAR	DCD (data carrier detect)
TIOCM_CD	see TIOCM_CAR
TIOCM RNG	RNG (ring)
TIOCM RI	see TIOCM RNG
TIOCM_DSR	DSR (data set ready)

TIOCMIWAIT

Argument: **int arg**

Wait for any of the 4 modem bits (DCD, RI, DSR, CTS) to change. The bits of interest are specified as a bit mask in *arg*, by ORing together any of the bit values, **TIOCM RNG**, **TIOCM_DSR**, **TIOCM_CD**, and **TIOCM_CTS**. The caller should use **TIOCGCOUNT** to see which bit has changed.

TIOCGCOUNT

Argument: **struct serial_icounter_struct *argp**

Get counts of input serial line interrupts (DCD, RI, DSR, CTS). The counts are written to the *serial_icounter_struct* structure pointed to by *argp*.

Note: both 1->0 and 0->1 transitions are counted, except for RI, where only 0->1 transitions are counted.

Marking a line as local

TIOCGSOFTCAR

Argument: **int *argp**

("Get software carrier flag") Get the status of the CLOCAL flag in the c_cflag field of the *termios* structure.

TIOCSSOFTCAR

Argument: **const int *argp**

("Set software carrier flag") Set the CLOCAL flag in the *termios* structure when **argp* is nonzero, and clear it otherwise.

If the **CLOCAL** flag for a line is off, the hardware carrier detect (DCD) signal is significant, and an **open(2)** of the corresponding terminal will block until DCD is asserted, unless the **O_NONBLOCK** flag is given. If **CLOCAL** is set, the line behaves as if DCD is always asserted. The software carrier flag is usually turned on for local devices, and is off for lines with modems.

Linux-specific

For the **TIOCLINUX** ioctl, see **ioctl_console(2)**.

Kernel debugging

```
#include <linux/tty.h>
```

```
TIOCTTYGSTRUCT
```

Argument: **struct tty_struct *argp**

Get the *tty_struct* corresponding to *fd*. This command was removed in Linux 2.5.67.

RETURN VALUE

The **ioctl(2)** system call returns 0 on success. On error, it returns -1 and sets *errno* to indicate the error.

ERRORS

EINVAL

Invalid command parameter.

ENOIOCTLCMD

Unknown command.

ENOTTY

Inappropriate *fd*.

EPERM

Insufficient permission.

EXAMPLES

Check the condition of DTR on the serial port.

```
#include <fcntl.h>
#include <stdio.h>
#include <sys/ioctl.h>
#include <unistd.h>

int
main(void)
{
    int fd, serial;

    fd = open("/dev/ttyS0", O_RDONLY);
    ioctl(fd, TIOCMGET, &serial);
    if (serial & TIOCM_DTR)
        puts("TIOCM_DTR is set");
    else
        puts("TIOCM_DTR is not set");
    close(fd);
}
```

Get or set arbitrary baudrate on the serial port.

```
/* SPDX-License-Identifier: GPL-2.0-or-later */

#include <asm/termbits.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
```

```

#include <sys/	ioctl.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
#if !defined BOTHER
    fprintf(stderr, "BOTHER is unsupported\n");
    /* Program may fallback to TCGETS/TCSETS with Bnnn constants */
    exit(EXIT_FAILURE);
#else
    /* Declare tio structure, its type depends on supported ioctl */
# if defined TCGETS2
    struct termios2 tio;
# else
    struct termios tio;
# endif
    int fd, rc;

    if (argc != 2 && argc != 3 && argc != 4) {
        fprintf(stderr, "Usage: %s device [output [input] ]\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fd = open(argv[1], O_RDWR | O_NONBLOCK | O_NOCTTY);
    if (fd < 0) {
        perror("open");
        exit(EXIT_FAILURE);
    }

    /* Get the current serial port settings via supported ioctl */
# if defined TCGETS2
    rc = ioctl(fd, TCGETS2, &tio);
# else
    rc = ioctl(fd, TCGETS, &tio);
# endif
    if (rc) {
        perror("TCGETS");
        close(fd);
        exit(EXIT_FAILURE);
    }

    /* Change baud rate when more arguments were provided */
    if (argc == 3 || argc == 4) {
        /* Clear the current output baud rate and fill a new value */
        tio.c_cflag &= ~CBAUD;
        tio.c_cflag |= BOTHER;
        tio.c_ospeed = atoi(argv[2]);

        /* Clear the current input baud rate and fill a new value */
        tio.c_cflag &= ~(CBAUD << IBSHIFT);
        tio.c_cflag |= BOTHER << IBSHIFT;
        /* When 4th argument is not provided reuse output baud rate */
        tio.c_ispeed = (argc == 4) ? atoi(argv[3]) : atoi(argv[2]);
    }
}

```

```
/* Set new serial port settings via supported ioctl */
# if defined TCSETS2
    rc = ioctl(fd, TCSETS2, &tio);
# else
    rc = ioctl(fd, TCSETS, &tio);
# endif
    if (rc) {
        perror("TCSETS");
        close(fd);
        exit(EXIT_FAILURE);
    }

    /* And get new values which were really configured */
# if defined TCGETS2
    rc = ioctl(fd, TCGETS2, &tio);
# else
    rc = ioctl(fd, TCGETS, &tio);
# endif
    if (rc) {
        perror("TCGETS");
        close(fd);
        exit(EXIT_FAILURE);
    }
}

close(fd);

printf("output baud rate: %u\n", tio.c_ospeed);
printf("input baud rate: %u\n", tio.c_ispeed);

exit(EXIT_SUCCESS);
#endif
}
```

NAME

ufw—framework – using the ufw framework

DESCRIPTION

ufw provides both a command line interface and a framework for managing a netfilter firewall. While the **ufw** command provides an easy to use interface for managing a firewall, the **ufw** framework provides the administrator methods to customize default behavior and add rules not supported by the command line tool. In this way, **ufw** can take full advantage of Linux netfilter's power and flexibility.

OVERVIEW

The framework provides boot time initialization, rules files for adding custom rules, a method for loading netfilter modules, configuration of kernel parameters and configuration of IPv6. The framework consists of the following files:

```
/lib/ufw/ufw-init
    initialization script

/etc/ufw(before).init
    initialization customization script run before ufw is initialized

/etc/ufw(after).init
    initialization customization script run after ufw is initialized

/etc/ufw(before[6].rules
    rules file containing rules evaluated before UI added rules

/etc/ufw(user[6].rules
    rules file containing UI added rules (managed with the ufw command)

/etc/ufw(after[6].rules
    rules file containing rules evaluated after UI added rules

/etc/default/ufw
    high level configuration

/etc/ufw/sysctl.conf
    kernel network tunables

/etc/ufw/ufw.conf
    additional high level configuration
```

BOOT INITIALIZATION

ufw is started on boot with /lib/ufw/ufw-init. This script is a standard SysV style initscript used by the **ufw** command and should not be modified. The /etc/before.init and /etc/after.init scripts may be used to perform any additional firewall configuration that is not yet supported in ufw itself and if they exist and are executable, ufw-init will execute these scripts. ufw-init will exit with error if either of these scripts exit with error. ufw-init supports the following arguments:

start:	loads the firewall
stop:	unloads the firewall
restart:	reloads the firewall
force-reload:	same as restart
status:	basic status of the firewall
force-stop:	same as stop, except does not check if the firewall is already loaded

flush-all:

flushes the built-in chains, deletes all non-built-in chains and resets the policy to ACCEPT
 ufw-init will call before.init and after.init with start, stop, status and flush-all, but typically, if used, these scripts need only implement start and stop.

ufw uses many user-defined chains in addition to the built-in iptables chains. If MANAGE_BUILTINS in /etc/default/ufw is set to 'yes', on stop and reload the built-in chains are flushed. If it is set to 'no', on stop and reload the **ufw** secondary chains are removed and the **ufw** primary chains are flushed. In addition to flushing the **ufw** specific chains, it keeps the primary chains in the same order with respect to any other user-defined chains that may have been added. This allows for **ufw** to interoperate with other software that may manage their own firewall rules.

To ensure your firewall is loading on boot, you must integrate this script into the boot process. Consult your distribution's documentation for the proper way to modify your boot process if **ufw** is not already integrated.

RULES FILES

ufw is in part a front-end for **iptables-restore**, with its rules saved in /etc/ufw/before.rules, /etc/ufw/after.rules and /etc/ufw/user.rules. Administrators can customize **before.rules** and **after.rules** as desired using the standard **iptables-restore** syntax. Rules are evaluated as follows: **before.rules** first, **user.rules** next, and **after.rules** last. IPv6 rules are evaluated in the same way, with the rules files named **before6.rules**, **user6.rules** and **after6.rules**. Please note that **ufw status** only shows rules added with **ufw** and not the rules found in the /etc/ufw rules files.

Important: **ufw** only uses the *filter table by default. You may add any other tables such as *nat, *raw and *mangle as desired. For each table a corresponding COMMIT statement is required.

After modifying any of these files, you must reload **ufw** for the rules to take effect. See the EXAMPLES section for common uses of these rules files.

MODULES

Netfilter has many different connection tracking modules. These modules are aware of the underlying protocol and allow the administrator to simplify his or her rule sets. You can adjust which netfilter modules to load by adjusting IPT_MODULES in /etc/default/ufw. Some popular modules to load are:

```
nf_conntrack_ftp
nf_nat_ftp
nf_conntrack_irc
nf_nat_irc
nf_conntrack_netbios_ns
nf_conntrack_pptp
nf_conntrack_tftp
nf_nat_tftp
nf_conntrack_sane
```

Unconditional loading of connection tracking modules (nf_conntrack_*) in this manner is deprecated. **ufw** continues to support the functionality but new configuration should only contain the specific modules required for the site. For more information, see CONNECTION HELPERS.

KERNEL PARAMETERS

ufw will read in /etc/ufw/sysctl.conf on boot when enabled. Please note that /etc/ufw/sysctl.conf overrides values in the system sysctl.conf (usually /etc/sysctl.conf). Administrators can change the file used by modifying /etc/default/ufw.

IPV6

IPv6 is enabled by default. When disabled, all incoming, outgoing and forwarded packets are dropped, with the exception of traffic on the loopback interface. To adjust this behavior, set IPV6 to 'yes' in /etc/default/ufw. See the **ufw** manual page for details.

EXAMPLES

As mentioned, **ufw** loads its rules files into the kernel by using the **iptables-restore** and **ip6tables-restore** commands. Users wanting to add rules to the **ufw** rules files manually must be familiar with these as well as the **iptables** and **ip6tables** commands. Below are some common examples of using the **ufw** rules files. All examples assume IPv4 only and that DEFAULT_FORWARD_POLICY in /etc/default/ufw is set to DROP.

IP Masquerading

To allow IP masquerading for computers from the 10.0.0.0/8 network on eth1 to share the single IP address on eth0:

Edit /etc/ufw/sysctl.conf to have:

```
net.ipv4.ip_forward=1
```

Add to the end of /etc/ufw/before.rules, after the *filter section:

```
*nat
:POSTROUTING ACCEPT [0:0]
-A POSTROUTING -s 10.0.0.0/8 -o eth0 -j MASQUERADE
COMMIT
```

If your firewall is using IPv6 tunnels or 6to4 and is also doing NAT, then you should not usually masquerade protocol '41' (ipv6) packets. For example, instead of the above, /etc/ufw/before.rules can be adjusted to have:

```
*nat
:POSTROUTING ACCEPT [0:0]
-A POSTROUTING -s 10.0.0.0/8 ! --protocol 41 -o eth0 -j MASQUERADE
COMMIT
```

Add the **ufw route** to allow the traffic:

```
ufw route allow in on eth1 out on eth0 from 10.0.0.0/8
```

Port Redirections

To forward tcp port 80 on eth0 to go to the webserver at 10.0.0.2:

Edit /etc/ufw/sysctl.conf to have:

```
net.ipv4.ip_forward=1
```

Add to the end of /etc/ufw/before.rules, after the *filter section:

```
*nat
:PREROUTING ACCEPT [0:0]
-A PREROUTING -p tcp -i eth0 --dport 80 -j DNAT \
--to-destination 10.0.0.2:80
COMMIT
```

Add the **ufw route** rule to allow the traffic:

```
ufw route allow in on eth0 to 10.0.0.2 port 80 proto tcp
```

Egress filtering

To block RFC1918 addresses going out of eth0:

Add the **ufw route** rules to reject the traffic:

```
ufw route reject out on eth0 to 10.0.0.0/8
ufw route reject out on eth0 to 172.16.0.0/12
ufw route reject out on eth0 to 192.168.0.0/16
```

Full example

This example combines the other examples and demonstrates a simple routing firewall. **Warning:** this setup is only an example to demonstrate the functionality of the **ufw** framework in a concise and simple manner and should not be used in production without understanding what each part does and does not do. Your firewall will undoubtedly want to be less open.

This router/firewall has two interfaces: eth0 (Internet facing) and eth1 (internal LAN). Internal clients have addresses on the 10.0.0.0/8 network and should be able to connect to anywhere on the Internet. Connections to port 80 from the Internet should be forwarded to 10.0.0.2. Access to ssh port 22 from the administrative workstation (10.0.0.100) to this machine should be allowed. Also make sure no internal traffic goes to the Internet.

Edit /etc/ufw/sysctl.conf to have:

```
net.ipv4.ip_forward=1
```

Add to the end of /etc/ufw/before.rules, after the *filter section:

```
*nat
:PREROUTING ACCEPT [0:0]
:POSTROUTING ACCEPT [0:0]
-A PREROUTING -p tcp -i eth0 --dport 80 -j DNAT \
--to-destination 10.0.0.2:80
-A POSTROUTING -s 10.0.0.0/8 -o eth0 -j MASQUERADE
COMMIT
```

Add the necessary **ufw** rules:

```
ufw route reject out on eth0 to 10.0.0.0/8
ufw route reject out on eth0 to 172.16.0.0/12
ufw route reject out on eth0 to 192.168.0.0/16
ufw route allow in on eth1 out on eth0 from 10.0.0.0/8
ufw route allow in on eth0 to 10.0.0.2 port 80 proto tcp
ufw allow in on eth1 from 10.0.0.100 to any port 22 proto tcp
```

CONNECTION HELPERS

Various protocols require the use of netfilter connection tracking helpers to group related packets into RELATED flows to make rulesets clearer and more precise. For example, with a couple of kernel modules and a couple of rules, a ruleset could simply allow a connection to FTP port 21, then the kernel would examine the traffic and mark the other FTP data packets as RELATED to the initial connection.

When the helpers were first introduced, one could only configure the modules as part of module load (eg, if your FTP server listened on a different port than 21, you'd have to load the nf_conntrack_ftp module specifying the correct port). Over time it was understood that unconditionally using connection helpers could lead to abuse, in part because some protocols allow user specified data that would allow traversing the firewall in undesired ways. As of kernel 4.7, automatic conntrack helper assignment (ie, handling packets for a given port and all IP addresses) is disabled (the old behavior can be restored by setting net/netfilter/nf_conntrack_helper=1 in /etc/ufw/sysctl.conf). Firewalls should now instead use the CT target to associate traffic with a particular helper and then set RELATED rules to use the helper. This allows sites to tailor the use of helpers and help avoid abuse.

In general, to use helpers securely, the following needs to happen:

1. net/netfilter/nf_conntrack_helper should be set to 0 (default)
2. create a rule for the start of a connection (eg for FTP, port 21)
3. create a helper rule to associate the helper with this connection
4. create a helper rule to associate a RELATED flow with this connection
5. if needed, add the corresponding nf_conntrack_* module to IPT_MODULES

6. optionally add the corresponding `nf_nat_*` module to `IPT_MODULES`

In general it is desirable to make connection helper rules as specific as possible and ensure anti-spoofing is correctly setup for your site to avoid security issues in your ruleset. For more information, see ANTI-SPOOFING, above, and <<https://home.regit.org/netfilter-en/secure-use-of-helpers/>>.

Currently helper rules must be managed in via the RULES FILES. A future version of **ufw** will introduce syntax for working with helper rules.

NOTES

When using ufw with libvirt and bridging, packets may be blocked. The libvirt team recommends that the following sysctl's be set to disable netfilter on the bridge:

```
net.bridge.bridge-nf-call-ip6tables = 0  
net.bridge.bridge-nf-call-iptables = 0  
net.bridge.bridge-nf-call-arptables = 0
```

Note that the bridge module must be loaded in to the kernel before these values are set. One way to ensure this works properly with ufw is to add 'bridge' to `IPT_MODULES` in `/etc/default/ufw`, and then add the above rules to `/etc/ufw/sysctl.conf`.

Alternatively to disabling netfilter on the bridge, you can configure iptables to allow all traffic to be forwarded across the bridge. Eg, add to `/etc/ufw/before.rules` within the `*filter` section:

```
-I FORWARD -m physdev --physdev-is-bridged -j ACCEPT
```

NAME

ufw – program for managing a netfilter firewall

DESCRIPTION

This program is for managing a Linux firewall and aims to provide an easy to use interface for the user.

USAGE

```
ufw [--dry-run] enable|disable|reload
ufw [--dry-run] default allow|deny|reject [incoming|outgoing|routed]
ufw [--dry-run] logging on|off|LEVEL
ufw [--dry-run] reset
ufw [--dry-run] status [verbose|numbered]
ufw [--dry-run] show REPORT
ufw [--dry-run] [delete] [insert NUM] [prepend] allow|deny|reject|limit [in|out] [log|log-all] [
PORT/[PROTOCOL] | APPNAME ] [comment COMMENT]
ufw [--dry-run] [rule] [delete] [insert NUM] [prepend] allow|deny|reject|limit [in|out] [on INTERFACE] [log|log-all] [proto PROTOCOL] [from ADDRESS [port PORT | app APPNAME ]] [to ADDRESS [port PORT | app APPNAME ]] [comment COMMENT]
ufw [--dry-run] route [delete] [insert NUM] [prepend] allow|deny|reject|limit [in|out on INTERFACE] [log|log-all] [proto PROTOCOL] [from ADDRESS [port PORT | app APPNAME]] [to ADDRESS [port PORT | app APPNAME]] [comment COMMENT]
ufw [--dry-run] [--force] delete NUM
ufw [--dry-run] app list|info|default|update
```

OPTIONS**--version**

show program's version number and exit

-h, --help

show help message and exit

--dry-run

don't modify anything, just show the changes

enable reloads firewall and enables firewall on boot.

disable unloads firewall and disables firewall on boot

reload reloads firewall

default allow|deny|reject DIRECTION

change the default policy for traffic going DIRECTION, where DIRECTION is one of **incoming**, **outgoing** or **routed**. Note that existing rules will have to be migrated manually when changing the default policy. See **RULE SYNTAX** for more on **deny** and **reject**.

logging on|off|LEVEL

toggle logging. Logged packets use the LOG_KERN syslog facility. Systems configured for rsyslog support may also log to /var/log/ufw.log. Specifying a LEVEL turns logging on for the specified LEVEL. The default log level is 'low'. See **LOGGING** for details.

reset Disables and resets firewall to installation defaults. Can also give the **--force** option to perform the reset without confirmation.

status show status of firewall and ufw managed rules. Use **status verbose** for extra information. In the status output, 'Anywhere' is synonymous with 'any', 0.0.0.0/0 (IPv4) and ::/0 (IPv6). Note that when using **status**, there is a subtle difference when reporting interfaces. For example, if the

following rules are added:

```
ufw allow in on eth0 from 192.168.0.0/16
ufw allow out on eth1 to 10.0.0.0/8
ufw route allow in on eth0 out on eth1 to 10.0.0.0/8 from 192.168.0.0/16
ufw limit 2222/tcp comment 'SSH port'
```

ufw status will output:

To	Action	From
--	---	---
Anywhere on eth0	ALLOW	192.168.0.0/16
10.0.0.0/8	ALLOW OUT	Anywhere on eth1
10.0.0.0/8 on eth1	ALLOW FWD	192.168.0.0/16 on eth0
Anywhere	LIMIT	Anywhere # SSH port

For the input and output rules, the interface is reported relative to the firewall system as an endpoint, whereas with route rules, the interface is reported relative to the direction packets flow through the firewall.

show REPORT

display information about the running firewall. See **REPORTS**

allow ARGS

add allow rule. See **RULE SYNTAX**

deny ARGS

add deny rule. See **RULE SYNTAX**

reject ARGS

add reject rule. See **RULE SYNTAX**

limit ARGS

add limit rule. See **RULE SYNTAX**

delete RULE|NUM

deletes the corresponding RULE

insert NUM RULE

insert the corresponding RULE as rule number NUM

prepend RULE

prepend the corresponding RULE to the top of the ruleset

RULE SYNTAX

Users can specify rules using either a simple syntax or a full syntax. The simple syntax only specifies the port and optionally the protocol to be allowed or denied on the host.

Both syntaxes support specifying a comment for the rule. For existing rules, specifying a different comment updates the comment and specifying "" removes the comment.

Example rules using the simple syntax:

```
ufw allow 53
```

This rule will allow tcp and udp port 53 to any address on this host. To specify a protocol, append '/protocol' to the port. For example:

```
ufw allow 25/tcp
```

This will allow tcp port 25 to any address on this host. **ufw** will also check /etc/services for the port and protocol if specifying a service by name. Eg:

```
ufw allow smtp
```

ufw supports both ingress and egress filtering and users may optionally specify a direction of either **in** or **out** for either incoming or outgoing traffic. If no direction is supplied, the rule applies to incoming traffic. Eg:

```
ufw allow in http
ufw reject out smtp
ufw reject telnet comment 'telnet is unencrypted'
```

Users can also use a fuller syntax, specifying the source and destination addresses and ports. This syntax is loosely based on OpenBSD's PF syntax. For example:

```
ufw deny proto tcp to any port 80
```

This will deny all traffic to tcp port 80 on this host. Another example:

```
ufw deny proto tcp from 10.0.0.0/8 to 192.168.0.1 port 25
```

This will deny all traffic from the RFC1918 Class A network to tcp port 25 with the address 192.168.0.1.

```
ufw deny proto tcp from 2001:db8::/32 to any port 25
```

This will deny all traffic from the IPv6 2001:db8::/32 to tcp port 25 on this host. IPv6 must be enabled in /etc/default/ufw for IPv6 firewalling to work.

```
ufw deny in on eth0 to 224.0.0.1 proto igmp
```

This will deny all igmp traffic to 224.0.0.1 on the eth0 interface.

```
ufw allow in on eth0 to 192.168.0.1 proto gre
```

This will allow all gre traffic to 192.168.0.1 on the eth0 interface.

```
ufw allow proto tcp from any to any port 80,443,8080:8090 comment 'web app'
```

The above will allow all traffic to tcp ports 80, 443 and 8080–8090 inclusive and adds a comment for the rule. When specifying multiple ports, the ports list must be numeric, cannot contain spaces and must be modified as a whole. Eg, in the above example you cannot later try to delete just the '443' port. You cannot specify more than 15 ports (ranges count as 2 ports, so the port count in the above example is 4).

ufw supports several different protocols. The following are valid in any rule and enabled when the protocol is not specified:

```
tcp
udp
```

The following have certain restrictions and are not enabled when the protocol is not specified:

```
ah    valid without port number
```

```
esp  valid without port number
gre  valid without port number
ipv6 valid for IPv4 addresses and without port number
igmp valid for IPv4 addresses and without port number
```

Rules for traffic not destined for the host itself but instead for traffic that should be routed/forwarded through the firewall should specify the **route** keyword before the rule (routing rules differ significantly from PF syntax and instead take into account netfilter FORWARD chain conventions). For example:

```
ufw route allow in on eth1 out on eth2
```

This will allow all traffic routed to eth2 and coming in on eth1 to traverse the firewall.

```
ufw route allow in on eth0 out on eth1 to 12.34.45.67 port 80 proto tcp
```

This rule allows any packets coming in on eth0 to traverse the firewall out on eth1 to tcp port 80 on 12.34.45.67.

In addition to routing rules and policy, you must also setup IP forwarding. This may be done by setting the following in /etc/ufw/sysctl.conf:

```
net/ipv4/ip_forward=1
net/ipv6/conf/default/forwarding=1
net/ipv6/conf/all/forwarding=1
```

then restarting the firewall:

```
ufw disable
ufw enable
```

Be aware that setting kernel tunables is operating system specific and **ufw** sysctl settings may be overridden. See the **sysctl** manual page for details.

ufw supports connection rate limiting, which is useful for protecting against brute-force login attacks. When a limit rule is used, **ufw** will normally allow the connection but will deny connections if an IP address attempts to initiate 6 or more connections within 30 seconds. See <http://www.debian-administration.org/articles/187> for details. Typical usage is:

```
ufw limit ssh/tcp
```

Sometimes it is desirable to let the sender know when traffic is being denied, rather than simply ignoring it. In these cases, use **reject** instead of **deny**. For example:

```
ufw reject auth
```

By default, **ufw** will apply rules to all available interfaces. To limit this, specify **DIRECTION on INTERFACE**, where DIRECTION is one of **in** or **out** (interface aliases are not supported). For example, to allow all new incoming http connections on eth0, use:

```
ufw allow in on eth0 to any port 80 proto tcp
```

To delete a rule, simply prefix the original rule with **delete** with or without the rule comment. For example, if the original rule was:

```
ufw deny 80/tcp
```

Use this to delete it:

```
ufw delete deny 80/tcp
```

You may also specify the rule by NUM, as seen in the **status numbered** output. For example, if you want to delete rule number '3', use:

```
ufw delete 3
```

If you have IPv6 enabled and are deleting a generic rule that applies to both IPv4 and IPv6 (eg 'ufw allow 22/tcp'), deleting by rule number will delete only the specified rule. To delete both with one command, prefix the original rule with **delete**.

To insert a rule, specify the new rule as normal, but prefix the rule with the rule number to insert. For example, if you have four rules, and you want to insert a new rule as rule number three, use:

```
ufw insert 3 deny to any port 22 from 10.0.0.135 proto tcp
```

Similarly, to add a rule before all other rules matching the rule's IP type, use the **prepend** rule:

```
ufw prepend deny from 1.2.3.4
```

This is particularly useful for dynamic firewalls as found in an IPS. Importantly, if the specified rule is an IPv4 rule, it will be prepended before all other IPv4 rules. If it is an IPv6 rule, it will be prepended before any IPv6 rules.

To see a list of numbered rules, use:

```
ufw status numbered
```

ufw supports per rule logging. By default, no logging is performed when a packet matches a rule. Specifying **log** will log all new connections matching the rule, and **log-all** will log all packets matching the rule. For example, to allow and log all new ssh connections, use:

```
ufw allow log 22/tcp
```

See **LOGGING** for more information on logging.

EXAMPLES

Deny all access to port 53:

```
ufw deny 53
```

Allow all access to tcp port 80:

```
ufw allow 80/tcp
```

Allow all access from RFC1918 networks to this host:

```
ufw allow from 10.0.0.0/8  
ufw allow from 172.16.0.0/12
```

```
ufw allow from 192.168.0.0/16
```

Deny access to udp port 514 from host 1.2.3.4:

```
ufw deny proto udp from 1.2.3.4 to any port 514
```

Allow access to udp 1.2.3.4 port 5469 from 1.2.3.5 port 5469:

```
ufw allow proto udp from 1.2.3.5 port 5469 to 1.2.3.4 port 5469
```

REMOTE MANAGEMENT

When running **ufw enable** or starting **ufw** via its initscript, **ufw** will flush its chains. This is required so **ufw** can maintain a consistent state, but it may drop existing connections (eg ssh). **ufw** does support adding rules before enabling the firewall, so administrators can do:

```
ufw allow proto tcp from any to any port 22
```

before running '**ufw enable**'. The rules will still be flushed, but the ssh port will be open after enabling the firewall. Please note that once ufw is 'enabled', **ufw** will not flush the chains when adding or removing rules (but will when modifying a rule or changing the default policy). By default, **ufw** will prompt when enabling the firewall while running under ssh. This can be disabled by using '**ufw --force enable**'.

APPLICATION INTEGRATION

ufw supports application integration by reading profiles located in /etc/ufw/applications.d. To list the names of application profiles known to **ufw**, use:

```
ufw app list
```

Users can specify an application name when adding a rule (quoting any profile names with spaces). For example, when using the simple syntax, users can use:

```
ufw allow <name>
```

Or for the extended syntax:

```
ufw allow from 192.168.0.0/16 to any app <name>
```

You should not specify the protocol with either syntax, and with the extended syntax, use **app** in place of the **port** clause.

Details on the firewall profile for a given application can be seen with:

```
ufw app info <name>
```

where '<name>' is one of the applications seen with the app list command. Users may also specify **all** to see the profiles for all known applications.

Syntax for the application profiles is a simple .INI format:

```
[<name>]
title=<title>
description=<description>
ports=<ports>
```

The 'ports' field may specify a '|'-separated list of ports/protocols where the protocol is optional. A comma-separated list or a range (specified with 'start:end') may also be used to specify multiple ports, in which case the protocol is required. For example:

```
[SomeService]
title=Some title
description=Some description
ports=12/udp|34|56,78:90/tcp
```

In the above example, 'SomeService' may be used in app rules and it specifies UDP port 12, TCP and UDP on port 34 and TCP ports 56 and 78-90 inclusive.

After creating or editing an application profile, users can run:

```
ufw app update <name>
```

This command will automatically update the firewall with updated profile information. If specify 'all' for name, then all the profiles will be updated. To update a profile and add a new rule to the firewall automatically, users can run:

```
ufw app update --add-new <name>
```

The behavior of the **update --add-new** command can be configured using:

```
ufw app default <policy>
```

The default application policy is **skip**, which means that the **update --add-new** command will do nothing. Users may also specify a policy of **allow** or **deny** so the **update --add-new** command may automatically update the firewall. **WARNING:** it may be a security risk to use a default **allow** policy for application profiles. Carefully consider the security ramifications before using a default **allow** policy.

LOGGING

ufw supports multiple logging levels. **ufw** defaults to a loglevel of 'low' when a loglevel is not specified. Users may specify a loglevel with:

```
ufw logging LEVEL
```

LEVEL may be 'off', 'low', 'medium', 'high' and 'full'. Log levels are defined as:

off disables ufw managed logging

low logs all blocked packets not matching the defined policy (with rate limiting), as well as packets matching logged rules

medium

log level low, plus all allowed packets not matching the defined policy, all INVALID packets, and all new connections. All logging is done with rate limiting.

high log level medium (without rate limiting), plus all packets with rate limiting

full log level high without rate limiting

Loglevels above medium generate a lot of logging output, and may quickly fill up your disk. Loglevel medium may generate a lot of logging output on a busy system.

Specifying 'on' simply enables logging at log level 'low' if logging is currently not enabled.

REPORTS

The following reports are supported. Each is based on the live system and with the exception of the **listening** report, is in raw iptables format:

```
raw
builtins
before-rules
user-rules
after-rules
logging-rules
listening
added
```

The **raw** report shows the complete firewall, while the others show a subset of what is in the **raw** report.

The **listening** report will display the ports on the live system in the listening state for tcp and the open state for udp, along with the address of the interface and the executable listening on the port. An '*' is used in place of the address of the interface when the executable is bound to all interfaces on that port. Following this information is a list of rules which may affect connections on this port. The rules are listed in the order they are evaluated by the kernel, and the first match wins. Please note that the default policy is not listed and tcp6 and udp6 are shown only if IPV6 is enabled.

The **added** report displays the list of rules as they were added on the command-line. This report does not show the status of the running firewall (use '**ufw status**' instead). Because rules are normalized by **ufw**, rules may look different than the originally added rule. Also, **ufw** does not record command ordering, so an equivalent ordering is used which lists IPv6-only rules after other rules.

NOTES

On installation, **ufw** is disabled with a default incoming policy of deny, a default forward policy of deny, and a default outgoing policy of allow, with stateful tracking for NEW connections for incoming and forwarded connections. In addition to the above, a default ruleset is put in place that does the following:

- DROP packets with RH0 headers
- DROP INVALID packets
- ACCEPT certain icmp packets (INPUT and FORWARD): destination-unreachable, source-quench, time-exceeded, parameter-problem, and echo-request for IPv4. destination-unreachable, packet-too-big, time-exceeded, parameter-problem, and echo-request for IPv6.
- ACCEPT icmpv6 packets for stateless autoconfiguration (INPUT)
- ACCEPT ping replies from IPv6 link-local (ffe8::/10) addresses (INPUT)
- ACCEPT DHCP client traffic (INPUT)
- DROP non-local traffic (INPUT)
- ACCEPT mDNS (zeroconf/bonjour/avahi 224.0.0.251 for IPv4 and ff02::fb for IPv6) for service discovery (INPUT)
- ACCEPT UPnP (239.255.255.250 for IPv4 and ff02::f for IPv6) for service discovery (INPUT)

Rule ordering is important and the first match wins. Therefore when adding rules, add the more specific rules first with more general rules later.

ufw is not intended to provide complete firewall functionality via its command interface, but instead provides an easy way to add or remove simple rules.

The status command shows basic information about the state of the firewall, as well as rules managed via the **ufw** command. It does not show rules from the rules files in /etc/ufw. To see the complete state of the

firewall, users can **ufw show raw**. This displays the filter, nat, mangle and raw tables using:

```
iptables -n -L -v -x -t <table>
ip6tables -n -L -v -x -t <table>
```

See the **iptables** and **ip6tables** documentation for more details.

If the default policy is set to REJECT, **ufw** may interfere with rules added outside of the ufw framework. See README for details.

IPv6 is allowed by default. To change this behavior to only accept IPv6 traffic on the loopback interface, set IPV6 to 'no' in /etc/default/ufw and reload **ufw**. When IPv6 is enabled, you may specify rules in the same way as for IPv4 rules, and they will be displayed with **ufw status**. Rules that match both IPv4 and IPv6 addresses apply to both IP versions. For example, when IPv6 is enabled, the following rule will allow access to port 22 for both IPv4 and IPv6 traffic:

```
ufw allow 22
```

IPv6 over IPv4 tunnels and 6to4 are supported by using the 'ipv6' protocol ('41'). This protocol can only be used with the full syntax. For example:

```
ufw allow to 10.0.0.1 proto ipv6
ufw allow to 10.0.0.1 from 10.4.0.0/16 proto ipv6
```

IPSec is supported by using the 'esp' ('50') and 'ah' ('51') protocols. These protocols can only be used with the full syntax. For example:

```
ufw allow to 10.0.0.1 proto esp
ufw allow to 10.0.0.1 from 10.4.0.0/16 proto esp
ufw allow to 10.0.0.1 proto ah
ufw allow to 10.0.0.1 from 10.4.0.0/16 proto ah
```

In addition to the command-line interface, **ufw** also provides a framework which allows administrators to modify default behavior as well as take full advantage of netfilter. See the **ufw-framework** manual page for more information.

AUTHOR

ufw is Copyright 2008-2021, Canonical Ltd.

NAME

umount, umount2 – unmount filesystem

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/mount.h>
int umount(const char *target);
int umount2(const char *target, int flags);
```

DESCRIPTION

umount() and **umount2()** remove the attachment of the (topmost) filesystem mounted on *target*.

Appropriate privilege (Linux: the **CAP_SYS_ADMIN** capability) is required to unmount filesystems.

Linux 2.1.116 added the **umount2()** system call, which, like **umount()**, unmounts a target, but allows additional *flags* controlling the behavior of the operation:

MNT_FORCE (since Linux 2.1.116)

Ask the filesystem to abort pending requests before attempting the unmount. This may allow the unmount to complete without waiting for an inaccessible server, but could cause data loss. If, after aborting requests, some processes still have active references to the filesystem, the unmount will still fail. As at Linux 4.12, **MNT_FORCE** is supported only on the following filesystems: 9p (since Linux 2.6.16), ceph (since Linux 2.6.34), cifs (since Linux 2.6.12), fuse (since Linux 2.6.16), lustre (since Linux 3.11), and NFS (since Linux 2.1.116).

MNT_DETACH (since Linux 2.4.11)

Perform a lazy unmount: make the mount unavailable for new accesses, immediately disconnect the filesystem and all filesystems mounted below it from each other and from the mount table, and actually perform the unmount when the mount ceases to be busy.

MNT_EXPIRE (since Linux 2.6.8)

Mark the mount as expired. If a mount is not currently in use, then an initial call to **umount2()** with this flag fails with the error **EAGAIN**, but marks the mount as expired. The mount remains expired as long as it isn't accessed by any process. A second **umount2()** call specifying **MNT_EXPIRE** unmounts an expired mount. This flag cannot be specified with either **MNT_FORCE** or **MNT_DETACH**.

UMOUNT_NOFOLLOW (since Linux 2.6.34)

Don't dereference *target* if it is a symbolic link. This flag allows security problems to be avoided in set-user-ID-*root* programs that allow unprivileged users to unmount filesystems.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

The error values given below result from filesystem type independent errors. Each filesystem type may have its own special errors and its own special behavior. See the Linux kernel source code for details.

EAGAIN

A call to **umount2()** specifying **MNT_EXPIRE** successfully marked an unbusy filesystem as expired.

EBUSY

target could not be unmounted because it is busy.

EFAULT

target points outside the user address space.

EINVAL

target is not a mount point.

EINVAL

target is locked; see **mount_namespaces(7)**.

EINVAL

umount2() was called with **MNT_EXPIRE** and either **MNT_DETACH** or **MNT_FORCE**.

EINVAL (since Linux 2.6.34)

umount2() was called with an invalid flag value in *fla gs*.

ENAMETOOLONG

A pathname was longer than **MAXPATHLEN**.

ENOENT

A pathname was empty or had a nonexistent component.

ENOMEM

The kernel could not allocate a free page to copy filenames or data into.

EPERM

The caller does not have the required privileges.

VERSIONS

MNT_DETACH and **MNT_EXPIRE** are available since glibc 2.11.

STANDARDS

These functions are Linux-specific and should not be used in programs intended to be portable.

NOTES**umount() and shared mounts**

Shared mounts cause any mount activity on a mount, including **umount()** operations, to be forwarded to every shared mount in the peer group and every slave mount of that peer group. This means that **umount()** of any peer in a set of shared mounts will cause all of its peers to be unmounted and all of their slaves to be unmounted as well.

This propagation of unmount activity can be particularly surprising on systems where every mount is shared by default. On such systems, recursively bind mounting the root directory of the filesystem onto a subdirectory and then later unmounting that subdirectory with **MNT_DETACH** will cause every mount in the mount namespace to be lazily unmounted.

To ensure **umount()** does not propagate in this fashion, the mount may be remounted using a **mount(2)** call with a *mount_flags* argument that includes both **MS_REC** and **MS_PRIVATE** prior to **umount()** being called.

Historical details

The original **umount()** function was called as *umount(device)* and would return **ENOTBLK** when called with something other than a block device. In Linux 0.98p4, a call to *umount(dir)* was added, in order to support anonymous devices. In Linux 2.3.99-pre7, the call to *umount(device)* was removed, leaving only *umount(dir)* (since now devices can be mounted in more than one place, so specifying the device does not suffice).

NAME

umount – unmount filesystems

SYNOPSIS

umount -a [-dflnrv] [-t fstype] [-O option...]

umount [-dflnrv] {directory|device}

umount -h|-V

DESCRIPTION

The **umount** command detaches the mentioned filesystem(s) from the file hierarchy. A filesystem is specified by giving the directory where it has been mounted. Giving the special device on which the filesystem lives may also work, but is obsolete, mainly because it will fail in case this device was mounted on more than one directory.

Note that a filesystem cannot be unmounted when it is 'busy' – for example, when there are open files on it, or when some process has its working directory there, or when a swap file on it is in use. The offending process could even be **umount** itself – it opens libc, and libc in its turn may open for example locale files. A lazy unmount avoids this problem, but it may introduce other issues. See **--lazy** description below.

OPTIONS**-a, --all**

All of the filesystems described in */proc/self/mountinfo* (or in deprecated */etc/mtab*) are unmounted, except the proc, devfs, devpts, sysfs, rpc_pipefs and nfsd filesystems. This list of the filesystems may be replaced by **--types** **umount** option.

-A, --all-targets

Unmount all mountpoints in the current mount namespace for the specified filesystem. The filesystem can be specified by one of the mountpoints or the device name (or UUID, etc.). When this option is used together with **--recursive**, then all nested mounts within the filesystem are recursively unmounted. This option is only supported on systems where */etc/mtab* is a symlink to */proc/mounts*.

-c, --no-canonicalize

Do not canonicalize paths. The paths canonicalization is based on **stat(2)** and **readlink(2)** system calls. These system calls may hang in some cases (for example on NFS if server is not available). The option has to be used with canonical path to the mount point.

This option is silently ignored by **umount** for non-root users.

For more details about this option see the **mount(8)** man page. Note that **umount** does not pass this option to the **/sbin/umount.type** helpers.

-d, --detach-loop

When the unmounted device was a loop device, also free this loop device. This option is unnecessary for devices initialized by **mount(8)**, in this case "autoclear" functionality is enabled by default.

--fake

Causes everything to be done except for the actual system call or umount helper execution; this 'fakes' unmounting the filesystem. It can be used to remove entries from the deprecated */etc/mtab* that were unmounted earlier with the **-n** option.

-f, --force

Force an unmount (in case of an unreachable NFS system).

Note that this option does not guarantee that umount command does not hang. It's strongly

recommended to use absolute paths without symlinks to avoid unwanted **readlink(2)** and **stat(2)** system calls on unreachable NFS in **umount**.

-i, --internal-only

Do not call the **/sbin/umount**,*filesystem* helper even if it exists. By default such a helper program is called if it exists.

-l, --lazy

Lazy unmount. Detach the filesystem from the file hierarchy now, and clean up all references to this filesystem as soon as it is not busy anymore.

A system reboot would be expected in near future if you're going to use this option for network filesystem or local filesystem with submounts. The recommended use-case for **umount -l** is to prevent hangs on shutdown due to an unreachable network share where a normal **umount** will hang due to a downed server or a network partition. Remounts of the share will not be possible.

-N, --namespace *ns*

Perform **umount** in the mount namespace specified by *ns*. *ns* is either PID of process running in that namespace or special file representing that namespace.

umount switches to the namespace when it reads */etc/fstab*, writes */etc/mtab* (or writes to */run/mount*) and calls **umount(2)** system call, otherwise it runs in the original namespace. It means that the target mount namespace does not have to contain any libraries or other requirements necessary to execute **umount(2)** command.

See **mount_namespaces(7)** for more information.

-n, --no-mtab

Unmount without writing in */etc/mtab*.

-O, --test-opts *option...*

Unmount only the filesystems that have the specified option set in */etc/fstab*. More than one option may be specified in a comma-separated list. Each option can be prefixed with **no** to indicate that no action should be taken for this option.

-q, --quiet

Suppress "not mounted" error messages.

-R, --recursive

Recursively unmount each specified directory. Recursion for each directory will stop if any unmount operation in the chain fails for any reason. The relationship between mountpoints is determined by */proc/self/mountinfo* entries. The filesystem must be specified by mountpoint path; a recursive unmount by device name (or UUID) is unsupported. Since version 2.37 it umounts also all over-mounted filesystems (more filesystems on the same mountpoint).

-r, --read-only

When an unmount fails, try to remount the filesystem read-only.

-t, --types *type...*

Indicate that the actions should only be taken on filesystems of the specified *type*. More than one type may be specified in a comma-separated list. The list of filesystem types can be prefixed with **no** to indicate that no action should be taken for all of the mentioned types. Note that **umount** reads information about mounted filesystems from kernel (*/proc/mounts*) and filesystem names may be different than filesystem names used in the */etc/fstab* (e.g., "nfs4" vs. "nfs").

-v, --verbose
Verbose mode.

-h, --help
Display help text and exit.

-V, --version
Print version and exit.

NON-SUPERUSER UMTOMTS

Normally, only the superuser can umount filesystems. However, when *fstab* contains the **user** option on a line, anybody can umount the corresponding filesystem. For more details see **mount(8)** man page.

Since version 2.34 the **umount** command can be used to perform umount operation also for fuse filesystems if kernel mount table contains user's ID. In this case *fstab* **user=** mount option is not required.

Since version 2.35 **umount** command does not exit when user permissions are inadequate by internal **libmount** security rules. It drops suid permissions and continue as regular non-root user. This can be used to support use-cases where root permissions are not necessary (e.g., fuse filesystems, user namespaces, etc).

LOOP DEVICE

The **umount** command will automatically detach loop device previously initialized by **mount(8)** command independently of */etc/mtab*.

In this case the device is initialized with "autoclear" flag (see **losetup(8)** output for more details), otherwise it's necessary to use the option **--detach-loop** or call **losetup -d device**. The autoclear feature is supported since Linux 2.6.25.

EXTERNAL HELPERS

The syntax of external umount helpers is:

```
umount.suffix {directory|device} [-flnrv] [-N namespace] [-t type.subtype]
```

where *suffix* is the filesystem type (or the value from a **uhelper=** or **helper=** marker in the *mtab* file). The **-t** option can be used for filesystems that have subtype support. For example:

```
umount.fuse -t fuse.sshfs
```

A **uhelper=***something* marker (unprivileged helper) can appear in the */etc/mtab* file when ordinary users need to be able to umount a mountpoint that is not defined in */etc/fstab* (for example for a device that was mounted by **udisks(1)**).

A **helper=***type* marker in the *mtab* file will redirect all umount requests to the **/sbin/umount.type** helper independently of UID.

Note that */etc/mtab* is currently deprecated and **helper=** and other userspace mount options are maintained by **libmount**.

ENVIRONMENT

LIBMOUNT_FSTAB=<path>
overrides the default location of the *fstab* file (ignored for **suid**)

LIBMOUNT_MTAB=<path>
overrides the default location of the *mtab* file (ignored for **suid**)

LIBMOUNT_DEBUG=all

enables **libmount** debug output

FILES

/etc/mtab

table of mounted filesystems (deprecated and usually replaced by symlink to */proc/mounts*)

/etc/fstab

table of known filesystems

/proc/self/mountinfo

table of mounted filesystems generated by kernel.

HISTORY

A **umount** command appeared in Version 6 AT&T UNIX.

SEE ALSO

umount(2), losetup(8), mount_namespaces(7), mount(8)

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **umount** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

umount.nfs(8) - Linux man page

Name

umount.nfs, umount.nfs4 - unmount a Network File System

Synopsis

umount.nfs *dir* [**-fvnrlh**]

Description

umount.nfs and **umount.nfs4** are a part of [nfs\(5\)](#) utilities package, which provides NFS client functionality.

umount.nfs4 and **umount.nfs** are meant to be used by the [umount\(8\)](#) command for unmounting NFS shares. This subcommand, however, can also be used as a standalone command with limited functionality.

dir is the directory on which the file system is mounted.

Options

-f

Force unmount the file system in case of unreachable NFS system.

-v

Be verbose.

-n

Do not update */etc/mtab*. By default, an entry is created in */etc/mtab* for every mounted file system. Use this option to skip deleting an entry.

-r

In case unmounting fails, try to mount read-only.

-l

Lazy unmount. Detach the file system from the file system hierarchy now, and cleanup all references to the file system as soon as it is not busy anymore.

-h

Print help message.

Note

NAME

umount.udisks2 – unmount file systems that have been mounted by UDisks2

DESCRIPTION

The **umount.udisks2** program is a helper for the **umount(8)** program. Its purpose is to clean up automatically created directories created at file system mount-time. It should never be called directly.

AUTHOR

This man page was originally written for UDisks2 by David Zeuthen <zeuthen@gmail.com> with a lot of help from many others.

BUGS

Please send bug reports to either the distribution bug tracker or the upstream bug tracker at
<https://github.com/storaged-project/udisks/issues>.

NAME

umount, umount2 – unmount filesystem

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/mount.h>
int umount(const char *target);
int umount2(const char *target, int flags);
```

DESCRIPTION

umount() and **umount2()** remove the attachment of the (topmost) filesystem mounted on *target*.

Appropriate privilege (Linux: the **CAP_SYS_ADMIN** capability) is required to unmount filesystems.

Linux 2.1.116 added the **umount2()** system call, which, like **umount()**, unmounts a target, but allows additional *flags* controlling the behavior of the operation:

MNT_FORCE (since Linux 2.1.116)

Ask the filesystem to abort pending requests before attempting the unmount. This may allow the unmount to complete without waiting for an inaccessible server, but could cause data loss. If, after aborting requests, some processes still have active references to the filesystem, the unmount will still fail. As at Linux 4.12, **MNT_FORCE** is supported only on the following filesystems: 9p (since Linux 2.6.16), ceph (since Linux 2.6.34), cifs (since Linux 2.6.12), fuse (since Linux 2.6.16), lustre (since Linux 3.11), and NFS (since Linux 2.1.116).

MNT_DETACH (since Linux 2.4.11)

Perform a lazy unmount: make the mount unavailable for new accesses, immediately disconnect the filesystem and all filesystems mounted below it from each other and from the mount table, and actually perform the unmount when the mount ceases to be busy.

MNT_EXPIRE (since Linux 2.6.8)

Mark the mount as expired. If a mount is not currently in use, then an initial call to **umount2()** with this flag fails with the error **EAGAIN**, but marks the mount as expired. The mount remains expired as long as it isn't accessed by any process. A second **umount2()** call specifying **MNT_EXPIRE** unmounts an expired mount. This flag cannot be specified with either **MNT_FORCE** or **MNT_DETACH**.

UMOUNT_NOFOLLOW (since Linux 2.6.34)

Don't dereference *target* if it is a symbolic link. This flag allows security problems to be avoided in set-user-ID-*root* programs that allow unprivileged users to unmount filesystems.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

The error values given below result from filesystem type independent errors. Each filesystem type may have its own special errors and its own special behavior. See the Linux kernel source code for details.

EAGAIN

A call to **umount2()** specifying **MNT_EXPIRE** successfully marked an unbusy filesystem as expired.

EBUSY

target could not be unmounted because it is busy.

EFAULT

target points outside the user address space.

EINVAL

target is not a mount point.

EINVAL

target is locked; see **mount_namespaces(7)**.

EINVAL

umount2() was called with **MNT_EXPIRE** and either **MNT_DETACH** or **MNT_FORCE**.

EINVAL (since Linux 2.6.34)

umount2() was called with an invalid flag value in *fla gs*.

ENAMETOOLONG

A pathname was longer than **MAXPATHLEN**.

ENOENT

A pathname was empty or had a nonexistent component.

ENOMEM

The kernel could not allocate a free page to copy filenames or data into.

EPERM

The caller does not have the required privileges.

VERSIONS

MNT_DETACH and **MNT_EXPIRE** are available since glibc 2.11.

STANDARDS

These functions are Linux-specific and should not be used in programs intended to be portable.

NOTES**umount() and shared mounts**

Shared mounts cause any mount activity on a mount, including **umount()** operations, to be forwarded to every shared mount in the peer group and every slave mount of that peer group. This means that **umount()** of any peer in a set of shared mounts will cause all of its peers to be unmounted and all of their slaves to be unmounted as well.

This propagation of unmount activity can be particularly surprising on systems where every mount is shared by default. On such systems, recursively bind mounting the root directory of the filesystem onto a subdirectory and then later unmounting that subdirectory with **MNT_DETACH** will cause every mount in the mount namespace to be lazily unmounted.

To ensure **umount()** does not propagate in this fashion, the mount may be remounted using a **mount(2)** call with a *mount_flags* argument that includes both **MS_REC** and **MS_PRIVATE** prior to **umount()** being called.

Historical details

The original **umount()** function was called as *umount(device)* and would return **ENOTBLK** when called with something other than a block device. In Linux 0.98p4, a call to *umount(dir)* was added, in order to support anonymous devices. In Linux 2.3.99-pre7, the call to *umount(device)* was removed, leaving only *umount(dir)* (since now devices can be mounted in more than one place, so specifying the device does not suffice).

NAME

uname – print system information

SYNOPSIS

uname [*OPTION*]...

DESCRIPTION

Print certain system information. With no OPTION, same as **-s**.

-a, --all

print all information, in the following order, except omit **-p** and **-i** if unknown:

-s, --kernel-name

print the kernel name

-n, --nodename

print the network node hostname

-r, --kernel-release

print the kernel release

-v, --kernel-version

print the kernel version

-m, --machine

print the machine hardware name

-p, --processor

print the processor type (non–portable)

-i, --hardware-platform

print the hardware platform (non–portable)

-o, --operating-system

print the operating system

--help display this help and exit

--version

output version information and exit

NAME

`uname` – get name and information about current kernel

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/utsname.h>
int uname(struct utsname *buf);
```

DESCRIPTION

`uname()` returns system information in the structure pointed to by *buf*. The *utsname* struct is defined in `<sys/utsname.h>`:

```
struct utsname {
    char sysname[];      /* Operating system name (e.g., "Linux") */
    char nodename[];     /* Name within communications network
                           to which the node is attached, if any */
    char release[];      /* Operating system release
                           (e.g., "2.6.28") */
    char version[];      /* Operating system version */
    char machine[];      /* Hardware type identifier */

#ifndef _GNU_SOURCE
    char domainname[];  /* NIS or YP domain name */
#endif
};
```

The length of the arrays in a *struct utsname* is unspecified (see NOTES); the fields are terminated by a null byte ('\0').

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS**FAULT**

buf is not valid.

STANDARDS

POSIX.1-2001, POSIX.1-2008, SVr4, 4.4BSD.

The *domainname* member (the NIS or YP domain name) is a GNU extension.

NOTES

The kernel has the name, release, version, and supported machine type built in. Conversely, the *nodename* field is configured by the administrator to match the network (this is what the BSD historically calls the "hostname", and is set via `sethostname(2)`). Similarly, the *domainname* field is set via `setdomainname(2)`.

The length of the fields in the struct varies. Some operating systems or libraries use a hardcoded 9 or 33 or 65 or 257. Other systems use **SYS_NMLN** or **_SYS_NMLN** or **UTSLEN** or **_UTSNAME_LENGTH**. Clearly, it is a bad idea to use any of these constants; just use `sizeof(...)`. SVr4 uses 257, "to support Internet hostnames" — this is the largest value likely to be encountered in the wild.

Part of the *utsname* information is also accessible via `/proc/sys/kernel/{ostype, hostname, osrelease, version, domainname}`.

C library/kernel differences

Over time, increases in the size of the *utsname* structure have led to three successive versions of `uname()`: `sys_olduname()` (slot `__NR_oldolduname`), `sys_uname()` (slot `__NR_olduname`), and `sys_newuname()` (slot `__NR_uname`). The first one used length 9 for all fields; the second used 65; the third also uses 65 but adds the *domainname* field. The glibc `uname()` wrapper function hides these details from applications, invoking the most recent version of the system call provided by the kernel.

SEE ALSO

uname(1), getdomainname(2), gethostname(2), uts_namespaces(7)

NAME

uniq – report or omit repeated lines

SYNOPSIS

uniq [*OPTION*]... [*INPUT* [*OUTPUT*]]

DESCRIPTION

Filter adjacent matching lines from *INPUT* (or standard input), writing to *OUTPUT* (or standard output).

With no options, matching lines are merged to the first occurrence.

Mandatory arguments to long options are mandatory for short options too.

-c, --count

prefix lines by the number of occurrences

-d, --repeated

only print duplicate lines, one for each group

-D

print all duplicate lines

--all-repeated[=METHOD]

like **-D**, but allow separating groups with an empty line; METHOD={none(default),prepend,separate}

-f, --skip-fields=N

avoid comparing the first N fields

--group[=METHOD]

show all items, separating groups with an empty line; METHOD={separate(default),prepend,append,both}

-i, --ignore-case

ignore differences in case when comparing

-s, --skip-chars=N

avoid comparing the first N characters

-u, --unique

only print unique lines

-z, --zero-terminated

line delimiter is NUL, not newline

-w, --check-chars=N

compare no more than N characters in lines

--help display this help and exit**--version**

output version information and exit

A field is a run of blanks (usually spaces and/or TABs), then non-blank characters. Fields are skipped before chars.

Note: 'uniq' does not detect repeated lines unless they are adjacent. You may want to sort the input first, or use 'sort -u' without 'uniq'.

NAME

unzip – list, test and extract compressed files in a ZIP archive

SYNOPSIS

unzip [-Z] [-cflptTuvz[abjnoqsCDKLMUVWX\$/:^]] file[.zip] [file(s) ...] [-x xfile(s) ...] [-d exdir]

DESCRIPTION

unzip will list, test, or extract files from a ZIP archive, commonly found on MS-DOS systems. The default behavior (with no options) is to extract into the current directory (and subdirectories below it) all files from the specified ZIP archive. A companion program, *zip(1)*, creates ZIP archives; both programs are compatible with archives created by PKWARE's *PKZIP* and *PKUNZIP* for MS-DOS, but in many cases the program options or default behaviors differ.

ARGUMENTS

file[.zip]

Path of the ZIP archive(s). If the file specification is a wildcard, each matching file is processed in an order determined by the operating system (or file system). Only the filename can be a wildcard; the path itself cannot. Wildcard expressions are similar to those supported in commonly used Unix shells (*sh*, *ksh*, *csh*) and may contain:

- * matches a sequence of 0 or more characters
- ? matches exactly 1 character
- [...] matches any single character found inside the brackets; ranges are specified by a beginning character, a hyphen, and an ending character. If an exclamation point or a caret ('!' or '^') follows the left bracket, then the range of characters within the brackets is complemented (that is, anything *except* the characters inside the brackets is considered a match). To specify a verbatim left bracket, the three-character sequence "[[]]" has to be used.

(Be sure to quote any character that might otherwise be interpreted or modified by the operating system, particularly under Unix and VMS.) If no matches are found, the specification is assumed to be a literal filename; and if that also fails, the suffix *.zip* is appended. Note that self-extracting ZIP files are supported, as with any other ZIP archive; just specify the *.exe* suffix (if any) explicitly.

[file(s)] An optional list of archive members to be processed, separated by spaces. (VMS versions compiled with VMSCLI defined must delimit files with commas instead. See **-v** in **OPTIONS** below.) Regular expressions (wildcards) may be used to match multiple members; see above. Again, be sure to quote expressions that would otherwise be expanded or modified by the operating system.

[-x xfile(s)]

An optional list of archive members to be excluded from processing. Since wildcard characters normally match ('/') directory separators (for exceptions see the option **-W**), this option may be used to exclude any files that are in subdirectories. For example, "unzip foo *.[ch] -x */*" would extract all C source files in the main directory, but none in any subdirectories. Without the **-x** option, all C source files in all directories within the zipfile would be extracted.

[-d exdir]

An optional directory to which to extract files. By default, all files and subdirectories are recreated in the current directory; the **-d** option allows extraction in an arbitrary directory (always assuming one has permission to write to the directory). This option need not appear at the end of the command line; it is also accepted before the zipfile specification (with the normal options), immediately after the zipfile specification, or between the *file(s)* and the **-x** option. The option and directory may be concatenated without any white space between them, but note that this may cause normal shell behavior to be suppressed. In particular, "-d ~" (tilde) is expanded by Unix C shells into the name of the user's home directory, but "-d ~" is treated as a literal subdirectory "~" of the current directory.

OPTIONS

Note that, in order to support obsolescent hardware, *unzip*'s usage screen is limited to 22 or 23 lines and should therefore be considered only a reminder of the basic *unzip* syntax rather than an exhaustive list of all possible flags. The exhaustive list follows:

- Z** *zipinfo(1)* mode. If the first option on the command line is **-Z**, the remaining options are taken to be *zipinfo(1)* options. See the appropriate manual page for a description of these options.
- A** [OS/2, Unix DLL] print extended help for the DLL's programming interface (API).
- c** extract files to stdout/screen ("CRT"). This option is similar to the **-p** option except that the name of each file is printed as it is extracted, the **-a** option is allowed, and ASCII-EBCDIC conversion is automatically performed if appropriate. This option is not listed in the *unzip* usage screen.
- f** freshen existing files, i.e., extract only those files that already exist on disk and that are newer than the disk copies. By default *unzip* queries before overwriting, but the **-o** option may be used to suppress the queries. Note that under many operating systems, the TZ (timezone) environment variable must be set correctly in order for **-f** and **-u** to work properly (under Unix the variable is usually set automatically). The reasons for this are somewhat subtle but have to do with the differences between DOS-format file times (always local time) and Unix-format times (always in GMT/UTC) and the necessity to compare the two. A typical TZ value is "PST8PDT" (US Pacific time with automatic adjustment for Daylight Savings Time or "summer time").
- l** list archive files (short format). The names, uncompressed file sizes and modification dates and times of the specified files are printed, along with totals for all files specified. If UnZip was compiled with OS2_EAS defined, the **-l** option also lists columns for the sizes of stored OS/2 extended attributes (EAs) and OS/2 access control lists (ACLs). In addition, the zipfile comment and individual file comments (if any) are displayed. If a file was archived from a single-case file system (for example, the old MS-DOS FAT file system) and the **-L** option was given, the filename is converted to lowercase and is prefixed with a caret (^).
- p** extract files to pipe (stdout). Nothing but the file data is sent to stdout, and the files are always extracted in binary format, just as they are stored (no conversions).
- t** test archive files. This option extracts each specified file in memory and compares the CRC (cyclic redundancy check, an enhanced checksum) of the expanded file with the original file's stored CRC value.
- T** [most OSes] set the timestamp on the archive(s) to that of the newest file in each one. This corresponds to *zip*'s **-go** option except that it can be used on wildcard zipfiles (e.g., "unzip -T *.zip") and is much faster.
- u** update existing files and create new ones if needed. This option performs the same function as the **-f** option, extracting (with query) files that are newer than those with the same name on disk, and in addition it extracts those files that do not already exist on disk. See **-f** above for information on setting the timezone properly.
- v** list archive files (verbose format) or show diagnostic version info. This option has evolved and now behaves as both an option and a modifier. As an option it has two purposes: when a zipfile is specified with no other options, **-v** lists archive files verbosely, adding to the basic **-l** info the compression method, compressed size, compression ratio and 32-bit CRC. In contrast to most of the competing utilities, *unzip* removes the 12 additional header bytes of encrypted entries from the compressed size numbers. Therefore, compressed size and compression ratio figures are independent of the entry's encryption status and show the correct compression performance. (The complete size of the encrypted compressed data stream for zipfile entries is reported by the more verbose *zipinfo(1)* reports, see the separate manual.) When no zipfile is specified (that is, the complete command is simply "unzip -v"), a diagnostic screen is printed. In addition to the normal header with release date and version, *unzip* lists the home Info-ZIP ftp site and where to find a list of other ftp and non-ftp sites; the target operating system for which it was compiled, as well as

(possibly) the hardware on which it was compiled, the compiler and version used, and the compilation date; any special compilation options that might affect the program's operation (see also **DECRYPTION** below); and any options stored in environment variables that might do the same (see **ENVIRONMENT OPTIONS** below). As a modifier it works in conjunction with other options (e.g., **-t**) to produce more verbose or debugging output; this is not yet fully implemented but will be in future releases.

- z** display only the archive comment.

MODIFIERS

- a** convert text files. Ordinarily all files are extracted exactly as they are stored (as "binary" files). The **-a** option causes files identified by *zip* as text files (those with the 't' label in *zipinfo* listings, rather than 'b') to be automatically extracted as such, converting line endings, end-of-file characters and the character set itself as necessary. (For example, Unix files use line feeds (LFs) for end-of-line (EOL) and have no end-of-file (EOF) marker; Macintoshes use carriage returns (CRs) for EOLs; and most PC operating systems use CR+LF for EOLs and control-Z for EOF. In addition, IBM mainframes and the Michigan Terminal System use EBCDIC rather than the more common ASCII character set, and NT supports Unicode.) Note that *zip*'s identification of text files is by no means perfect; some "text" files may actually be binary and vice versa. *unzip* therefore prints "[text]" or "[binary]" as a visual check for each file it extracts when using the **-a** option. The **-aa** option forces all files to be extracted as text, regardless of the supposed file type. On VMS, see also **-S**.
 - b** [general] treat all files as binary (no text conversions). This is a shortcut for---**a**.
 - b** [Tandem] force the creation files with filecode type 180 ('C') when extracting Zip entries marked as "text". (On Tandem, **-a** is enabled by default, see above).
 - b** [VMS] auto-convert binary files (see **-a** above) to fixed-length, 512-byte record format. Doubling the option (**-bb**) forces all files to be extracted in this format. When extracting to standard output (**-c** or **-p** option in effect), the default conversion of text record delimiters is disabled for binary (**-b**) resp. all (**-bb**) files.
 - B** [when compiled with UNIXBACKUP defined] save a backup copy of each overwritten file. The backup file is gets the name of the target file with a tilde and optionally a unique sequence number (up to 5 digits) appended. The sequence number is applied whenever another file with the original name plus tilde already exists. When used together with the "overwrite all" option **-o**, numbered backup files are never created. In this case, all backup files are named as the original file with an appended tilde, existing backup files are deleted without notice. This feature works similarly to the default behavior of *emacs*(1) in many locations.
- Example: the old copy of "foo" is renamed to "foo~".
- Warning: Users should be aware that the **-B** option does not prevent loss of existing data under all circumstances. For example, when *unzip* is run in overwrite-all mode, an existing "foo~" file is deleted before *unzip* attempts to rename "foo" to "foo~". When this rename attempt fails (because of a file locks, insufficient privileges, or ...), the extraction of "foo~" gets cancelled, but the old backup file is already lost. A similar scenario takes place when the sequence number range for numbered backup files gets exhausted (99999, or 65535 for 16-bit systems). In this case, the backup file with the maximum sequence number is deleted and replaced by the new backup version without notice.
- C** use case-insensitive matching for the selection of archive entries from the command-line list of extract selection patterns. *unzip*'s philosophy is "you get what you ask for" (this is also responsible for the **-L/-U** change; see the relevant options below). Because some file systems are fully case-sensitive (notably those under the Unix operating system) and because both ZIP archives and *unzip* itself are portable across platforms, *unzip*'s default behavior is to match both wildcard and literal filenames case-sensitively. That is, specifying "makefile" on the command line will *only* match "makefile" in the archive, not "Makefile" or "MAKEFILE" (and similarly for wildcard specifications). Since this does not correspond to the behavior of many other operating/file

systems (for example, OS/2 HPFS, which preserves mixed case but is not sensitive to it), the **-C** option may be used to force all filename matches to be case-insensitive. In the example above, all three files would then match “`makefile`” (or “`make*`”, or similar). The **-C** option affects file specs in both the normal file list and the excluded-file list (xlist).

Please note that the **-C** option does neither affect the search for the zipfile(s) nor the matching of archive entries to existing files on the extraction path. On a case-sensitive file system, *unzip* will never try to overwrite a file “`FOO`” when extracting an entry “`foo`”!

- D** skip restoration of timestamps for extracted items. Normally, *unzip* tries to restore all meta-information for extracted items that are supplied in the Zip archive (and do not require privileges or impose a security risk). By specifying **-D**, *unzip* is told to suppress restoration of timestamps for directories explicitly created from Zip archive entries. This option only applies to ports that support setting timestamps for directories (currently ATheOS, BeOS, MacOS, OS/2, Unix, VMS, Win32, for other *unzip* ports, **-D** has no effect). The duplicated option **-DD** forces suppression of timestamp restoration for all extracted entries (files and directories). This option results in setting the timestamps for all extracted entries to the current time.
- On VMS, the default setting for this option is **-D** for consistency with the behaviour of BACKUP: file timestamps are restored, timestamps of extracted directories are left at the current time. To enable restoration of directory timestamps, the negated option **--D** should be specified. On VMS, the option **-D** disables timestamp restoration for all extracted Zip archive items. (Here, a single **-D** on the command line combines with the default **-D** to do what an explicit **-DD** does on other systems.)
- E** [MacOS only] display contents of MacOS extra field during restore operation.
- F** [Acorn only] suppress removal of NFS filetype extension from stored filenames.
- F** [non-Acorn systems supporting long filenames with embedded commas, and only if compiled with ACORN_FTYPE_NFS defined] translate filetype information from ACORN RISC OS extra field blocks into a NFS filetype extension and append it to the names of the extracted files. (When the stored filename appears to already have an appended NFS filetype extension, it is replaced by the info from the extra field.)
- i** [MacOS only] ignore filenames stored in MacOS extra fields. Instead, the most compatible filename stored in the generic part of the entry’s header is used.
- j** junk paths. The archive’s directory structure is not recreated; all files are deposited in the extraction directory (by default, the current one).
- J** [BeOS only] junk file attributes. The file’s BeOS file attributes are not restored, just the file’s data.
- J** [MacOS only] ignore MacOS extra fields. All Macintosh specific info is skipped. Data-fork and resource-fork are restored as separate files.
- K** [AtheOS, BeOS, Unix only] retain SUID/SGID/Tacky file attributes. Without this flag, these attribute bits are cleared for security reasons.
- L** convert to lowercase any filename originating on an uppercase-only operating system or file system. (This was *unzip*’s default behavior in releases prior to 5.11; the new default behavior is identical to the old behavior with the **-U** option, which is now obsolete and will be removed in a future release.) Depending on the archiver, files archived under single-case file systems (VMS, old MS-DOS FAT, etc.) may be stored as all-uppercase names; this can be ugly or inconvenient when extracting to a case-preserving file system such as OS/2 HPFS or a case-sensitive one such as under Unix. By default *unzip* lists and extracts such filenames exactly as they’re stored (excepting truncation, conversion of unsupported characters, etc.); this option causes the names of all files from certain systems to be converted to lowercase. The **-LL** option forces conversion of every filename to lowercase, regardless of the originating file system.
- M** pipe all output through an internal pager similar to the Unix *more*(1) command. At the end of a screenful of output, *unzip* pauses with a “**--More--**” prompt; the next screenful may be viewed

by pressing the Enter (Return) key or the space bar. *unzip* can be terminated by pressing the “q” key and, on some systems, the Enter/Return key. Unlike Unix *more*(1), there is no forward-searching or editing capability. Also, *unzip* doesn’t notice if long lines wrap at the edge of the screen, effectively resulting in the printing of two or more lines and the likelihood that some text will scroll off the top of the screen before being viewed. On some systems the number of available lines on the screen is not detected, in which case *unzip* assumes the height is 24 lines.

- n** never overwrite existing files. If a file already exists, skip the extraction of that file without prompting. By default *unzip* queries before extracting any file that already exists; the user may choose to overwrite only the current file, overwrite all files, skip extraction of the current file, skip extraction of all existing files, or rename the current file.
- N** [Amiga] extract file comments as Amiga filenotes. File comments are created with the -c option of *zip*(1), or with the -N option of the Amiga port of *zip*(1), which stores filenotes as comments.
- o** overwrite existing files without prompting. This is a dangerous option, so use it with care. (It is often used with **-f**, however, and is the only way to overwrite directory EAs under OS/2.)
- P password** use *password* to decrypt encrypted zipfile entries (if any). **THIS IS INSECURE!** Many multi-user operating systems provide ways for any user to see the current command line of any other user; even on stand-alone systems there is always the threat of over-the-shoulder peeking. Storing the plaintext password as part of a command line in an automated script is even worse. Whenever possible, use the non-echoing, interactive prompt to enter passwords. (And where security is truly important, use strong encryption such as Pretty Good Privacy instead of the relatively weak encryption provided by standard zipfile utilities.)
- q** perform operations quietly (**-qq** = even quieter). Ordinarily *unzip* prints the names of the files it’s extracting or testing, the extraction methods, any file or zipfile comments that may be stored in the archive, and possibly a summary when finished with each archive. The **-q[q]** options suppress the printing of some or all of these messages.
- s** [OS/2, NT, MS-DOS] convert spaces in filenames to underscores. Since all PC operating systems allow spaces in filenames, *unzip* by default extracts filenames with spaces intact (e.g., “EA DATA. SF”). This can be awkward, however, since MS-DOS in particular does not gracefully support spaces in filenames. Conversion of spaces to underscores can eliminate the awkwardness in some cases.
- S** [VMS] convert text files (**-a**, **-aa**) into Stream_LF record format, instead of the text-file default, variable-length record format. (Stream_LF is the default record format of VMS *unzip*. It is applied unless conversion (**-a**, **-aa** and/or **-b**, **-bb**) is requested or a VMS-specific entry is processed.)
- U** [UNICODE_SUPPORT only] modify or disable UTF-8 handling. When UNICODE_SUPPORT is available, the option **-U** forces *unzip* to escape all non-ASCII characters from UTF-8 coded filenames as “#Uxxxx” (for UCS-2 characters, or “#Lxxxxxx” for unicode codepoints needing 3 octets). This option is mainly provided for debugging purpose when the fairly new UTF-8 support is suspected to mangle up extracted filenames.
The option **-UU** allows to entirely disable the recognition of UTF-8 encoded filenames. The handling of filename codings within *unzip* falls back to the behaviour of previous versions.
[old, obsolete usage] leave filenames uppercase if created under MS-DOS, VMS, etc. See **-L** above.
- V** retain (VMS) file version numbers. VMS files can be stored with a version number, in the format *file.ext ;##*. By default the “;##” version numbers are stripped, but this option allows them to be retained. (On file systems that limit filenames to particularly short lengths, the version numbers may be truncated or stripped regardless of this option.)
- W** [only when WILD_STOP_AT_DIR compile-time option enabled] modifies the pattern matching routine so that both ‘?’ (single-char wildcard) and ‘*’ (multi-char wildcard) do not match the directory separator character ‘/’. (The two-character sequence “**” acts as a multi-char wildcard

that includes the directory separator in its matched characters.) Examples:

```
"*.c" matches "foo.c" but not "mydir/foo.c"
"**.c" matches both "foo.c" and "mydir/foo.c"
"*/*.c" matches "bar/foo.c" but not "baz/bar/foo.c"
"?*/*" matches "ab/foo" and "abc/foo"
but not "a/foo" or "a/b/foo"
```

This modified behaviour is equivalent to the pattern matching style used by the shells of some of UnZip's supported target OSs (one example is Acorn RISC OS). This option may not be available on systems where the Zip archive's internal directory separator character '/' is allowed as regular character in native operating system filenames. (Currently, UnZip uses the same pattern matching rules for both wildcard zipfile specifications and zip entry selection patterns in most ports. For systems allowing '/' as regular filename character, the -W option would not work as expected on a wildcard zipfile specification.)

- X** [VMS, Unix, OS/2, NT, Tandem] restore owner/protection info (UICs and ACL entries) under VMS, or user and group info (UID/GID) under Unix, or access control lists (ACLs) under certain network-enabled versions of OS/2 (Warp Server with IBM LAN Server/Requester 3.0 to 5.0; Warp Connect with IBM Peer 1.0), or security ACLs under Windows NT. In most cases this will require special system privileges, and doubling the option (-XX) under NT instructs *unzip* to use privileges for extraction; but under Unix, for example, a user who belongs to several groups can restore files owned by any of those groups, as long as the user IDs match his or her own. Note that ordinary file attributes are always restored--this option applies only to optional, extra ownership info available on some operating systems. [NT's access control lists do not appear to be especially compatible with OS/2's, so no attempt is made at cross-platform portability of access privileges. It is not clear under what conditions this would ever be useful anyway.]
- Y** [VMS] treat archived file name endings of ".nnn" (where "nnn" is a decimal number) as if they were VMS version numbers (";nnn"). (The default is to treat them as file types.) Example:
"a.b.3" -> "a.b;3".
- \$** [MS-DOS, OS/2, NT] restore the volume label if the extraction medium is removable (e.g., a diskette). Doubling the option (-\$\$) allows fixed media (hard disks) to be labelled as well. By default, volume labels are ignored.
- / extensions** [Acorn only] overrides the extension list supplied by *Unzip\$Ext* environment variable. During extraction, filename extensions that match one of the items in this extension list are swapped in front of the base name of the extracted file.
- :** [all but Acorn, VM/CMS, MVS, Tandem] allows to extract archive members into locations outside of the current "extraction root folder". For security reasons, *unzip* normally removes "parent dir" path components ("..") from the names of extracted file. This safety feature (new for version 5.50) prevents *unzip* from accidentally writing files to "sensitive" areas outside the active extraction folder tree head. The -: option lets *unzip* switch back to its previous, more liberal behaviour, to allow exact extraction of (older) archives that used ".." components to create multiple directory trees at the level of the current extraction folder. This option does not enable writing explicitly to the root directory ("/"). To achieve this, it is necessary to set the extraction target folder to root (e.g. -d /). However, when the -: option is specified, it is still possible to implicitly write to the root directory by specifying enough ".." path components within the zip archive. Use this option with extreme caution.
- ^** [Unix only] allow control characters in names of extracted ZIP archive entries. On Unix, a file name may contain any (8-bit) character code with the two exception '/' (directory delimiter) and NUL (0x00, the C string termination indicator), unless the specific file system has more restrictive conventions. Generally, this allows to embed ASCII control characters (or even sophisticated control sequences) in file names, at least on 'native' Unix file systems. However, it may be highly suspicious to make use of this Unix "feature". Embedded control characters in file names might

have nasty side effects when displayed on screen by some listing code without sufficient filtering. And, for ordinary users, it may be difficult to handle such file names (e.g. when trying to specify it for open, copy, move, or delete operations). Therefore, *unzip* applies a filter by default that removes potentially dangerous control characters from the extracted file names. The **-^** option allows to override this filter in the rare case that embedded filename control characters are to be intentionally restored.

- 2** [VMS] force unconditionally conversion of file names to ODS2-compatible names. The default is to exploit the destination file system, preserving case and extended file name characters on an ODS5 destination file system; and applying the ODS2-compatibility file name filtering on an ODS2 destination file system.

ENVIRONMENT OPTIONS

unzip's default behavior may be modified via options placed in an environment variable. This can be done with any option, but it is probably most useful with the **-a**, **-L**, **-C**, **-q**, **-o**, or **-n** modifiers: make *unzip* auto-convert text files by default, make it convert filenames from uppercase systems to lowercase, make it match names case-insensitively, make it quieter, or make it always overwrite or never overwrite files as it extracts them. For example, to make *unzip* act as quietly as possible, only reporting errors, one would use one of the following commands:

Unix Bourne shell:

```
UNZIP=-qq; export UNZIP
```

Unix C shell:

```
setenv UNZIP -qq
```

OS/2 or MS-DOS:

```
set UNZIP=-qq
```

VMS (quotes for *lowercase*):

```
define UNZIP_OPTS "-qq"
```

Environment options are, in effect, considered to be just like any other command-line options, except that they are effectively the first options on the command line. To override an environment option, one may use the “minus operator” to remove it. For instance, to override one of the quiet-flags in the example above, use the command

```
unzip --q[other options] zipfile
```

The first hyphen is the normal switch character, and the second is a minus sign, acting on the q option. Thus the effect here is to cancel one quantum of quietness. To cancel both quiet flags, two (or more) minuses may be used:

```
unzip -t--q zipfile
unzip ---qt zipfile
```

(the two are equivalent). This may seem awkward or confusing, but it is reasonably intuitive: just ignore the first hyphen and go from there. It is also consistent with the behavior of Unix *nice*(1).

As suggested by the examples above, the default variable names are UNZIP_OPTS for VMS (where the symbol used to install *unzip* as a foreign command would otherwise be confused with the environment variable), and UNZIP for all other operating systems. For compatibility with *zip*(1), UNZIPOPT is also accepted (don't ask). If both UNZIP and UNZIPOPT are defined, however, UNZIP takes precedence. *unzip*'s diagnostic option (**-v** with no zipfile name) can be used to check the values of all four possible *unzip* and *zipinfo* environment variables.

The timezone variable (TZ) should be set according to the local timezone in order for the **-f** and **-u** to operate correctly. See the description of **-f** above for details. This variable may also be necessary to get timestamps of extracted files to be set correctly. The WIN32 (Win9x/ME/NT4/2K/XP/2K3) port of *unzip* gets the timezone configuration from the registry, assuming it is correctly set in the Control Panel. The TZ variable is ignored for this port.

DECRIPTION

Encrypted archives are fully supported by Info-ZIP software, but due to United States export restrictions, de-/encryption support might be disabled in your compiled binary. However, since spring 2000, US export restrictions have been liberated, and our source archives do now include full crypt code. In case you need binary distributions with crypt support enabled, see the file "WHERE" in any Info-ZIP source or binary distribution for locations both inside and outside the US.

Some compiled versions of *unzip* may not support decryption. To check a version for crypt support, either attempt to test or extract an encrypted archive, or else check *unzip*'s diagnostic screen (see the **-v** option above) for "[decryption]" as one of the special compilation options.

As noted above, the **-P** option may be used to supply a password on the command line, but at a cost in security. The preferred decryption method is simply to extract normally; if a zipfile member is encrypted, *unzip* will prompt for the password without echoing what is typed. *unzip* continues to use the same password as long as it appears to be valid, by testing a 12-byte header on each file. The correct password will always check out against the header, but there is a 1-in-256 chance that an incorrect password will as well. (This is a security feature of the PKWARE zipfile format; it helps prevent brute-force attacks that might otherwise gain a large speed advantage by testing only the header.) In the case that an incorrect password is given but it passes the header test anyway, either an incorrect CRC will be generated for the extracted data or else *unzip* will fail during the extraction because the "decrypted" bytes do not constitute a valid compressed data stream.

If the first password fails the header check on some file, *unzip* will prompt for another password, and so on until all files are extracted. If a password is not known, entering a null password (that is, just a carriage return or "Enter") is taken as a signal to skip all further prompting. Only unencrypted files in the archive(s) will thereafter be extracted. (In fact, that's not quite true; older versions of *zip(1)* and *zipcloak(1)* allowed null passwords, so *unzip* checks each encrypted file to see if the null password works. This may result in "false positives" and extraction errors, as noted above.)

Archives encrypted with 8-bit passwords (for example, passwords with accented European characters) may not be portable across systems and/or other archivers. This problem stems from the use of multiple encoding methods for such characters, including Latin-1 (ISO 8859-1) and OEM code page 850. DOS *PKZIP* 2.04g uses the OEM code page; Windows *PKZIP* 2.50 uses Latin-1 (and is therefore incompatible with DOS *PKZIP*); Info-ZIP uses the OEM code page on DOS, OS/2 and Win3.x ports but ISO coding (Latin-1 etc.) everywhere else; and Nico Mak's *WinZip* 6.x does not allow 8-bit passwords at all. *UnZip* 5.3 (or newer) attempts to use the default character set first (e.g., Latin-1), followed by the alternate one (e.g., OEM code page) to test passwords. On EBCDIC systems, if both of these fail, EBCDIC encoding will be tested as a last resort. (EBCDIC is not tested on non-EBCDIC systems, because there are no known archivers that encrypt using EBCDIC encoding.) ISO character encodings other than Latin-1 are not supported. The new addition of (partially) Unicode (resp. UTF-8) support in *UnZip* 6.0 has not yet been adapted to the encryption password handling in *unzip*. On systems that use UTF-8 as native character encoding, *unzip* simply tries decryption with the native UTF-8 encoded password; the built-in attempts to check the password in translated encoding have not yet been adapted for UTF-8 support and will consequently fail.

EXAMPLES

To use *unzip* to extract all members of the archive *letters.zip* into the current directory and subdirectories below it, creating any subdirectories as necessary:

```
unzip letters
```

To extract all members of *letters.zip* into the current directory only:

```
unzip -j letters
```

To test *letters.zip*, printing only a summary message indicating whether the archive is OK or not:

```
unzip -tq letters
```

To test *all* zipfiles in the current directory, printing only the summaries:

```
unzip -tq \*.zip
```

(The backslash before the asterisk is only required if the shell expands wildcards, as in Unix; double quotes could have been used instead, as in the source examples below.) To extract to standard output all members of *letters.zip* whose names end in *.tex*, auto-converting to the local end-of-line convention and piping the output into *more(1)*:

```
unzip -ca letters \*.tex | more
```

To extract the binary file *paper1.dvi* to standard output and pipe it to a printing program:

```
unzip -p articles paper1.dvi | dvips
```

To extract all FORTRAN and C source files--*.f, *.c, *.h, and Makefile--into the /tmp directory:

```
unzip source.zip ".*.[fch]" Makefile -d /tmp
```

(the double quotes are necessary only in Unix and only if globbing is turned on). To extract all FORTRAN and C source files, regardless of case (e.g., both *.c and *.C, and any makefile, Makefile, MAKEFILE or similar):

```
unzip -C source.zip ".*.[fch]" makefile -d /tmp
```

To extract any such files but convert any uppercase MS-DOS or VMS names to lowercase and convert the line-endings of all of the files to the local standard (without respect to any files that might be marked “binary”):

```
unzip -aaCL source.zip ".*.[fch]" makefile -d /tmp
```

To extract only newer versions of the files already in the current directory, without querying (NOTE: be careful of unzipping in one timezone a zipfile created in another--ZIP archives other than those created by Zip 2.1 or later contain no timezone information, and a “newer” file from an eastern timezone may, in fact, be older):

```
unzip -fo sources
```

To extract newer versions of the files already in the current directory and to create any files not already there (same caveat as previous example):

```
unzip -uo sources
```

To display a diagnostic screen showing which *unzip* and *zipinfo* options are stored in environment variables, whether decryption support was compiled in, the compiler with which *unzip* was compiled, etc.:

```
unzip -v
```

In the last five examples, assume that UNZIP or UNZIP_OPTS is set to -q. To do a singly quiet listing:

```
unzip -l file.zip
```

To do a doubly quiet listing:

```
unzip -ql file.zip
```

(Note that the “.zip” is generally not necessary.) To do a standard listing:

```
unzip --ql file.zip
```

or

```
unzip -l-q file.zip
```

or

```
unzip -l--q file.zip
```

(Extra minuses in options don’t hurt.)

TIPS

The current maintainer, being a lazy sort, finds it very useful to define a pair of aliases: *tt* for ‘‘*unzip -tq*’’ and *ii* for ‘‘*unzip -Z*’’ (or ‘‘*zipinfo*’’). One may then simply type ‘‘*tt zipfile*’’ to test an archive, something that is worth making a habit of doing. With luck *unzip* will report ‘‘No errors detected in compressed data of *zipfile.zip*,’’ after which one may breathe a sigh of relief.

The maintainer also finds it useful to set the UNZIP environment variable to “-aL” and is tempted to add

“-C” as well. His ZIPINFO variable is set to “-z”.

DIAGNOSTICS

The exit status (or error level) approximates the exit codes defined by PKWARE and takes on the following values, except under VMS:

- 0 normal; no errors or warnings detected.
- 1 one or more warning errors were encountered, but processing completed successfully anyway. This includes zipfiles where one or more files was skipped due to unsupported compression method or encryption with an unknown password.
- 2 a generic error in the zipfile format was detected. Processing may have completed successfully anyway; some broken zipfiles created by other archivers have simple workarounds.
- 3 a severe error in the zipfile format was detected. Processing probably failed immediately.
- 4 *unzip* was unable to allocate memory for one or more buffers during program initialization.
- 5 *unzip* was unable to allocate memory or unable to obtain a tty to read the decryption password(s).
- 6 *unzip* was unable to allocate memory during decompression to disk.
- 7 *unzip* was unable to allocate memory during in-memory decompression.
- 8 [currently not used]
- 9 the specified zipfiles were not found.
- 10 invalid options were specified on the command line.
- 11 no matching files were found.
- 50 the disk is (or was) full during extraction.
- 51 the end of the ZIP archive was encountered prematurely.
- 80 the user aborted *unzip* prematurely with control-C (or similar)
- 81 testing or extraction of one or more files failed due to unsupported compression methods or unsupported decryption.
- 82 no files were found due to bad decryption password(s). (If even one file is successfully processed, however, the exit status is 1.)

VMS interprets standard Unix (or PC) return values as other, scarier-looking things, so *unzip* instead maps them into VMS-style status codes. The current mapping is as follows: 1 (success) for normal exit, 0x7fff0001 for warning errors, and (0x7fff000? + 16*normal_unzip_exit_status) for all other errors, where the ‘?’ is 2 (error) for *unzip* values 2, 9-11 and 80-82, and 4 (fatal error) for the remaining ones (3-8, 50, 51). In addition, there is a compilation option to expand upon this behavior: defining RETURN_CODES results in a human-readable explanation of what the error status means.

BUGS

Multi-part archives are not yet supported, except in conjunction with *zip*. (All parts must be concatenated together in order, and then “*zip -F*” (for *zip 2.x*) or “*zip -FF*” (for *zip 3.x*) must be performed on the concatenated archive in order to “fix” it. Also, *zip 3.0* and later can combine multi-part (split) archives into a combined single-file archive using “*zip -s- inarchive -O outarchive*”. See the *zip 3* manual page for more information.) This will definitely be corrected in the next major release.

Archives read from standard input are not yet supported, except with *funzip* (and then only the first member of the archive can be extracted).

Archives encrypted with 8-bit passwords (e.g., passwords with accented European characters) may not be portable across systems and/or other archivers. See the discussion in **DECRYPTION** above.

unzip's **-M** ("more") option tries to take into account automatic wrapping of long lines. However, the code may fail to detect the correct wrapping locations. First, TAB characters (and similar control sequences) are not taken into account, they are handled as ordinary printable characters. Second, depending on the actual system / OS port, *unzip* may not detect the true screen geometry but rather rely on "commonly used" default dimensions. The correct handling of tabs would require the implementation of a query for the actual tabulator setup on the output console.

Dates, times and permissions of stored directories are not restored except under Unix. (On Windows NT and successors, timestamps are now restored.)

[MS-DOS] When extracting or testing files from an archive on a defective floppy diskette, if the "Fail" option is chosen from DOS's "Abort, Retry, Fail?" message, older versions of *unzip* may hang the system, requiring a reboot. This problem appears to be fixed, but control-C (or control-Break) can still be used to terminate *unzip*.

Under DEC Ultrix, *unzip* would sometimes fail on long zipfile (bad CRC, not always reproducible). This was apparently due either to a hardware bug (cache memory) or an operating system bug (improper handling of page faults?). Since Ultrix has been abandoned in favor of Digital Unix (OSF/1), this may not be an issue anymore.

[Unix] Unix special files such as FIFO buffers (named pipes), block devices and character devices are not restored even if they are somehow represented in the zipfile, nor are hard-linked files relinked. Basically the only file types restored by *unzip* are regular files, directories and symbolic (soft) links.

[OS/2] Extended attributes for existing directories are only updated if the **-o** ("overwrite all") option is given. This is a limitation of the operating system; because directories only have a creation time associated with them, *unzip* has no way to determine whether the stored attributes are newer or older than those on disk. In practice this may mean a two-pass approach is required: first unpack the archive normally (with or without freshening/updating existing files), then overwrite just the directory entries (e.g., "*unzip -o foo */*").

[VMS] When extracting to another directory, only the *[foo]* syntax is accepted for the **-d** option; the simple Unix *foo* syntax is silently ignored (as is the less common VMS *foo.dir* syntax).

[VMS] When the file being extracted already exists, *unzip*'s query only allows skipping, overwriting or renaming; there should additionally be a choice for creating a new version of the file. In fact, the "overwrite" choice does create a new version; the old version is not overwritten or deleted.

AUTHORS

The primary Info-ZIP authors (current semi-active members of the Zip-Bugs workgroup) are: Ed Gordon (Zip, general maintenance, shared code, Zip64, Win32, Unix, Unicode); Christian Spieler (UnZip maintenance coordination, VMS, MS-DOS, Win32, shared code, general Zip and UnZip integration and optimization); Onno van der Linden (Zip); Mike White (Win32, Windows GUI, Windows DLLs); Kai Uwe Rommel (OS/2, Win32); Steven M. Schweda (VMS, Unix, support of new features); Paul Kienitz (Amiga, Win32, Unicode); Chris Herborth (BeOS, QNX, Atari); Jonathan Hudson (SMS/QDOS); Sergio Monesi (Acorn RISC OS); Harald Denker (Atari, MVS); John Bush (Solaris, Amiga); Hunter Goatley (VMS, Info-ZIP Site maintenance); Steve Salisbury (Win32); Steve Miller (Windows CE GUI), Johnny Lee (MS-DOS, Win32, Zip64); and Dave Smith (Tandem NSK).

The following people were former members of the Info-ZIP development group and provided major contributions to key parts of the current code: Greg "Cave Newt" Roelofs (UnZip, unshrink decompression); Jean-loup Gailly (deflate compression); Mark Adler (inflate decompression, fUnZip).

The author of the original unzip code upon which Info-ZIP's was based is Samuel H. Smith; Carl Mascott did the first Unix port; and David P. Kirschbaum organized and led Info-ZIP in its early days with Keith Petersen hosting the original mailing list at WSMR-SimTel20. The full list of contributors to UnZip has grown quite large; please refer to the CONTRIBS file in the UnZip source distribution for a relatively complete version.

NAME

unzipsfx – self-extracting stub for prepending to ZIP archives

SYNOPSIS

<name of unzipsfx+archive combo> [**-cfptuz[ajnoqsCLV\$]**] [*file(s)* ... [**-x xfile(s)** ...]]

DESCRIPTION

unzipsfx is a modified version of *unzip(1)* designed to be prepended to existing ZIP archives in order to form self-extracting archives. Instead of taking its first non-flag argument to be the zipfile(s) to be extracted, *unzipsfx* seeks itself under the name by which it was invoked and tests or extracts the contents of the appended archive. Because the executable stub adds bulk to the archive (the whole purpose of which is to be as small as possible), a number of the less-vital capabilities in regular *unzip* have been removed. Among these are the usage (or help) screen, the listing and diagnostic functions (**-l** and **-v**), the ability to decompress older compression formats (the “reduce,” “shrink” and “implode” methods). The ability to extract to a directory other than the current one can be selected as a compile-time option, which is now enabled by default since UnZipSFX version 5.5. Similarly, decryption is supported as a compile-time option but should be avoided unless the attached archive contains encrypted files. Starting with release 5.5, another compile-time option adds a simple “run command after extraction” feature. This feature is currently incompatible with the “extract to different directory” feature and remains disabled by default.

Note that self-extracting archives made with unzipsfx are no more (or less) portable across different operating systems than is the unzip executable itself. In general a self-extracting archive made on a particular Unix system, for example, will only self-extract under the same flavor of Unix. Regular *unzip* may still be used to extract the embedded archive as with any normal zipfile, although it will generate a harmless warning about extra bytes at the beginning of the zipfile. *Despite this*, however, the self-extracting archive is technically *not* a valid ZIP archive, and PKUNZIP may be unable to test or extract it. This limitation is due to the simplistic manner in which the archive is created; the internal directory structure is not updated to reflect the extra bytes prepended to the original zipfile.

ARGUMENTS

[*file(s)*] An optional list of archive members to be processed. Regular expressions (wildcards) similar to those in Unix *egrep(1)* may be used to match multiple members. These wildcards may contain:

- * matches a sequence of 0 or more characters
- ? matches exactly 1 character
- [...] matches any single character found inside the brackets; ranges are specified by a beginning character, a hyphen, and an ending character. If an exclamation point or a caret ('!' or '^') follows the left bracket, then the range of characters within the brackets is complemented (that is, anything *except* the characters inside the brackets is considered a match).

(Be sure to quote any character that might otherwise be interpreted or modified by the operating system, particularly under Unix and VMS.)

[**-x xfile(s)**]

An optional list of archive members to be excluded from processing. Since wildcard characters match directory separators ('/'), this option may be used to exclude any files that are in subdirectories. For example, “*foosfx *.[ch] -x */**” would extract all C source files in the main directory, but none in any subdirectories. Without the **-x** option, all C source files in all directories within the zipfile would be extracted.

If *unzipsfx* is compiled with SFX_EXDIR defined, the following option is also enabled:

[**-d exdir**]

An optional directory to which to extract files. By default, all files and subdirectories are recreated in the current directory; the **-d** option allows extraction in an arbitrary directory (always assuming one has permission to write to the directory). The option and directory may be concatenated without any white space between them, but note that this may cause normal shell behavior to be suppressed. In particular, “**-d ~**” (tilde) is expanded by Unix C shells into the name of the user’s home directory, but “**-d ~**” is treated as a literal subdirectory “**~**” of the current directory.

OPTIONS

unzipsfx supports the following *unzip(1)* options: **-c** and **-p** (e xtract to standard output/screen), **-f** and **-u** (freshen and update existing files upon extraction), **-t** (test archive) and **-z** (print archive comment). All normal listing options (**-l**, **-v** and **-Z**) have been removed, but the testing option (**-t**) may be used as a “poor man’s” listing. Alternatively, those creating self-extracting archives may wish to include a short listing in the zipfile comment.

See *unzip(1)* for a more complete description of these options.

MODIFIERS

unzipsfx currently supports all *unzip(1)* modifiers: **-a** (con vert text files), **-n** (never overwrite), **-o** (over-write without prompting), **-q** (operate quietly), **-C** (match names case-insensitively), **-L** (convert uppercase-OS names to lowercase), **-j** (junk paths) and **-V** (retain version numbers); plus the following operating-system specific options: **-X** (restore VMS o wner/protection info), **-s** (convert spaces in filenames to underscores [DOS, OS/2, NT]) and **-\$** (restore volume label [DOS, OS/2, NT, Amiga]).

(Support for regular ASCII text-conversion may be removed in future versions, since it is simple enough for the archive’s creator to ensure that text files have the appropriate format for the local OS. EBCDIC conversion will of course continue to be supported since the zipfile format implies ASCII storage of text files.)

See *unzip(1)* for a more complete description of these modifiers.

ENVIRONMENT OPTIONS

unzipsfx uses the same environment variables as *unzip(1)* does, although this is likely to be an issue only for the person creating and testing the self-extracting archive. See *unzip(1)* for details.

DECRYPTION

Decryption is supported exactly as in *unzip(1)*; that is, interactively with a non-echoing prompt for the password(s). See *unzip(1)* for details. Once again, note that if the archive has no encrypted files there is no reason to use a version of *unzipsfx* with decryption support; that only adds to the size of the archive.

AUTORUN COMMAND

When *unzipsfx* was compiled with **CHEAP_SFX_AUTORUN** defined, a simple “command autorun” feature is supported. You may enter a command into the Zip archive comment, using the following format:

```
$AUTORUN$> [ command line string ]
```

When *unzipsfx* recognizes the “\$AUTORUN\$>” token at the beginning of the Zip archive comment, the remainder of the first line of the comment (until the first newline character) is passed as a shell command to the operating system using the C rtl “system” function. Before executing the command, *unzipsfx* displays the command on the console and prompts the user for confirmation. When the user has switched off prompting by specifying the **-q** option, autorun commands are never executed.

In case the archive comment contains additional lines of text, the remainder of the archive comment following the first line is displayed normally, unless quiet operation was requested by supplying a **-q** option.

EXAMPLES

To create a self-extracting archive *letters* from a regular zipfile *letters.zip* and change the new archive’s permissions to be world-executable under Unix:

```
cat unzipsfx letters.zip > letters
chmod 755 letters
zip -A letters
```

To create the same archive under MS-DOS, OS/2 or NT (note the use of the **/b** [binary] option to the *copy* command):

```
copy /b unzipsfx.exe+letters.zip letters.exe
zip -A letters.exe
```

Under VMS:

```
copy unzipsfx.exe,letters.zip letters.exe
letters == "$currentdisk:[currentdir]letters.exe"
```

```
zip -A letters.exe
```

(The VMS *append* command may also be used. The second command installs the new program as a “foreign command” capable of taking arguments. The third line assumes that Zip is already installed as a foreign command.) Under AmigaDOS:

```
MakeSFX letters letters.zip UnZipSFX
```

(MakeSFX is included with the UnZip source distribution and with Amiga binary distributions. “zip -A” doesn’t work on Amiga self-extracting archives.) To test (or list) the newly created self-extracting archive:

```
letters -t
```

To test *letters* quietly, printing only a summary message indicating whether the archive is OK or not:

```
letters -tqq
```

To extract the complete contents into the current directory, recreating all files and subdirectories as necessary:

```
letters
```

To extract all *.txt files (in Unix quote the ‘*’):

```
letters *.txt
```

To extract everything *except* the *.txt files:

```
letters -x *.txt
```

To extract only the README file to standard output (the screen):

```
letters -c README
```

To print only the zipfile comment:

```
letters -z
```

LIMITATIONS

The principle and fundamental limitation of *unzipsfx* is that it is not portable across architectures or operating systems, and therefore neither are the resulting archives. For some architectures there is limited portability, however (e.g., between some flavors of Intel-based Unix).

Another problem with the current implementation is that any archive with “junk” prepended to the beginning technically is no longer a zipfile (unless *zip(1)* is used to adjust the zipfile offsets appropriately, as noted above). *unzip(1)* takes note of the prepended bytes and ignores them since some file-transfer protocols, notably MacBinary, are also known to prepend junk. But PKWARE’s archiver suite may not be able to deal with the modified archive unless its offsets have been adjusted.

unzipsfx has no knowledge of the user’s PATH, so in general an archive must either be in the current directory when it is invoked, or else a full or relative path must be given. If a user attempts to extract the archive from a directory in the PATH other than the current one, *unzipsfx* will print a warning to the effect, “can’t find myself.” This is always true under Unix and may be true in some cases under MS-DOS, depending on the compiler used (Microsoft C fully qualifies the program name, but other compilers may not). Under OS/2 and NT there are operating-system calls available that provide the full path name, so the archive may be invoked from anywhere in the user’s path. The situation is not known for AmigaDOS, Atari TOS, MacOS, etc.

As noted above, a number of the normal *unzip(1)* functions have been removed in order to make *unzipsfx* smaller: usage and diagnostic info, listing functions and extraction to other directories. Also, only stored and deflated files are supported. The latter limitation is mainly relevant to those who create SFX archives, however.

VMS users must know how to set up self-extracting archives as foreign commands in order to use any of *unzipsfx*’s options. This is not necessary for simple extraction, but the command to do so then becomes, e.g., “run *letters*” (to continue the examples given above).

unzipsfx on the Amiga requires the use of a special program, MakeSFX, in order to create working self-extracting archives; simple concatenation does not work. (For technically oriented users, the attached archive is defined as a “debug hunk.”) There may be compatibility problems between the ROM levels of older Amigas and newer ones.

All current bugs in *unzip(1)* exist in *unzipsfx* as well.

DIAGNOSTICS

unzipsfx’s exit status (error level) is identical to that of *unzip(1)*; see the corresponding man page.

NAME

update-grub, **update-grub2** – stub for grub-mkconfig

SYNOPSIS

update-grub

DESCRIPTION

update-grub is a stub for running **grub-mkconfig -o /boot/grub/grub.cfg** to generate a grub2 config file.

SEE ALSO

grub-mkconfig(8)

NAME

update-grub, **update-grub2** – stub for grub-mkconfig

SYNOPSIS

update-grub

DESCRIPTION

update-grub is a stub for running **grub-mkconfig -o /boot/grub/grub.cfg** to generate a grub2 config file.

SEE ALSO

grub-mkconfig(8)

NAME

updatedb – update a database for plocate

SYNOPSIS

updatedb [*OPTION*]...

DESCRIPTION

updatedb creates or updates a database used by **locate(1)**. If the database already exists, its data is reused to avoid rereading directories that have not changed.

updatedb is usually run daily from a **systemd.timer(8)** to update the default database.

EXIT STATUS

updatedb returns with exit status 0 on success, 1 on error.

OPTIONS

The **PRUNE_BIND_MOUNTS**, **PRUNEFS**, **PRUNENAMES** and **PRUNEPATHS** variables, which are modified by some of the options, are documented in detail in **updatedb.conf(5)**.

-f, --add-prunefs *FS*

Add entries in white-space-separated list *FS* to **PRUNEFS**.

-n, --add-prunenames *NAMES*

Add entries in white-space-separated list *NAMES* to **PRUNENAMES**.

-e, --add-prunepaths *PATHS*

Add entries in white-space-separated list *PATHS* to **PRUNEPATHS**.

-e, --add-single-prunepath *PATH*

Add *PATH* to **PRUNEPATHS**. Note that this is currently the only way to add a path with a space in it.

-U, --database-root *PATH*

Store only results of scanning the file system subtree rooted at *PATH* to the generated database. The whole file system is scanned by default.

locate(1) outputs entries as absolute path names which don't contain symbolic links, regardless of the form of *PATH*.

--debug-pruning

Write debugging information about pruning decisions to standard error output.

-h, --help

Write a summary of the available options to standard output and exit successfully.

-o, --output *FILE*

Write the database to *FILE* instead of using the default database.

--prune-bind-mounts *FLAG*

Set **PRUNE_BIND_MOUNTS** to *FLAG*, overriding the configuration file.

--prunefs *FS*

Set **PRUNEFS** to *FS*, overriding the configuration file.

--prunenames *NAMES*

Set **PRUNENAMES** to *NAMES*, overriding the configuration file.

--prunepaths *PATHS*

Set **PRUNEPATHS** to *PATHS*, overriding the configuration file.

-l, --require-visibility *FLAG*

Set the "require file visibility before reporting it" flag in the generated database to *FLAG*.

If *FLAG* is **0** or **no**, or if the database file is readable by "others" or it is not owned by **plocate**, **locate**(1) outputs the database entries even if the user running **located**(1) could not have read the directory necessary to find out the file described by the database entry.

If *FLAG* is **1** or **yes** (the default), **locate**(1) checks the permissions of parent directories of each entry before reporting it to the invoking user. To make the file existence truly hidden from other users, the database group is set to **plocate** and the database permissions prohibit reading the database by users using other means than **locate**(1), which is set-gid **plocate**.

Note that the visibility flag is checked only if the database is owned by **plocate** and it is not readable by "others".

-v, --verbose

Output path names of files to standard output, as soon as they are found.

-V, --version

Write information about the version and license of **locate** on standard output and exit successfully.

EXAMPLES

To create a private plocate database as a user other than **root**, run

updatedb -l 0 -o db_file -U source_directory

Note that all users that can read *db_file* can get the complete list of files in the subtree of *source_directory*.

FILES

/etc/updatedb.conf

A configuration file. See **updatedb.conf**(5). Uses exactly the same format as the one used by **mlocate**(1)'s updatedb, so they can be shared.

/var/lib/plocate/plocate.db

The database updated by default.

SECURITY

Databases built with **--require-visibility no** allow users to find names of files and directories of other users, which they would not otherwise be able to do.

NAME

uptime – Tell how long the system has been running.

SYNOPSIS

uptime [*options*]

DESCRIPTION

uptime gives a one line display of the following information. The current time, how long the system has been running, how many users are currently logged on, and the system load averages for the past 1, 5, and 15 minutes.

This is the same information contained in the header line displayed by **w(1)**.

System load averages is the average number of processes that are either in a runnable or uninterruptable state. A process in a runnable state is either using the CPU or waiting to use the CPU. A process in uninterruptable state is waiting for some I/O access, eg waiting for disk. The averages are taken over the three time intervals. Load averages are not normalized for the number of CPUs in a system, so a load average of 1 means a single CPU system is loaded all the time while on a 4 CPU system it means it was idle 75% of the time.

OPTIONS

-p, --pretty

show uptime in pretty format

-h, --help

display this help text

-s, --since

system up since, in yyyy-mm-dd HH:MM:SS format

-V, --version

display version information and exit

FILES

/var/run/utmp

information about who is currently logged on

/proc process information

AUTHORS

uptime was written by Larry Greenfield <greenfie@gauss.rutgers.edu> and Michael K. Johnson <johnsonm@sunsite.unc.edu>

REPORTING BUGS

Please send bug reports to <procps@freelists.org>

NAME

useradd – create a new user or update default new user information

SYNOPSIS

useradd [*options*] *LOGIN*

useradd –D

useradd –D [*options*]

DESCRIPTION

useradd is a low level utility for adding users. On Debian, administrators should usually use **adduser(8)** instead.

When invoked without the **–D** option, the **useradd** command creates a new user account using the values specified on the command line plus the default values from the system. Depending on command line options, the **useradd** command will update system files and may also create the new user's home directory and copy initial files.

By default, a group will also be created for the new user (see **–g**, **–N**, **–U**, and **USERGROUPS_ENAB**).

OPTIONS

The options which apply to the **useradd** command are:

--badname

Allow names that do not conform to standards.

–b, --base-dir *BASE_DIR*

The default base directory for the system if **–d HOME_DIR** is not specified. *BASE_DIR* is concatenated with the account name to define the home directory. If the **–m** option is not used, *BASE_DIR* must exist.

If this option is not specified, **useradd** will use the base directory specified by the **HOME** variable in /etc/default/useradd, or /home by default.

–c, --comment *COMMENT*

Any text string. It is generally a short description of the login, and is currently used as the field for the user's full name.

–d, --home-dir *HOME_DIR*

The new user will be created using *HOME_DIR* as the value for the user's login directory. The default is to append the *LOGIN* name to *BASE_DIR* and use that as the login directory name. The directory *HOME_DIR* does not have to exist but will not be created if it is missing.

–D, --defaults

See below, the subsection "Changing the default values".

–e, --expiredate *EXPIRE_DATE*

The date on which the user account will be disabled. The date is specified in the format *YYYY-MM-DD*.

If not specified, **useradd** will use the default expiry date specified by the **EXPIRE** variable in /etc/default/useradd, or an empty string (no expiry) by default.

–f, --inactive *INACTIVE*

The number of days after a password expires until the account is permanently disabled. A value of 0 disables the account as soon as the password has expired, and a value of –1 disables the feature.

If not specified, **useradd** will use the default inactivity period specified by the **INACTIVE** variable in /etc/default/useradd, or –1 by default.

–g, --gid *GROUP*

The group name or number of the user's initial login group. The group name must exist. A group

number must refer to an already existing group.

If not specified, the behavior of **useradd** will depend on the **USERGROUPS_ENAB** variable in /etc/login.defs. If this variable is set to *yes* (or **-U**/**--user-group** is specified on the command line), a group will be created for the user, with the same name as her loginname. If the variable is set to *no* (or **-N**/**--no-user-group** is specified on the command line), useradd will set the primary group of the new user to the value specified by the **GROUP** variable in /etc/default/useradd, or 100 by default.

-G, --groups GROUP1[,GROUP2,...,[GROUPN]]

A list of supplementary groups which the user is also a member of. Each group is separated from the next by a comma, with no intervening whitespace. The groups are subject to the same restrictions as the group given with the **-g** option. The default is for the user to belong only to the initial group.

-h, --help

Display help message and exit.

-k, --skel SKEL_DIR

The skeleton directory, which contains files and directories to be copied in the user's home directory, when the home directory is created by **useradd**.

This option is only valid if the **-m** (or **--create-home**) option is specified.

If this option is not set, the skeleton directory is defined by the **SKEL** variable in /etc/default/useradd or, by default, /etc/skel.

If possible, the ACLs and extended attributes are copied.

-K, --key KEY=VALUE

Overrides /etc/login.defs defaults (**UID_MIN**, **UID_MAX**, **UMASK**, **PASS_MAX_DAYS** and others).

Example: **-K PASS_MAX_DAYS=-1** can be used when creating system account to turn off password aging, even though system account has no password at all. Multiple **-K** options can be specified, e.g.:
-K UID_MIN=100 -K UID_MAX=499

-l, --no-log-init

Do not add the user to the lastlog and faillog databases.

By default, the user's entries in the lastlog and faillog databases are reset to avoid reusing the entry from a previously deleted user.

For the compatibility with previous Debian's **useradd**, the **-O** option is also supported.

-m, --create-home

Create the user's home directory if it does not exist. The files and directories contained in the skeleton directory (which can be defined with the **-k** option) will be copied to the home directory.

By default, if this option is not specified and **CREATE_HOME** is not enabled, no home directories are created.

-M, --no-create-home

Do not create the user's home directory, even if the system wide setting from /etc/login.defs (**CREATE_HOME**) is set to *yes*.

-N, --no-user-group

Do not create a group with the same name as the user, but add the user to the group specified by the **-g** option or by the **GROUP** variable in /etc/default/useradd.

The default behavior (if the **-g**, **-N**, and **-U** options are not specified) is defined by the

USERGROUPS_ENAB variable in /etc/login.defs.

-o, --non-unique

Allow the creation of a user account with a duplicate (non-unique) UID.

This option is only valid in combination with the **-u** option.

-p, --password *PASSWORD*

The encrypted password, as returned by **crypt(3)**. The default is to disable the password.

Note: This option is not recommended because the password (or encrypted password) will be visible by users listing the processes.

You should make sure the password respects the system's password policy.

-r, --system

Create a system account.

System users will be created with no aging information in /etc/shadow, and their numeric identifiers are chosen in the **SYS_UID_MIN**–**SYS_UID_MAX** range, defined in /etc/login.defs, instead of **UID_MIN**–**UID_MAX** (and their **GID** counterparts for the creation of groups).

Note that **useradd** will not create a home directory for such a user, regardless of the default setting in /etc/login.defs (**CREATE_HOME**). You have to specify the **-m** options if you want a home directory for a system account to be created.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-P, --prefix *PREFIX_DIR*

Apply changes in the *PREFIX_DIR* directory and use the configuration files from the *PREFIX_DIR* directory. This option does not chroot and is intended for preparing a cross-compilation target. Some limitations: NIS and LDAP users/groups are not verified. PAM authentication is using the host files. No SELINUX support.

-s, --shell *SHELL*

The name of the user's login shell. The default is to leave this field blank, which causes the system to select the default login shell specified by the **SHELL** variable in /etc/default/useradd, or an empty string by default.

-u, --uid *UID*

The numerical value of the user's ID. This value must be unique, unless the **-o** option is used. The value must be non-negative. The default is to use the smallest ID value greater than or equal to **UID_MIN** and greater than every other user.

See also the **-r** option and the **UID_MAX** description.

-U, --user-group

Create a group with the same name as the user, and add the user to this group.

The default behavior (if the **-g**, **-N**, and **-U** options are not specified) is defined by the **USERGROUPS_ENAB** variable in /etc/login.defs.

-Z, --selinux-user *SEUSER*

The SELinux user for the user's login. The default is to leave this field blank, which causes the system to select the default SELinux user.

Changing the default values

When invoked with only the **-D** option, **useradd** will display the current default values. When invoked with **-D** plus other options, **useradd** will update the default values for the specified options. Valid default-changing options are:

-b, --base-dir *BASE_DIR*

The path prefix for a new user's home directory. The user's name will be affixed to the end of *BASE_DIR* to form the new user's home directory name, if the **-d** option is not used when creating a new account.

This option sets the **HOME** variable in /etc/default/useradd.

-e, --expiredate *EXPIRE_DATE*

The date on which the user account is disabled.

This option sets the **EXPIRE** variable in /etc/default/useradd.

-f, --inactive *INACTIVE*

The number of days after a password has expired before the account will be disabled.

This option sets the **INACTIVE** variable in /etc/default/useradd.

-g, --gid *GROUP*

The group name or ID for a new user's initial group (when the **-N**/**--no-user-group** is used or when the **USERGROUPS_ENAB** variable is set to *no* in /etc/login.defs). The named group must exist, and a numerical group ID must have an existing entry.

This option sets the **GROUP** variable in /etc/default/useradd.

-s, --shell *SHELL*

The name of a new user's login shell.

This option sets the **SHELL** variable in /etc/default/useradd.

NOTES

The system administrator is responsible for placing the default user files in the /etc/skel/ directory (or any other skeleton directory specified in /etc/default/useradd or on the command line).

CAVEATS

You may not add a user to a NIS or LDAP group. This must be performed on the corresponding server.

Similarly, if the username already exists in an external user database such as NIS or LDAP, **useradd** will deny the user account creation request.

It is usually recommended to only use usernames that begin with a lower case letter or an underscore, followed by lower case letters, digits, underscores, or dashes. They can end with a dollar sign. In regular expression terms: [a-z_][a-z0-9_-]*[\$]?

On Debian, the only constraints are that usernames must neither start with a dash ('-') nor plus ('+') nor tilde ('~') nor contain a colon (':'), a comma (','), or a whitespace (space: ' ', end of line: '\n', tabulation: '\t', etc.). Note that using a slash ('/') may break the default algorithm for the definition of the user's home directory.

On Ubuntu, the same constraints as Debian are in place, with the additional constraint that the username cannot be fully numeric. This includes octal and hexadecimal syntax.

Usernames may only be up to 32 characters long.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

CREATE_HOME (boolean)

Indicate if a home directory should be created by default for new users.

This setting does not apply to system users, and can be overridden on the command line.

GID_MAX (number), **GID_MIN** (number)

Range of group IDs used for the creation of regular groups by **useradd**, **groupadd**, or **newusers**.

The default value for **GID_MIN** (resp. **GID_MAX**) is 1000 (resp. 60000).

HOME_MODE (number)

The mode for new home directories. If not specified, the **UMASK** is used to create the mode.

useradd and **newusers** use this to set the mode of the home directory they create.

LASTLOG_UID_MAX (number)

Highest user ID number for which the lastlog entries should be updated. As higher user IDs are usually tracked by remote user identity and authentication services there is no need to create a huge sparse lastlog file for them.

No **LASTLOG_UID_MAX** option present in the configuration means that there is no user ID limit for writing lastlog entries.

MAIL_DIR (string)

The mail spool directory. This is needed to manipulate the mailbox when its corresponding user account is modified or deleted. If not specified, a compile-time default is used.

MAIL_FILE (string)

Defines the location of the users mail spool files relatively to their home directory.

The **MAIL_DIR** and **MAIL_FILE** variables are used by **useradd**, **usermod**, and **userdel** to create, move, or delete the user's mail spool.

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

PASS_MAX_DAYS (number)

The maximum number of days a password may be used. If the password is older than this, a password change will be forced. If not specified, -1 will be assumed (which disables the restriction).

PASS_MIN_DAYS (number)

The minimum number of days allowed between password changes. Any password changes attempted sooner than this will be rejected. If not specified, -1 will be assumed (which disables the restriction).

PASS_WARN_AGE (number)

The number of days warning given before a password expires. A zero means warning is given only upon the day of expiration, a negative value means no warning is given. If not specified, no warning will be provided.

SUB_GID_MIN (number), **SUB_GID_MAX** (number), **SUB_GID_COUNT** (number)

If /etc/subuid exists, the commands **useradd** and **newusers** (unless the user already have subordinate group IDs) allocate **SUB_GID_COUNT** unused group IDs from the range **SUB_GID_MIN** to **SUB_GID_MAX** for each new user.

The default values for **SUB_GID_MIN**, **SUB_GID_MAX**, **SUB_GID_COUNT** are respectively 100000, 600100000 and 65536.

SUB_UID_MIN (number), **SUB_UID_MAX** (number), **SUB_UID_COUNT** (number)

If /etc/subuid exists, the commands **useradd** and **newusers** (unless the user already have subordinate user IDs) allocate **SUB_UID_COUNT** unused user IDs from the range **SUB_UID_MIN** to **SUB_UID_MAX** for each new user.

The default values for **SUB_UID_MIN**, **SUB_UID_MAX**, **SUB_UID_COUNT** are respectively 100000, 600100000 and 65536.

SYS_GID_MAX (number), **SYS_GID_MIN** (number)

Range of group IDs used for the creation of system groups by **useradd**, **groupadd**, or **newusers**.

The default value for **SYS_GID_MIN** (resp. **SYS_GID_MAX**) is 101 (resp. **GID_MIN**-1).

SYS_UID_MAX (number), **SYS_UID_MIN** (number)

Range of user IDs used for the creation of system users by **useradd** or **newusers**.

The default value for **SYS_UID_MIN** (resp. **SYS_UID_MAX**) is 101 (resp. **UID_MIN**-1).

UID_MAX (number), **UID_MIN** (number)

Range of user IDs used for the creation of regular users by **useradd** or **newusers**.

The default value for **UID_MIN** (resp. **UID_MAX**) is 1000 (resp. 60000).

UMASK (number)

The file mode creation mask is initialized to this value. If not specified, the mask will be initialized to 022.

useradd and **newusers** use this mask to set the mode of the home directory they create if **HOME_MODE** is not set.

It is also used by **pam_umask** as the default umask value.

USERGROUPS_ENAB (boolean)

If set to **yes**, **userdel** will remove the user's group if it contains no more members, and **useradd** will create by default a group with the name of the user.

FILES

/etc/passwd

User account information.

/etc/shadow

Secure user account information.

/etc/group

Group account information.

/etc/gshadow

Secure group account information.

/etc/default/useradd

Default values for account creation.

/etc/skel/

Directory containing default files.

/etc/subgid

Per user subordinate group IDs.

/etc/subuid

Per user subordinate user IDs.

/etc/login.defs
Shadow password suite configuration.

EXIT VALUES

The **useradd** command exits with the following values:

- 0* success
- 1* can't update password file
- 2* invalid command syntax
- 3* invalid argument to option
- 4* UID already in use (and no **-o**)
- 6* specified group doesn't exist
- 9* username already in use
- 10* can't update group file
- 12* can't create home directory
- 14* can't update SELinux user mapping

chfn(1), chsh(1), passwd(1), crypt(3), groupadd(8), groupdel(8), groupmod(8), login.defs(5), newusers(8), subgid(5), subuid(5), userdel(8), usermod(8).

NAME

userdel – delete a user account and related files

SYNOPSIS

userdel [options] *LOGIN*

DESCRIPTION

userdel is a low level utility for removing users. On Debian, administrators should usually use **deluser(8)** instead.

The **userdel** command modifies the system account files, deleting all entries that refer to the user name *LOGIN*. The named user must exist.

OPTIONS

The options which apply to the **userdel** command are:

-f, --force

This option forces the removal of the user account, even if the user is still logged in. It also forces **userdel** to remove the user's home directory and mail spool, even if another user uses the same home directory or if the mail spool is not owned by the specified user. If **USERGROUPS_ENAB** is defined to *yes* in /etc/login.defs and if a group exists with the same name as the deleted user, then this group will be removed, even if it is still the primary group of another user.

Note: This option is dangerous and may leave your system in an inconsistent state.

-h, --help

Display help message and exit.

-r, --remove

Files in the user's home directory will be removed along with the home directory itself and the user's mail spool. Files located in other file systems will have to be searched for and deleted manually.

The mail spool is defined by the **MAIL_DIR** variable in the login.defs file.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-P, --prefix *PREFIX_DIR*

Apply changes in the *PREFIX_DIR* directory and use the configuration files from the *PREFIX_DIR* directory. This option does not chroot and is intended for preparing a cross-compilation target. Some limitations: NIS and LDAP users/groups are not verified. PAM authentication is using the host files. No SELINUX support.

-Z, --selinux-user

Remove any SELinux user mapping for the user's login.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

MAIL_DIR (string)

The mail spool directory. This is needed to manipulate the mailbox when its corresponding user account is modified or deleted. If not specified, a compile-time default is used.

MAIL_FILE (string)

Defines the location of the users mail spool files relatively to their home directory.

The **MAIL_DIR** and **MAIL_FILE** variables are used by **useradd**, **usermod**, and **userdel** to create, move, or delete the user's mail spool.

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

USERDEL_CMD (string)

If defined, this command is run when removing a user. It should remove any at/cron/print jobs etc. owned by the user to be removed (passed as the first argument).

The return code of the script is not taken into account.

Here is an example script, which removes the user's cron, at and print jobs:

```
#!/bin/sh

# Check for the required argument.
if [ $# != 1 ]; then
    echo "Usage: $0 username"
    exit 1
fi

# Remove cron jobs.
crontab -r -u $1

# Remove at jobs.
# Note that it will remove any jobs owned by the same UID,
# even if it was shared by a different username.
AT_SPOOL_DIR=/var/spool/cron/atjobs
find $AT_SPOOL_DIR -name "[^.]*" -type f -user $1 -delete \;

# Remove print jobs.
lprm $1

# All done.
exit 0
```

USERGROUPS_ENAB (boolean)

If set to yes, **userdel** will remove the user's group if it contains no more members, and **useradd** will create by default a group with the name of the user.

FILES

/etc/group

Group account information.

/etc/login.defs

Shadow password suite configuration.

/etc/passwd

User account information.

/etc/shadow

Secure user account information.

/etc/subgid

Per user subordinate group IDs.

/etc/subuid

Per user subordinate user IDs.

EXIT VALUES

The **userdel** command exits with the following values:

0

success

1

can't update password file

2

invalid command syntax

6

specified user doesn't exist

8

user currently logged in

10

can't update group file

12

can't remove home directory

CAVEATS

userdel will not allow you to remove an account if there are running processes which belong to this account. In that case, you may have to kill those processes or lock the user's password or account and remove the account later. The **-f** option can force the deletion of this account.

You should manually check all file systems to ensure that no files remain owned by this user.

You may not remove any NIS attributes on a NIS client. This must be performed on the NIS server.

If **USERGROUPS_ENAB** is defined to *yes* in /etc/login.defs, **userdel** will delete the group with the same name as the user. To avoid inconsistencies in the passwd and group databases, **userdel** will check that this group is not used as a primary group for another user, and will just warn without deleting the group otherwise. The **-f** option can force the deletion of this group.

SEE ALSO

chfn(1), **chsh(1)**, **passwd(1)**, **login.defs(5)**, **gpasswd(8)**, **groupadd(8)**, **groupdel(8)**, **groupmod(8)**, **subgid(5)**, **subuid(5)**, **useradd(8)**, **usermod(8)**.

NAME

usermod – modify a user account

SYNOPSIS

usermod [*options*] *LOGIN*

DESCRIPTION

The **usermod** command modifies the system account files to reflect the changes that are specified on the command line.

OPTIONS

The options which apply to the **usermod** command are:

-a, --append

Add the user to the supplementary group(s). Use only with the **-G** option.

-b, --badnames

Allow names that do not conform to standards.

-c, --comment *COMMENT*

The new value of the user's password file comment field. It is normally modified using the **chfn(1)** utility.

-d, --home *HOME_DIR*

The user's new login directory.

If the **-m** option is given, the contents of the current home directory will be moved to the new home directory, which is created if it does not already exist.

-e, --expiredate *EXPIRE_DATE*

The date on which the user account will be disabled. The date is specified in the format *YYYY-MM-DD*.

An empty *EXPIRE_DATE* argument will disable the expiration of the account.

This option requires a /etc/shadow file. A /etc/shadow entry will be created if there were none.

-f, --inactive *INACTIVE*

The number of days after a password expires until the account is permanently disabled.

A value of 0 disables the account as soon as the password has expired, and a value of -1 disables the feature.

This option requires a /etc/shadow file. A /etc/shadow entry will be created if there were none.

-g, --gid *GROUP*

The group name or number of the user's new initial login group. The group must exist.

Any file from the user's home directory owned by the previous primary group of the user will be owned by this new group.

The group ownership of files outside of the user's home directory must be fixed manually.

-G, --groups *GROUP1[,GROUP2,...[,GROUPN]]*

A list of supplementary groups which the user is also a member of. Each group is separated from the next by a comma, with no intervening whitespace. The groups are subject to the same restrictions as the group given with the **-g** option.

If the user is currently a member of a group which is not listed, the user will be removed from the group. This behaviour can be changed via the **-a** option, which appends the user to the current supplementary group list.

-l, --login NEW_LOGIN

The name of the user will be changed from *LOGIN* to *NEW_LOGIN*. Nothing else is changed. In particular, the user's home directory or mail spool should probably be renamed manually to reflect the new login name.

-L, --lock

Lock a user's password. This puts a '!' in front of the encrypted password, effectively disabling the password. You can't use this option with **-p** or **-U**.

Note: if you wish to lock the account (not only access with a password), you should also set the *EXPIRE_DATE* to *1*.

-m, --move-home

Move the content of the user's home directory to the new location.

This option is only valid in combination with the **-d** (or **--home**) option.

usermod will try to adapt the ownership of the files and to copy the modes, ACL and extended attributes, but manual changes might be needed afterwards.

-o, --non-unique

When used with the **-u** option, this option allows to change the user ID to a non-unique value.

-p, --password PASSWORD

The encrypted password, as returned by **crypt(3)**.

Note: This option is not recommended because the password (or encrypted password) will be visible by users listing the processes.

The password will be written in the local /etc/passwd or /etc/shadow file. This might differ from the password database configured in your PAM configuration.

You should make sure the password respects the system's password policy.

-R, --root CHROOT_DIR

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-P, --prefix PREFIX_DIR

Apply changes in the *PREFIX_DIR* directory and use the configuration files from the *PREFIX_DIR* directory. This option does not chroot and is intended for preparing a cross-compilation target. Some limitations: NIS and LDAP users/groups are not verified. PAM authentication is using the host files. No SELINUX support.

-s, --shell SHELL

The name of the user's new login shell. Setting this field to blank causes the system to select the default login shell.

-u, --uid UID

The new numerical value of the user's ID.

This value must be unique, unless the **-o** option is used. The value must be non-negative.

The user's mailbox, and any files which the user owns and which are located in the user's home directory will have the file user ID changed automatically.

The ownership of files outside of the user's home directory must be fixed manually.

No checks will be performed with regard to the **UID_MIN**, **UID_MAX**, **SYS_UID_MIN**, or

SYS_UID_MAX from /etc/login.defs.

-U, --unlock

Unlock a user's password. This removes the '!' in front of the encrypted password. You can't use this option with **-p** or **-L**.

Note: if you wish to unlock the account (not only access with a password), you should also set the **EXPIRE_DATE** (for example to 99999, or to the **EXPIRE** value from /etc/default/useradd).

-v, --add-subuids FIRST-LAST

Add a range of subordinate uids to the user's account.

This option may be specified multiple times to add multiple ranges to a users account.

No checks will be performed with regard to **SUB_UID_MIN**, **SUB_UID_MAX**, or **SUB_UID_COUNT** from /etc/login.defs.

-V, --del-subuids FIRST-LAST

Remove a range of subordinate uids from the user's account.

This option may be specified multiple times to remove multiple ranges to a users account. When both **--del-subuids** and **--add-subuids** are specified, the removal of all subordinate uid ranges happens before any subordinate uid range is added.

No checks will be performed with regard to **SUB_UID_MIN**, **SUB_UID_MAX**, or **SUB_UID_COUNT** from /etc/login.defs.

-w, --add-subgids FIRST-LAST

Add a range of subordinate gids to the user's account.

This option may be specified multiple times to add multiple ranges to a users account.

No checks will be performed with regard to **SUB_GID_MIN**, **SUB_GID_MAX**, or **SUB_GID_COUNT** from /etc/login.defs.

-W, --del-subgids FIRST-LAST

Remove a range of subordinate gids from the user's account.

This option may be specified multiple times to remove multiple ranges to a users account. When both **--del-subgids** and **--add-subgids** are specified, the removal of all subordinate gid ranges happens before any subordinate gid range is added.

No checks will be performed with regard to **SUB_GID_MIN**, **SUB_GID_MAX**, or **SUB_GID_COUNT** from /etc/login.defs.

-Z, --selinux-user SEUSER

The new SELinux user for the user's login.

A blank **SEUSER** will remove the SELinux user mapping for user **LOGIN** (if any).

CAVEATS

You must make certain that the named user is not executing any processes when this command is being executed if the user's numerical user ID, the user's name, or the user's home directory is being changed. **usermod** checks this on Linux. On other platforms it only uses utmp to check if the user is logged in.

You must change the owner of any **crontab** files or **at** jobs manually.

You must make any changes involving NIS on the NIS server.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

LASTLOG_UID_MAX (number)

Highest user ID number for which the lastlog entries should be updated. As higher user IDs are usually tracked by remote user identity and authentication services there is no need to create a huge sparse lastlog file for them.

No **LASTLOG_UID_MAX** option present in the configuration means that there is no user ID limit for writing lastlog entries.

MAIL_DIR (string)

The mail spool directory. This is needed to manipulate the mailbox when its corresponding user account is modified or deleted. If not specified, a compile-time default is used.

MAIL_FILE (string)

Defines the location of the users mail spool files relatively to their home directory.

The **MAIL_DIR** and **MAIL_FILE** variables are used by **useradd**, **usermod**, and **userdel** to create, move, or delete the user's mail spool.

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

SUB_GID_MIN (number), **SUB_GID_MAX** (number), **SUB_GID_COUNT** (number)

If /etc/subuid exists, the commands **useradd** and **newusers** (unless the user already have subordinate group IDs) allocate **SUB_GID_COUNT** unused group IDs from the range **SUB_GID_MIN** to **SUB_GID_MAX** for each new user.

The default values for **SUB_GID_MIN**, **SUB_GID_MAX**, **SUB_GID_COUNT** are respectively 100000, 600100000 and 65536.

SUB_UID_MIN (number), **SUB_UID_MAX** (number), **SUB_UID_COUNT** (number)

If /etc/subuid exists, the commands **useradd** and **newusers** (unless the user already have subordinate user IDs) allocate **SUB_UID_COUNT** unused user IDs from the range **SUB_UID_MIN** to **SUB_UID_MAX** for each new user.

The default values for **SUB_UID_MIN**, **SUB_UID_MAX**, **SUB_UID_COUNT** are respectively 100000, 600100000 and 65536.

FILES

/etc/group

NAME

`vgcfgbackup` – Backup volume group configuration(s)

SYNOPSIS

```
vgcfgbackup
  [ option_args ]
  [ position_args ]
```

DESCRIPTION

`vgcfgbackup` creates back up files containing metadata of VGs. If no VGs are named, back up files are created for all VGs. See `vgcfgrestore` for information on using the back up files.

In a default installation, each VG is backed up into a separate file bearing the name of the VG in the directory `/etc/lvm/backup`.

To use an alternative back up file, use `-f`. In this case, when backing up multiple VGs, the file name is treated as a template, with %s replaced by the VG name.

NB. This DOES NOT back up the data content of LVs.

It may also be useful to regularly back up the files in `/etc/lvm`.

USAGE

```
vgcfgbackup
  [ -f|--file String ]
  [ --foreign ]
  [ --ignorelockingfailure ]
  [ --readonly ]
  [ --reportformat basic|json ]
  [ COMMON_OPTIONS ]
  [ VG ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See `lvm.conf(5)` for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See `lvm.conf(5)` for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--file String

Write the backup to the named file. When backing up more than one VG, the file name is treated as a template, and %s is replaced by the VG name.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme

caution. (For automatic no, see `-qq`.)

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkKmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgcfgrestore – Restore volume group configuration

SYNOPSIS

```
vgcfgrestore option_args position_args
  [ option_args ]
  [ position_args ]

  --commandprofile String
  --config String
  -d|--debug
  --driverloaded y|n
  -f|--file String
  --force
  -h|--help
  -l|--list
  --lockopt String
  --longhelp
  -M|--metadatatype lvm2
  --nolocking
  --profile String
  -q|--quiet
  -t|--test
  -v|--verbose
  --version
  -y|--yes
```

DESCRIPTION

vgcfgrestore restores the metadata of a VG from a text back up file produced by **vgcfgbackup**. This writes VG metadata onto the devices specified in back up file.

A back up file can be specified with **--file**. If no backup file is specified, the most recent one is used. Use **--list** for a list of the available back up and archive files of a VG.

WARNING: When a VG contains thin pools, changes to thin metadata cannot be reverted, and data loss may occur if thin metadata has changed. The force option is required to restore in this case.

USAGE

Restore VG metadata from last backup.

```
vgcfgrestore VG
  [ COMMON_OPTIONS ]
```

Restore VG metadata from specified file.

```
vgcfgrestore -f|--file String VG
  [ COMMON_OPTIONS ]
```

List all VG metadata backups.

```
vgcfgrestore -l|--list VG
  [ COMMON_OPTIONS ]
```

List one VG metadata backup file.

```
vgcfgrestore -l|--list -f|--file String
```

```
[ COMMON_OPTIONS ]
[ VG ]
```

Common options for command:

```
[ -M|--metadatatype lvm2 ]
[ --force ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--file *String*

Read metadata backup from the named file. Usually this file was created by vgcfgbackup.

--force ...

Force metadata restore even with thin pool LVs. Use with extreme caution. Most changes to thin metadata cannot be reverted. You may lose data if you restore metadata that does not match the thin pool kernel metadata precisely.

-h|--help

Display help text.

-l|--list

List metadata backup and archive files pertaining to the VG. May be used with --file. Does not restore the VG.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-M|--metadatatype lvm2

Specifies the type of on-disk metadata to use. **lvm2** (or just **2**) is the current, standard format. **lvm1** (or just **1**) is no longer used.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkKmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NOTES

To replace PVs, **vgdisplay --partial --verbose** will show the UUIDs and sizes of any PVs that are no longer present. If a PV in the VG is lost and you wish to substitute another of the same size, use **pvcreate --restorefile filename --uuid uuid** (plus additional arguments as appropriate) to initialise it with the same UUID as the missing PV. Repeat for all other missing PVs in the VG. Then use **vgcfgrestore --file filename** to restore the VG's metadata.

NAME

vgchange – Change volume group attributes

SYNOPSIS

```
vgchange option_args position_args
  [ option_args ]
  [ position_args ]

-a|--activate y|n|ay
  --activationmode partial|degraded|complete
  --addtag Tag
  --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit
-A|--autobackup y|n
  --commandprofile String
  --config String
-d|--debug
  --deltag Tag
  --detachprofile
  --driverloaded y|n
-f|--force
-h|--help
-K|--ignoreactivationskip
  --ignorelockingfailure
  --ignoremonitoring
  --lockopt String
  --lockstart
  --lockstop
  --locktype sanlock|dlm|none
-l|--logicalvolume Number
  --longhelp
-p|--maxphysicalvolumes Number
  --metadaprofile String
  --monitor y|n
  --nolocking
  --noudevsync
-P|--partial
-s|--physicalextentsize Size[m|UNIT]
  --poll y|n
  --profile String
  --pvmetadatacopies 0|1|2
-q|--quiet
  --readonly
  --refresh
  --reportformat basic|json
-x|--resizeable y|n
-S|--select String
  --sysinit
  --systemid String
-t|--test
-u|--uuid
-v|--verbose
  --version
  --[vg]metadatacopies all|unmanaged|Number
-y|--yes
```

DESCRIPTION

`vgchange` changes VG attributes, changes LV activation in the kernel, and includes other utilities for VG maintenance.

USAGE

Change a general VG attribute.

For options listed in parentheses, any one is required, after which the others are optional.

vgchange

```
( -l|--logicalvolume Number,
  -p|--maxphysicalvolumes Number,
  -u|--uuid,
  -s|--physicalextentsize Size[m|UNIT],
  -x|--resizeable y|n,
  --addtag Tag,
  --deltag Tag,
  --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit,
  --pvmetadatacopies 0|1|2,
  --[vg]metadatacopies all|unmanaged|Number,
  --profile String,
  --detachprofile,
  --metadataprofile String)
[ -A|--autobackup y|n ]
[ -S|--select String ]
[ -f|--force ]
[ --poll y|n ]
[ --ignoremonitoring ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

Start or stop monitoring LVs from dmeventd.

vgchange ---monitor y|n

```
[ -A|--autobackup y|n ]
[ -S|--select String ]
[ -f|--force ]
[ --sysinit ]
[ --ignorelockingfailure ]
[ --poll y|n ]
[ --ignoremonitoring ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

Start or stop processing LV conversions.

vgchange ---poll y|n

```
[ -A|--autobackup y|n ]
[ -S|--select String ]
[ -f|--force ]
[ --ignorelockingfailure ]
```

```
[ --ignoremonitoring ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

-
Activate or deactivate LVs.

```
vgchange -a|--activate y|n|ay
[ -K|--ignoreactivationskip ]
[ -P|--partial ]
[ -A|--autobackup y|n ]
[ -S|--select String ]
[ -f|--force ]
[ --activationmode partial|degraded|complete ]
[ --sysinit ]
[ --readonly ]
[ --ignorelockingfailure ]
[ --monitor y|n ]
[ --poll y|n ]
[ --ignoremonitoring ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

-
Reactivate LVs using the latest metadata.

```
vgchange --refresh
[ -A|--autobackup y|n ]
[ -S|--select String ]
[ -f|--force ]
[ --sysinit ]
[ --ignorelockingfailure ]
[ --poll y|n ]
[ --ignoremonitoring ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

-
Change the system ID of a VG.

```
vgchange --systemid String VG
[ COMMON_OPTIONS ]
```

-
Start the lockspace of a shared VG in lvmlockd.

```
vgchange --lockstart
[ -S|--select String ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

Stop the lockspace of a shared VG in lvmlockd.

```
vgchange --lockstop
[ -S|--select String ]
[ COMMON_OPTIONS ]
[ VG|Tag|Select ... ]
```

Change the lock type for a shared VG.

```
vgchange --locktype sanlock|dlm|none VG
[ COMMON_OPTIONS ]
```

Common options for command:

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-a|--activate y|n|ay

Change the active state of LVs. An active LV can be used through a block device, allowing data on the LV to be accessed. **y** makes LVs active, or available. **n** makes LVs inactive, or unavailable. The block device for the LV is added or removed from the system using device-mapper in the kernel. A symbolic link /dev/VGName/LVName pointing to the device node is also added/removed. All software and scripts should access the device through the symbolic link and present this as the name of the device. The location and name of the underlying device node may depend on the distribution, configuration (e.g. udev), or release version. **ay** specifies autoactivation, in which case an LV is activated only if it matches an item in lvm.conf activation/auto_activation_volume_list. If the list is not set, all LVs are considered to match, and if the list is set but empty, no LVs match. Autoactivation should be used during system boot to make it possible to select which LVs should be automatically activated by the system. See **lvmlockd(8)** for more information about activation options **ey** and **sy** for shared VGs.

--activationmode partial|degraded|complete

Determines if LV activation is allowed when PVs are missing, e.g. because of a device failure. **complete** only allows LVs with no missing PVs to be activated, and is the most restrictive mode. **degraded** allows RAID LVs with missing PVs to be activated. (This does not include the "mirror" type, see "raid1" instead.) **partial** allows any LV with missing PVs to be activated, and should only be used for recovery or repair. For default, see lvm.conf/activation_mode. See **lvmraid(7)** for more information.

--addtag Tag

Adds a tag to a PV, VG or LV. This option can be repeated to add multiple tags at once. See **lvm(8)**

for information about tags.

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--deltag Tag

Deletes a tag from a PV, VG or LV. This option can be repeated to delete multiple tags at once. See **lvm(8)** for information about tags.

--detachprofile

Detaches a metadata profile from a VG or LV. See **lvm.conf(5)** for more information about profiles.

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--ignoreactivationskip

Ignore the "activation skip" LV flag during activation to allow LVs with the flag set to be activated.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--ignoremonitoring

Do not interact with dmeventd unless --monitor is specified. Do not use this if dmeventd is already monitoring a device.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--lockstart

Start the lockspace of a shared VG in lvmlockd. lvmlockd locks becomes available for the VG, allowing LVM to use the VG. See **lvmlockd(8)** for more information.

--lockstop

Stop the lockspace of a shared VG in lvmlockd. lvmlockd locks become unavailable for the VG, preventing LVM from using the VG. See **lvmlockd(8)** for more information.

--locktype sanlock|dlm|none

Change the VG lock type to or from a shared lock type used with lvmlockd. See **lvmlockd(8)** for more information.

-l|--logicalvolume Number

Sets the maximum number of LVs allowed in a VG.

--longhelp

Display long help text.

-p|--maxphysicalvolumes Number

Sets the maximum number of PVs that can belong to the VG. The value 0 removes any limitation. For large numbers of PVs, also see options **--pvmetadatacopies**, and **--vgmetadatacopies** for improving performance.

--metadataprofile String

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--monitor y|n

Start (yes) or stop (no) monitoring an LV with dmeventd. dmeventd monitors kernel events for an LV, and performs automated maintenance for the LV in response to specific events. See **dmeventd(8)** for more information.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

-P|--partial

Commands will do their best to activate LVs with missing PV extents. Missing extents may be replaced with error or zero segments according to the lvm.conf `missing_stripe_filler` setting. Metadata may not be changed with this option.

-s|--physicalextentsize Size[m|UNIT]

Sets the physical extent size of PVs in the VG. The value must be either a power of 2 of at least 1 sector (where the sector size is the largest sector size of the PVs currently used in the VG), or at least 128KiB. Once this value has been set, it is difficult to change without recreating the VG, unless no extents need moving. Before increasing the physical extent size, you might need to use `lvresize`, `pvresize` and/or `pvmove` so that everything fits. For example, every contiguous range of extents used in a LV must start and end on an extent boundary.

--poll y|n

When yes, start the background transformation of an LV. An incomplete transformation, e.g. `pvmove` or `lvconvert` interrupted by reboot or crash, can be restarted from the last checkpoint with **--poll y**. When no, background transformation of an LV will not occur, and the transformation will not complete. It may not be appropriate to immediately poll an LV after activation, in which case **--poll n** can be used to defer polling until a later **--poll y** command.

--profile String

An alias for **--commandprofile** or **--metadataprofile**, depending on the command.

--pvmetadatacopies 0|1|2

The number of metadata areas to set aside on a PV for storing VG metadata. When 2, one copy of the VG metadata is stored at the front of the PV and a second copy is stored at the end. When 1,

one copy of the VG metadata is stored at the front of the PV. When 0, no copies of the VG metadata are stored on the given PV. This may be useful in VGs containing many PVs (this places limitations on the ability to use vgsplit later.)

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--refresh

If the LV is active, reload its metadata. This is not necessary in normal operation, but may be useful if something has gone wrong, or if some form of manual LV sharing is being used.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-x|--resizable y|n

Enables or disables the addition or removal of PVs to/from a VG (by vgextend/vgreduce).

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--sysinit

Indicates that vgchange/lvchange is being invoked from early system initialisation scripts (e.g. rc.sysinit or an initrd), before writable filesystems are available. As such, some functionality needs to be disabled and this option acts as a shortcut which selects an appropriate set of options. Currently, this is equivalent to using --ignorelockingfailure, --ignoremonitoring, --poll n, and setting env var LVM_SUPPRESS_LOCKING_FAILURE_MESSAGES. vgchange/lvchange skip autoactivation, and defer to pvscan autoactivation.

--systemid String

Changes the system ID of the VG. Using this option requires caution because the VG may become foreign to the host running the command, leaving the host unable to access it. See **lvmsystemid(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-u|--uuid

Generate new random UUID for specified VGs.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

--[vg]metadatacopies all|unmanaged|Number

Number of copies of the VG metadata that are kept. VG metadata is kept in VG metadata areas on PVs in the VG, i.e. reserved space at the start and/or end of the PVs. Keeping a copy of the VG metadata on every PV can reduce performance in VGs containing a large number of PVs. When this number is set to a non-zero value, LVM will automatically choose PVs on which to store metadata, using the metadataignore flags on PVs to achieve the specified number. The number can also be replaced with special string values: **unmanaged** causes LVM to not automatically manage the PV metadataignore flags. **all** causes LVM to first clear the metadataignore flags on all PVs, and then to become unmanaged.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

Select

Select indicates that a required positional parameter can be omitted if the **--select** option is used. No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, **LVM_VG_NAME** can generally be substituted for a required VG parameter.

NOTES

If vgchange recognizes COW snapshot LVs that were dropped because they ran out of space, it displays a message informing the administrator that the snapshots should be removed.

EXAMPLES

Activate all LVs in all VGs on all existing devices.

vgchange -a y

Change the maximum number of LVs for an inactive VG.

vgchange -l 128 vg00

NAME

vgck – Check the consistency of volume group(s)

SYNOPSIS

```
vgck option_args position_args
      [ option_args ]
      [ position_args ]
```

DESCRIPTION

vgck checks LVM metadata for consistency.

USAGE

Read and display information about a VG.

```
vgck
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
      [ VG|Tag ... ]
```

Rewrite VG metadata to correct problems.

```
vgck --updatemetadata VG
      [ COMMON_OPTIONS ]
```

Common options for command:

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded **y|n**

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--updatemetadata

Update VG metadata to correct problems. If VG metadata was updated while a PV was missing, and the PV reappears with an old version of metadata, then this option (or any other command that writes metadata) will update the metadata on the previously missing PV. If a PV was removed from a VG while it was missing, and the PV reappears, using this option will clear the outdated metadata from the previously missing PV. If metadata text is damaged on one PV, using this option will replace the damaged metadata text. For more severe damage, e.g. with headers, see **pvck(8)**.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is

specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgconvert – Change volume group metadata format

SYNOPSIS

```
vgconvert position_args
      [ option_args ]
```

DESCRIPTION

vgconvert is no longer a part of LVM. It was removed along with support for the LVM1 format. Use an older version of LVM to convert VGs from the LVM1 format to LVM2.

USAGE

```
vgconvert VG ...
      [ -f|--force ]
      [ -M|--metadatatype lvm2 ]
      [ --labelsector Number ]
      [ --bootloaderaresize Size[m|UNIT] ]
      [ --pvmetadatacopies 0|1|2 ]
      [ --metadatasize Size[m|UNIT] ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**--bootloaderaresize** *Size[m|UNIT]*

Reserve space for the bootloader between the LVM metadata area and the first PE. The bootloader area is reserved for bootloaders to embed their own data or metadata; LVM will not use it. The bootloader area begins where the first PE would otherwise be located. The first PE is moved out by the size of the bootloader area, and then moved out further if necessary to match the data alignment. The start of the bootloader area is always aligned, see also **--dataalignment** and **--dataalignmentoffset**. The bootloader area may be larger than requested due to the alignment, but it's never less than the requested size. To see the bootloader area start and size of an existing PV use **pvs -o +pv_ba_start,pv_ba_size**.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--labelsector *Number*

By default the PV is labelled with an LVM2 identifier in its second sector (sector 1). This lets you use a different sector near the start of the disk (between 0 and 3 inclusive – see LABEL_SCAN_SECTORS in the source). Use with care.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--metadatasize *Size[m|UNIT]*

The approximate amount of space used for each VG metadata area. The size may be rounded.

-M|--metadatatype lvm2

Specifies the type of on-disk metadata to use. **lvm2** (or just **2**) is the current, standard format. **lvm1** (or just **1**) is no longer used.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

--pvmetadatacopies 0|1|2

The number of metadata areas to set aside on a PV for storing VG metadata. When 2, one copy of the VG metadata is stored at the front of the PV and a second copy is stored at the end. When 1, one copy of the VG metadata is stored at the front of the PV. When 0, no copies of the VG metadata are stored on the given PV. This may be useful in VGs containing many PVs (this places limitations on the ability to use vgsplit later.)

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkKmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgcreate – Create a volume group

SYNOPSIS

```
vgcreate position_args
      [ option_args ]
```

DESCRIPTION

vgcreate creates a new VG on block devices. If the devices were not previously initialized as PVs with **pvcreate(8)**, **vgcreate** will initialize them, making them PVs. The **pvcreate** options for initializing devices are also available with **vgcreate**.

When **vgcreate** uses an existing PV, that PV's existing values for metadata size, PE start, etc, are used, even if different values are specified in the **vgcreate** command. To change these values, first use **pvremove** on the device.

USAGE

```
vgcreate VG_new PV ...
      [ -A|--autobackup y|n ]
      [ -c|--clustered y|n ]
      [ -l|--maxlogicalvolumes Number ]
      [ -p|--maxphysicalvolumes Number ]
      [ -M|--metadatatype lvm2 ]
      [ -s|--physicalextentsize Size[m|UNIT] ]
      [ -f|--force ]
      [ -Z|--zero y|n ]
      [ --addtag Tag ]
      [ --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit ]
      [ --metadataprofile String ]
      [ --labelsector Number ]
      [ --metadatasize Size[m|UNIT] ]
      [ --pvmetadatacopies 0|1|2 ]
      [ --[vg]metadatacopies all|unmanaged|Number ]
      [ --reportformat basic|json ]
      [ --dataalignment Size[k|UNIT] ]
      [ --dataalignmentoffset Size[k|UNIT] ]
      [ --shared ]
      [ --systemid String ]
      [ --locktype sanlock|dlm|none ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
```

[--version]

OPTIONS

--addtag *Tag*

Adds a tag to a PV, VG or LV. This option can be repeated to add multiple tags at once. See **lvm(8)** for information about tags.

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

-c|--clustered y|n

This option was specific to clvm and is now replaced by the --shared option with **lvmlockd(8)**.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--dataalignment *Size[k|UNIT]*

Align the start of a PV data area with a multiple of this number. To see the location of the first Physical Extent (PE) of an existing PV, use pvs -o +pe_start. In addition, it may be shifted by an alignment offset, see --dataalignmentoffset. Also specify an appropriate PE size when creating a VG.

--dataalignmentoffset *Size[k|UNIT]*

Shift the start of the PV data area by this additional offset.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--labelsector *Number*

By default the PV is labelled with an LVM2 identifier in its second sector (sector 1). This lets you use a different sector near the start of the disk (between 0 and 3 inclusive – see LA-BEL_SCAN_SECTORS in the source). Use with care.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--locktype **sanlock|dlm|none**

Specify the VG lock type directly in place of using --shared. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-l|--maxlogicalvolumes *Number*

Sets the maximum number of LVs allowed in a VG.

-p|--maxphysicalvolumes *Number*

Sets the maximum number of PVs that can belong to the VG. The value 0 removes any limitation. For large numbers of PVs, also see options --pvmetadacopies, and --vgmetadacopies for improving performance.

--metadataprofile *String*

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--metadatasize *Size[m|UNIT]*

The approximate amount of space used for each VG metadata area. The size may be rounded.

-M|--metadatatype **lvm2**

Specifies the type of on-disk metadata to use. **lvm2** (or just **2**) is the current, standard format. **lvm1** (or just **1**) is no longer used.

--nolocking

Disable locking.

-s|--physicalextentsize *Size[m|UNIT]*

Sets the physical extent size of PVs in the VG. The value must be either a power of 2 of at least 1 sector (where the sector size is the largest sector size of the PVs currently used in the VG), or at least 128KiB. Once this value has been set, it is difficult to change without recreating the VG, unless no extents need moving.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

--pvmetadacopies **0|1|2**

The number of metadata areas to set aside on a PV for storing VG metadata. When 2, one copy of the VG metadata is stored at the front of the PV and a second copy is stored at the end. When 1, one copy of the VG metadata is stored at the front of the PV. When 0, no copies of the VG metadata are stored on the given PV. This may be useful in VGs containing many PVs (this places limitations on the ability to use vgsplit later.)

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat **basic|json**

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--shared

Create a shared VG using lvmlockd if LVM is compiled with lockd support. lvmlockd will select lock type sanlock or dlm depending on which lock manager is running. This allows multiple hosts to share a VG on shared devices. lvmlockd and a lock manager must be configured and running. See **lvmlockd(8)** for more information about shared VGs.

--systemid *String*

Specifies the system ID that will be given to the new VG, overriding the system ID of the host

running the command. A VG is normally created without this option, in which case the new VG is given the system ID of the host creating it. Using this option requires caution because the system ID of the new VG may not match the system ID of the host running the command, leaving the VG inaccessible to the host. See **lvmsystemid(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

--[vg]metadatacopies all|unmanaged|Number

Number of copies of the VG metadata that are kept. VG metadata is kept in VG metadata areas on PVs in the VG, i.e. reserved space at the start and/or end of the PVs. Keeping a copy of the VG metadata on every PV can reduce performance in VGs containing a large number of PVs. When this number is set to a non-zero value, LVM will automatically choose PVs on which to store metadata, using the metadataignore flags on PVs to achieve the specified number. The number can also be replaced with special string values: **unmanaged** causes LVM to not automatically manage the PV metadataignore flags. **all** causes LVM to first clear the metadataignore flags on all PVs, and then to become unmanaged.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

-Z|--zero y|n

Controls if the first 4 sectors (2048 bytes) of the device are wiped. The default is to wipe these sectors unless either or both of **--restorefile** or **--uuid** are specified.

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkKmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Create a VG with two PVs, using the default physical extent size.
vgcreate myvg /dev/sdk1 /dev/sdl1

NAME

vgdisplay – Display volume group information

SYNOPSIS

```
vgdisplay
[ option_args ]
[ position_args ]
```

DESCRIPTION

vgdisplay shows the attributes of VGs, and the associated PVs and LVs.

vgs(8) is a preferred alternative that shows the same information and more, using a more compact and configurable output format.

USAGE

```
vgdisplay
[ -A|--activevolumegroups ]
[ -c|--colon ]
[ -C|--columns ]
[ -o|--options String ]
[ -S|--select String ]
[ -s|--short ]
[ -O|--sort String ]
[ --aligned ]
[ --binary ]
[ --configreport log|vg|lv|pv|pvseg|seg ]
[ --foreign ]
[ --ignoreclockingfailure ]
[ --logonly ]
[ --noheadings ]
[ --nosuffix ]
[ --readonly ]
[ --reportformat basic|json ]
[ --shared ]
[ --separator String ]
[ --unbuffered ]
[ --units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E ]
[ COMMON_OPTIONS ]
[ VG|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**-A|--activevolumegroups**

Only select active VGs. The VG is considered active if at least one of its LVs is active.

--aligned

Use with --separator to align the output columns

--binary

Use binary values "0" or "1" instead of descriptive literal values for columns that have exactly two valid values to report (not counting the "unknown" value which denotes that the value could not be determined).

-c|--colon

Generate colon separated output for easier parsing in scripts or programs. Also see **vgs(8)** which provides considerably more control over the output.

-C|--columns

Display output in columns, the equivalent of **vgs(8)**. Options listed are the same as options given in **vgs(8)**.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--configreport *log|vg|lv|pv|pvseg|seg*

See **lvmreport(7)**.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--logonly

Suppress command report and display only log report.

--longhelp

Display long help text.

--noheadings

Suppress the headings line that is normally the first line of output. Useful if grepping the output.

--nolocking

Disable locking.

--nosuffix

Suppress the suffix on output sizes. Use with **--units** (except h and H) if processing the output.

-o|--options String

Comma-separated, ordered list of fields to display in columns. String arg syntax is:
`[+|-#]Field1[,Field2 ...]` The prefix + will append the specified fields to the default fields, - will remove the specified fields from the default fields, and # will compact specified fields (removing them when empty for all rows.) Use **-o help** to view the list of all available fields. Use separate lists of fields to add, remove or compact by repeating the **-o** option: `-o+field1,field2 -o-field3,field4 -o#field5`. These lists are evaluated from left to right. Use field name **lv_all** to view all LV fields, **vg_all** all VG fields, **pv_all** all PV fields, **pvseg_all** all PV segment fields, **seg_all** all LV segment fields, and **pvseg_all** all PV segment columns. See the lvm.conf report section for more config options. See **Ivmreport(7)** for more information about reporting.

--profile String

An alias for **--commandprofile** or **--metadataprofile**, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides **--debug** and **--verbose**. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **Ivmreport(7)** for more information.

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by **--select help** and **Ivmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See **--options help** for selectable object fields. Rows can be displayed with an additional "selected" field (**-o selected**) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--separator String

String to use to separate each column. Useful if grepping the output.

--shared

Report/display shared VGs that would otherwise be skipped when lvmlockd is not being used on the host. See **Ivmlockd(8)** for more information about shared VGs.

-s|--short

Give a short listing showing the existence of VGs.

-O|--sort String

Comma-separated ordered list of columns to sort by. Replaces the default selection. Precede any column with - for a reverse sort on that column.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--unbuffered

Produce output immediately without sorting or aligning the columns properly.

--units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E

All sizes are output in these units: human-(r)eadable with '<' rounding indicator, (h)uman-readable, (b)ytes, (s)ectors, (k)ilobytes, (m)egabytes, (g)igabytes, (t)erabytes, (p)etabytes, (e)xabytes. Capitalise to use multiples of 1000 (S.I.) instead of 1024. Custom units can be specified, e.g. --units 3M.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgexport – Unregister volume group(s) from the system

SYNOPSIS

```
vgexport option_args position_args
      [ option_args ]
```

DESCRIPTION

vgexport changes a VG into the exported state, which ensures that the VG and its disks are not being used, and cannot be used until the VG is imported by **vgimport**(8). Putting a VG into an unusable, offline state can be useful when doing things like moving a VG's disks to another system. Exporting a VG provides some protection from its LVs being accidentally used, or being used by an automated system before it's ready.

A VG cannot be exported until all of its LVs are inactive.

LVM commands will ignore an exported VG or report an error if a command tries to use it.

For an exported VG, the **vgs** command will display attribute, and the **pvs** command will display attribute. Both **vgs** and **pvs** will display report field.

vgexport clears the VG system ID, and **vgimport** sets the VG system ID to match the host running **vgimport** (if the host has a system ID).

USAGE

Export specified VGs.

```
vgexport VG|Tag|Select ...
      [ -S|--select String ]
      [ COMMON_OPTIONS ]
```

Export all VGs.

```
vgexport -a|--all
      [ COMMON_OPTIONS ]
```

Common options for command:

```
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-a|--all

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadaprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat *basic|json*

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-S|--select *String*

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **--qq**.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

Select

Select indicates that a required positional parameter can be omitted if the **--select** option is used. No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgextend – Add physical volumes to a volume group

SYNOPSIS

```
vgextend position_args
      [ option_args ]
```

DESCRIPTION

vgextend adds one or more PVs to a VG. This increases the space available for LVs in the VG.

Also, PVs that have gone missing and then returned, e.g. due to a transient device failure, can be added back to the VG without re-initializing them (see **--restoremissing**).

If the specified PVs have not yet been initialized with **pvcreate**, **vgextend** will initialize them. In this case **pvcreate** options can be used, e.g. **--labelsector**, **--metadatasize**, **--metadataignore**, **--pvmetadatacopies**, **--dataalignment**, **--dataalignmentoffset**.

USAGE

```
vgextend VG PV ...
      [ -A|--autobackup y|n ]
      [ -f|--force ]
      [ -Z|--zero y|n ]
      [ -M|--metadatatype lvm2 ]
      [ --labelsector Number ]
      [ --metadatasize Size[m|UNIT] ]
      [ --pvmetadatacopies 0|1|2 ]
      [ --metadataignore y|n ]
      [ --dataalignment Size[k|UNIT] ]
      [ --dataalignmentoffset Size[k|UNIT] ]
      [ --reportformat basic|json ]
      [ --restoremissing ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--dataalignment *Size[k|UNIT]*

Align the start of a PV data area with a multiple of this number. To see the location of the first Physical Extent (PE) of an existing PV, use pvs -o +pe_start. In addition, it may be shifted by an alignment offset, see --dataalignmentoffset. Also specify an appropriate PE size when creating a VG.

--dataalignmentoffset *Size[k|UNIT]*

Shift the start of the PV data area by this additional offset.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--labelsector *Number*

By default the PV is labelled with an LVM2 identifier in its second sector (sector 1). This lets you use a different sector near the start of the disk (between 0 and 3 inclusive – see LA-BEL_SCAN_SECTORS in the source). Use with care.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--metadataignore *y|n*

Specifies the metadataignore property of a PV. If yes, metadata areas on the PV are ignored, and lvm will not store metadata in the metadata areas of the PV. If no, lvm will store metadata on the PV.

--metadatasize *Size[m|UNIT]*

The approximate amount of space used for each VG metadata area. The size may be rounded.

-M|--metadatatype *lvm2*

Specifies the type of on-disk metadata to use. **lvm2** (or just **2**) is the current, standard format. **lvm1** (or just **1**) is no longer used.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

--pvmetadatacopies *0|1|2*

The number of metadata areas to set aside on a PV for storing VG metadata. When 2, one copy of the VG metadata is stored at the front of the PV and a second copy is stored at the end. When 1, one copy of the VG metadata is stored at the front of the PV. When 0, no copies of the VG metadata are stored on the given PV. This may be useful in VGs containing many PVs (this places limitations on the ability to use vgsplit later.)

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--restoremissing

Add a PV back into a VG after the PV was missing and then returned, e.g. due to a transient failure. The PV is not reinitialized.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

-Z|--zero y|n

Controls if the first 4 sectors (2048 bytes) of the device are wiped. The default is to wipe these sectors unless either or both of --restorefile or --uuid are specified.

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Add two PVs to a VG.

```
vgextend vg00 /dev/sda4 /dev/sdn1
```

NAME

vgimport – Register exported volume group with system

SYNOPSIS

```
vgimport option_args position_args  
[ option_args ]
```

DESCRIPTION

vgimport makes exported VGs known to the system again, perhaps after moving the PVs from a different system.

vgexport clears the VG system ID, and vgimport sets the VG system ID to match the host running vgimport (if the host has a system ID).

USAGE

Import specified VGs.

```
vgimport VG|Tag|Select ...  
[ -S|--select String ]  
[ COMMON_OPTIONS ]
```

Import all VGs.

```
vgimport -a|--all  
[ COMMON_OPTIONS ]
```

Common options for command:

```
[ -f|--force ]  
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]  
[ -h|--help ]  
[ -q|--quiet ]  
[ -t|--test ]  
[ -v|--verbose ]  
[ -y|--yes ]  
[ --commandprofile String ]  
[ --config String ]  
[ --driverloaded y|n ]  
[ --lockopt String ]  
[ --longhelp ]  
[ --nolocking ]  
[ --profile String ]  
[ --version ]
```

OPTIONS

-a|--all

Import all visible VGs.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES**VG**

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

Select

Select indicates that a required positional parameter can be omitted if the **--select** option is used. No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

`vgimportclone` – Import a VG from cloned PVs

SYNOPSIS

```
vgimportclone position_args
    [ option_args ]
```

DESCRIPTION

`vgimportclone` imports a VG from duplicated PVs, e.g. created by a hardware snapshot of existing PVs.

A duplicated VG cannot be used until it is made to coexist with the original VG. `vgimportclone` renames the VG associated with the specified PVs and changes the associated VG and PV UUIDs.

USAGE

```
vgimportclone PV ...
    [ -n|--basevgname VG ]
    [ -i|--import ]
    [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-n|--basevgname *String*

By default the snapshot VG will be renamed to the original name plus a numeric suffix to avoid duplicate naming (e.g. 'test_vg' would be renamed to 'test_vg1'). This option will override the base VG name that is used for all VG renames. If a VG already exists with the specified name a numeric suffix will be added (like the previous example) to make it unique.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

-i|--import

Import exported VGs. Otherwise VGs that have been exported will not be changed (nor will their associated PVs).

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

An original VG "vg00" has PVs "/dev/sda" and "/dev/sdb". The corresponding PVs from a hardware snapshot are "/dev/sdc" and "/dev/sdd". Rename the VG associated with "/dev/sdc" and "/dev/sdd" from "vg00"

to "vg00_snap" (and change associated UUIDs).

vgimportclone --basevgname vg00_snap /dev/sdc /dev/sdd

NAME

vgmerge – Merge volume groups

SYNOPSIS

```
vgmerge position_args
      [ option_args ]
```

DESCRIPTION

vgmerge merges two existing VGs. The inactive source VG is merged into the destination VG if physical extent sizes are equal and PV and LV summaries of both VGs fit into the destination VG's limits.

USAGE

```
vgmerge VG VG
      [ -A|--autobackup y|n ]
      [ -l|--list ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

-l|--list

Display merged destination VG like vgdisplay -v.

--lockopt *String*
 Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp
 Display long help text.

--nolocking
 Disable locking.

--profile *String*
 An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...
 Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

-t|--test
 Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...
 Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version
 Display version information.

-y|--yes
 Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Merge an inactive VG named "vg00" into the active or inactive VG named "databases", giving verbose run-time information.

vgmerge -v databases vg00

NAME

vgmknodes – Create the special files for volume group devices in /dev

SYNOPSIS

```
vgmknodes
[ option_args ]
[ position_args ]
```

DESCRIPTION

vgmknodes checks the LVM device nodes in /dev that are needed for active LVs and creates any that are missing and removes unused ones.

This command should not usually be needed if all the system components are interoperating correctly.

USAGE

```
vgmknodes
[ --ignorelockingfailure ]
[ --refresh ]
[ --reportformat basic|json ]
[ COMMON_OPTIONS ]
[ VG|LV|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded **y|n**

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*
 Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp
 Display long help text.

--nolocking
 Disable locking.

--profile *String*
 An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...
 Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--refresh
 If the LV is active, reload its metadata. This is not necessary in normal operation, but may be useful if something has gone wrong, or if some form of manual LV sharing is being used.

--reportformat basic|json
 Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test
 Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...
 Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version
 Display version information.

-y|--yes
 Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see --qq.)

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where

capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm**(8) for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgreduce – Remove physical volume(s) from a volume group

SYNOPSIS

```
vgreduce option_args position_args
      [ option_args ]
      -a|--all
      -A|--autobackup y|n
      --commandprofile String
      --config String
      -d|--debug
      --driverloaded y|n
      -f|--force
      -h|--help
      --lockopt String
      --longhelp
      --mirrorsonly
      --nolocking
      --profile String
      -q|--quiet
      --removemissing
      --reportformat basic|json
      -t|--test
      -v|--verbose
      --version
      -y|--yes
```

DESCRIPTION

vgreduce removes one or more unused PVs from a VG.

USAGE

Remove a PV from a VG.

```
vgreduce VG PV ...
      [ COMMON_OPTIONS ]
```

Remove all unused PVs from a VG.

```
vgreduce -a|--all VG
      [ COMMON_OPTIONS ]
```

Remove all missing PVs from a VG.

```
vgreduce --removemissing VG
      [ --mirrorsonly ]
      [ COMMON_OPTIONS ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ -f|--force ]
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
```

```
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**-a|--all**

Removes all empty PVs if none are named on the command line.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--mirrorsonly

Only remove missing PVs from mirror LVs.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--removemissing

Removes all missing PVs from the VG, if there are no LVs allocated on them. This resumes normal operation of the VG (new LVs may again be created, changed and so on). If this is not possible because LVs are referencing the missing PVs, this option can be combined with --force to have the command remove any partial LVs. In this case, any LVs and dependent snapshots that were partly on the missing disks are removed completely, including those parts on disks that are still present. If LVs spanned several disks, including ones that are lost, salvaging some data first may be possible by activating LVs in partial mode.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see --qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

lvmsystemid(7) lvmreport(7) lvmraid(7) lvmthin(7) lvmcache(7)

NAME

vgremove – Remove volume group(s)

SYNOPSIS

```
vgremove position_args
      [ option_args ]
```

DESCRIPTION

vgremove removes one or more VGs. If LVs exist in the VG, a prompt is used to confirm LV removal.

If one or more PVs in the VG are lost, consider **vgreduce --removemissing** to make the VG metadata consistent again.

Repeat the force option (**-ff**) to forcibly remove LVs in the VG without confirmation.

USAGE

```
vgremove VG|Tag|Select ...
      [ -f|--force ]
      [ -S|--select String ]
      [ --noudevsync ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded **y|n**

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

Select

Select indicates that a required positional parameter can be omitted if the **--select** option is used.
No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgrename – Rename a volume group

SYNOPSIS

```
vgrename position_args
      [ option_args ]
```

DESCRIPTION

vgrename renames a VG.

All VGs visible to a system need to have different names, otherwise many LVM commands will refuse to run or give warning messages. VGs with the same name can occur when disks are moved between machines, or filters are changed. If a newly connected disk has a VG with the same name as the VG containing the root filesystem, the machine may not boot correctly. When two VGs have the same name, the VG UUID can be used in place of the source VG name.

USAGE

Rename a VG.

```
vgrename VG VG_new
      [ COMMON_OPTIONS ]
```

Rename a VG by specifying the VG UUID.

```
vgrename String VG_new
      [ COMMON_OPTIONS ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ -f|--force ]
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-A|--autobackup *y|n*

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same

format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is

specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Rename VG "vg02" to "myvg":

```
vgrename vg02 myvg
```

Rename the VG with the specified UUID to "myvg".

```
vgrename Zvlifi-Ep3t-e0Ng-U42h-o0ye-KHu1-nl7Ns4 myvg
```

NAME

vgs – Display information about volume groups

SYNOPSIS

```
vgs
  [ option_args ]
  [ position_args ]
```

DESCRIPTION

vgs produces formatted output about VGs.

USAGE

```
vgs
  [ -a|--all ]
  [ -o|--options String ]
  [ -S|--select String ]
  [ -O|--sort String ]
  [ --aligned ]
  [ --binary ]
  [ --configreport log|vg|lv|pv|pvseg|seg ]
  [ --foreign ]
  [ --ignorelockingfailure ]
  [ --logonly ]
  [ --nameprefixes ]
  [ --noheadings ]
  [ --nosuffix ]
  [ --readonly ]
  [ --reportformat basic|json ]
  [ --rows ]
  [ --separator String ]
  [ --shared ]
  [ --unbuffered ]
  [ --units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E ]
  [ --unquoted ]
  [ COMMON_OPTIONS ]
  [ VG|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**--aligned**

Use with --separator to align the output columns

-a|--all

List all VGs. Equivalent to not specifying any VGs.

--binary

Use binary values "0" or "1" instead of descriptive literal values for columns that have exactly two valid values to report (not counting the "unknown" value which denotes that the value could not be determined).

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--configreport log|vg|lv|pv|pvseg|seg

See **lvmreport(7)**.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--logonly

Suppress command report and display only log report.

--longhelp

Display long help text.

--nameprefixes

Add an "LVM2_" prefix plus the field name to the output. Useful with --noheadings to produce a list of field=value pairs that can be used to set environment variables (for example, in udev rules).

--noheadings

Suppress the headings line that is normally the first line of output. Useful if grepping the output.

--nolocking

Disable locking.

--nosuffix

Suppress the suffix on output sizes. Use with --units (except h and H) if processing the output.

-o|--options *String*

Comma-separated, ordered list of fields to display in columns. String arg syntax is:
[+|-#]Field1[,Field2 ...] The prefix + will append the specified fields to the default fields, - will remove the specified fields from the default fields, and # will compact specified fields (removing them when empty for all rows.) Use **-o help** to view the list of all available fields. Use separate lists of fields to add, remove or compact by repeating the -o option: -o+field1,field2 -o-

field3,field4 -o#field5. These lists are evaluated from left to right. Use field name **lv_all** to view all LV fields, **vg_all** all VG fields, **pv_all** all PV fields, **pvseg_all** all PV segment fields, **seg_all** all LV segment fields, and **pvseg_all** all PV segment columns. See the lvm.conf report section for more config options. See **lvmreport(7)** for more information about reporting.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat **basic|json**

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--rows

Output columns as rows.

-S|--select *String*

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--separator *String*

String to use to separate each column. Useful if grepping the output.

--shared

Report/display shared VGs that would otherwise be skipped when lvmlockd is not being used on the host. See **lvmlockd(8)** for more information about shared VGs.

-O|--sort *String*

Comma-separated ordered list of columns to sort by. Replaces the default selection. Precede any column with - for a reverse sort on that column.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--unbuffered

Produce output immediately without sorting or aligning the columns properly.

--units **r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E**

All sizes are output in these units: human-(r)eadable with '<' rounding indicator, (h)uman-readable, (b)ytes, (s)ectors, (k)ilobytes, (m)egabytes, (g)igabytes, (t)erabytes, (p)etabytes, (e)xabytes. Capitalise to use multiples of 1000 (S.I.) instead of 1024. Custom units can be specified, e.g.

--units 3M.

--unquoted

When used with --nameprefixes, output values in the field=value pairs are not quoted.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NOTES

The vg_attr bits are:

- 1 Permissions: (w)ritable, (r)ead-only
- 2 Resi(z)eable
- 3 E(x)ported
- 4 (p)artial: one or more physical volumes belonging to the volume group are missing from the system
- 5 Allocation policy: (c)ontiguous, c(l)ing, (n)ormal, (a)nywhere
- 6 (c)lustered, (s)hared

NAME

vgscan – Search for all volume groups

SYNOPSIS

```
vgscan
  [ option_args ]
```

DESCRIPTION

vgscan scans all supported LVM block devices in the system for VGs.

USAGE

```
vgscan
  [ --ignorelockingfailure ]
  [ --mknodes ]
  [ --notifydbus ]
  [ --reportformat basic|json ]
  [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**--commandprofile** *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--mknodes

Also checks the LVM special files in /dev that are needed for active LVs and creates any missing ones and removes unused ones.

--nolocking

Disable locking.

--notifydbus

Send a notification to D-Bus. The command will exit with an error if LVM is not built with support for D-Bus notification, or if the notify_dbus config setting is disabled.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*String*

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

vgsplit – Move physical volumes into a new or existing volume group

SYNOPSIS

```
vgsplit option_args position_args
      [ option_args ]
```

DESCRIPTION

vgsplit moves one or more PVs from a source VG (the first VG arg) to a destination VG (the second VG arg). The PV(s) to move are named after the source and destination VGs, or an LV is named, in which case the PVs underlying the LV are moved.

If the destination VG does not exist, a new VG is created (command options can be used to specify properties of the new VG, also see **vgcreate(8)**.)

LVs cannot be split between VGs; each LV must be entirely on the PVs in the source or destination VG.

vgsplit can only move complete PVs. (See **pvmove(8)** for moving part of a PV.)

USAGE

Split a VG by specified PVs.

```
vgsplit VG VG PV ...
      [ COMMON_OPTIONS ]
```

Split a VG by PVs in a specified LV.

```
vgsplit -n|--name LV VG VG
      [ COMMON_OPTIONS ]
```

Common options for command:

- [**-A|--autobackup** *y|n*]
- [**-l|--maxlogicalvolumes** *Number*]
- [**-p|--maxphysicalvolumes** *Number*]
- [**-M|--metadatatype** *lvm2*]
- [**--alloc** *contiguous|cling|cling_by_tags|normal|anywhere|inherit*]
- [**--[vg]metadatacopies** *all|unmanaged|Number*]

Common options for lvm:

- [**-d|--debug**]
- [**-h|--help**]
- [**-q|--quiet**]
- [**-t|--test**]
- [**-v|--verbose**]
- [**-y|--yes**]
- [**--commandprofile** *String*]
- [**--config** *String*]
- [**--driverloaded** *y|n*]
- [**--lockopt** *String*]
- [**--longhelp**]
- [**--nolocking**]
- [**--profile** *String*]
- [**--version**]

OPTIONS

--alloc *contiguous|cling|cling_by_tags|normal|anywhere|inherit*

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange,

or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-l|--maxlogicalvolumes Number

Sets the maximum number of LVs allowed in a VG.

-p|--maxphysicalvolumes Number

Sets the maximum number of PVs that can belong to the VG. The value 0 removes any limitation. For large numbers of PVs, also see options **--pvmetadacopies**, and **--vgmetadacopies** for improving performance.

-M|--metadatatype lvm2

Specifies the type of on-disk metadata to use. **lvm2** (or just **2**) is the current, standard format.

lvm1 (or just **1**) is no longer used.

-n|--name String

Move only PVs used by the named LV.

--nolocking

Disable locking.

--profile String

An alias for **--commandprofile** or **--metadaprofile**, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides **--debug** and **--verbose**. Repeat once to also suppress any prompts with answer 'no'.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all

metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

--[vg]metadatacopies all|unmanaged|Number

Number of copies of the VG metadata that are kept. VG metadata is kept in VG metadata areas on PVs in the VG, i.e. reserved space at the start and/or end of the PVs. Keeping a copy of the VG metadata on every PV can reduce performance in VGs containing a large number of PVs. When this number is set to a non-zero value, LVM will automatically choose PVs on which to store metadata, using the metadataignore flags on PVs to achieve the specified number. The number can also be replaced with special string values: **unmanaged** causes LVM to not automatically manage the PV metadataignore flags. **all** causes LVM to first clear the metadataignore flags on all PVs, and then to become unmanaged.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, **LVM_VG_NAME** can generally be substituted for a required VG parameter.

NAME

vim – Vi IMproved, a programmer's text editor

SYNOPSIS

```
vim [options] [file ..]
vim [options] -
vim [options] -t tag
vim [options] -q [errorfile]

ex
view
gvim gview evim eview
rvim rview rgvim rgview
```

DESCRIPTION

Vim is a text editor that is upwards compatible to Vi. It can be used to edit all kinds of plain text. It is especially useful for editing programs.

There are a lot of enhancements above Vi: multi level undo, multi windows and buffers, syntax highlighting, command line editing, filename completion, on-line help, visual selection, etc.. See ":help vi_diff.txt" for a summary of the differences between **Vim** and Vi.

While running **Vim** a lot of help can be obtained from the on-line help system, with the ":help" command. See the ON-LINE HELP section below.

Most often **Vim** is started to edit a single file with the command

```
vim file
```

More generally **Vim** is started with:

```
vim [options] [filelist]
```

If the filelist is missing, the editor will start with an empty buffer. Otherwise exactly one out of the following four may be used to choose one or more files to be edited.

- | | |
|----------------|---|
| file .. | A list of filenames. The first one will be the current file and read into the buffer. The cursor will be positioned on the first line of the buffer. You can get to the other files with the ":next" command. To edit a file that starts with a dash, precede the filelist with "--". |
| - | The file to edit is read from stdin. Commands are read from stderr, which should be a tty. |
| -t {tag} | The file to edit and the initial cursor position depends on a "tag", a sort of goto label. {tag} is looked up in the tags file, the associated file becomes the current file and the associated command is executed. Mostly this is used for C programs, in which case {tag} could be a function name. The effect is that the file containing that function becomes the current file and the cursor is positioned on the start of the function. See ":help tag-commands". |
| -q [errorfile] | Start in quickFix mode. The file [errorfile] is read and the first error is displayed. If [errorfile] is omitted, the filename is obtained from the 'errorfile' option (defaults to "AztecC.Err" for the Amiga, "errors.err" on other systems). Further errors can be jumped to with the ":cn" command. See ":help quickfix". |

Vim behaves differently, depending on the name of the command (the executable may still be the same file).

- | | |
|------|---|
| vim | The "normal" way, everything is default. |
| ex | Start in Ex mode. Go to Normal mode with the ":vi" command. Can also be done with the "-e" argument. |
| view | Start in read-only mode. You will be protected from writing the files. Can also be done with the "-R" argument. |

gvim gview

The GUI version. Starts a new window. Can also be done with the "-g" argument.

evim eview

The GUI version in easy mode. Starts a new window. Can also be done with the "-y" argument.

rvim rview rgvim rgview

Like the above, but with restrictions. It will not be possible to start shell commands, or suspend **Vim**. Can also be done with the "-Z" argument.

OPTIONS

The options may be given in any order, before or after filenames. Options without an argument can be combined after a single dash.

- +[num] For the first file the cursor will be positioned on line "num". If "num" is missing, the cursor will be positioned on the last line.
- +/ {pat} For the first file the cursor will be positioned in the line with the first occurrence of {pat}. See ":help search-pattern" for the available search patterns.
- +{command}
- c {command} {command} will be executed after the first file has been read. {command} is interpreted as an Ex command. If the {command} contains spaces it must be enclosed in double quotes (this depends on the shell that is used). Example: vim "+set si" main.c
Note: You can use up to 10 "+" or "-c" commands.
- S {file} {file} will be sourced after the first file has been read. This is equivalent to -c "source {file} ". {file} cannot start with '-'. If {file} is omitted "Session.vim" is used (only works when -S is the last argument).
- cmd {command} Like using "-c", but the command is executed just before processing any vimrc file. You can use up to 10 of these commands, independently from "-c" commands.
- A If **Vim** has been compiled with ARABIC support for editing right-to-left oriented files and Arabic keyboard mapping, this option starts **Vim** in Arabic mode, i.e. 'arabic' is set. Otherwise an error message is given and **Vim** aborts.
- b Binary mode. A few options will be set that makes it possible to edit a binary or executable file.
- C Compatible. Set the 'compatible' option. This will make **Vim** behave mostly like Vi, even though a .vimrc file exists.
- d Start in diff mode. There should between two to eight file name arguments. **Vim** will open all the files and show differences between them. Works like vimdiff(1).
- d {device} Open {device} for use as a terminal. Only on the Amiga. Example: "-d con:20/30/600/150".
- D Debugging. Go to debugging mode when executing the first command from a script.
- e Start **Vim** in Ex mode, just like the executable was called "ex".
- E Start **Vim** in improved Ex mode, just like the executable was called "exim".
- f Foreground. For the GUI version, **Vim** will not fork and detach from the shell it was started in. On the Amiga, **Vim** is not restarted to open a new window. This option should be used when **Vim** is executed by a program that will wait for the edit session to finish (e.g. mail). On the Amiga the ":sh" and ":!" commands will not work.
- nofork Foreground. For the GUI version, **Vim** will not fork and detach from the shell it was started in.

- F If **Vim** has been compiled with FKMAP support for editing right-to-left oriented files and Farsi keyboard mapping, this option starts **Vim** in Farsi mode, i.e. 'fkmap' and 'rightleft' are set. Otherwise an error message is given and **Vim** aborts.
- g If **Vim** has been compiled with GUI support, this option enables the GUI. If no GUI support was compiled in, an error message is given and **Vim** aborts.
- h Give a bit of help about the command line arguments and options. After this **Vim** exits.
- H If **Vim** has been compiled with RIGHTLEFT support for editing right-to-left oriented files and Hebrew keyboard mapping, this option starts **Vim** in Hebrew mode, i.e. 'hkmap' and 'rightleft' are set. Otherwise an error message is given and **Vim** aborts.
- i {viminfo} Specifies the filename to use when reading or writing the viminfo file, instead of the default "~/viminfo". This can also be used to skip the use of the .viminfo file, by giving the name "NONE".
- L Same as -r.
- l Lisp mode. Sets the 'lisp' and 'showmatch' options on.
- m Modifying files is disabled. Resets the 'write' option. You can still modify the buffer, but writing a file is not possible.
- M Modifications not allowed. The 'modifiable' and 'write' options will be unset, so that changes are not allowed and files can not be written. Note that these options can be set to enable making modifications.
- N No-compatible mode. Resets the 'compatible' option. This will make **Vim** behave a bit better, but less Vi compatible, even though a .vimrc file does not exist.
- n No swap file will be used. Recovery after a crash will be impossible. Handy if you want to edit a file on a very slow medium (e.g. floppy). Can also be done with ":set uc=0". Can be undone with ":set uc=200".
- nb Become an editor server for NetBeans. See the docs for details.
- o[N] Open N windows stacked. When N is omitted, open one window for each file.
- O[N] Open N windows side by side. When N is omitted, open one window for each file.
- p[N] Open N tab pages. When N is omitted, open one tab page for each file.
- R Read-only mode. The 'readonly' option will be set. You can still edit the buffer, but will be prevented from accidentally overwriting a file. If you do want to overwrite a file, add an exclamation mark to the Ex command, as in ":w!". The -R option also implies the -n option (see above). The 'readonly' option can be reset with ":set noro". See ":help 'readonly'".
- r List swap files, with information about using them for recovery.
- r {file} Recovery mode. The swap file is used to recover a crashed editing session. The swap file is a file with the same filename as the text file with ".swp" appended. See ":help recovery".
- s Silent mode. Only when started as "Ex" or when the "-e" option was given before the "-s" option.
- s {scriptin} The script file {scriptin} is read. The characters in the file are interpreted as if you had typed them. The same can be done with the command ":source! {scriptin}". If the end of the file is reached before the editor exits, further characters are read from the keyboard.
- T {terminal} Tells **Vim** the name of the terminal you are using. Only required when the automatic way doesn't work. Should be a terminal known to **Vim** (builtin) or defined in the termcap or terminfo file.
- u {vimrc} Use the commands in the file {vimrc} for initializations. All the other initializations are skipped. Use this to edit a special kind of files. It can also be used to skip all initializations

by giving the name "NONE". See ":help initialization" within vim for more details.

- U {gvimrc} Use the commands in the file {gvimrc} for GUI initializations. All the other GUI initializations are skipped. It can also be used to skip all GUI initializations by giving the name "NONE". See ":help gui-init" within vim for more details.
- V[N] Verbose. Give messages about which files are sourced and for reading and writing a viminfo file. The optional number N is the value for 'verbose'. Default is 10.
- v Start **Vim** in Vi mode, just like the executable was called "vi". This only has effect when the executable is called "ex".
- w {scriptout} All the characters that you type are recorded in the file {scriptout}, until you exit **Vim**. This is useful if you want to create a script file to be used with "vim -s" or ":source!". If the {scriptout} file exists, characters are appended.
- W {scriptout} Like -w, but an existing file is overwritten.
- x Use encryption when writing files. Will prompt for a crypt key.
- X Don't connect to the X server. Shortens startup time in a terminal, but the window title and clipboard will not be used.
- y Start **Vim** in easy mode, just like the executable was called "evim" or "eview". Makes **Vim** behave like a click-and-type editor.
- Z Restricted mode. Works like the executable starts with "r".
- Denotes the end of the options. Arguments after this will be handled as a file name. This can be used to edit a filename that starts with a '-'.
- clean Do not use any personal configuration (vimrc, plugins, etc.). Useful to see if a problem reproduces with a clean Vim setup.
- echo-wid GTK GUI only: Echo the Window ID on stdout.
- help Give a help message and exit, just like "-h".
- literal Take file name arguments literally, do not expand wildcards. This has no effect on Unix where the shell expands wildcards.
- nopugin Skip loading plugins. Implied by -u NONE.
- remote Connect to a Vim server and make it edit the files given in the rest of the arguments. If no server is found a warning is given and the files are edited in the current Vim.
- remote-expr {expr} Connect to a Vim server, evaluate {expr} in it and print the result on stdout.
- remote-send {keys} Connect to a Vim server and send {keys} to it.
- remote-silent As --remote, but without the warning when no server is found.
- remote-wait As --remote, but Vim does not exit until the files have been edited.
- remote-wait-silent As --remote-wait, but without the warning when no server is found.
- serverlist List the names of all Vim servers that can be found.
- servername {name} Use {name} as the server name. Used for the current Vim, unless used with a --remote argument, then it's the name of the server to connect to.

--socketid {id}
 GTK GUI only: Use the GtkPlug mechanism to run gvim in another window.

--startuptime {file}
 During startup write timing messages to the file {fname}.

--version Print version information and exit.

ON-LINE HELP

Type ":help" in **Vim** to get started. Type ":help subject" to get help on a specific subject. For example: ":help ZZ" to get help for the "ZZ" command. Use <Tab> and CTRL-D to complete subjects ("help cmd-line-completion"). Tags are present to jump from one place to another (sort of hypertext links, see ":help"). All documentation files can be viewed in this way, for example ":help syntax.txt".

FILES

/usr/share/vim/vim82/doc/*.txt
 The **Vim** documentation files. Use ":help doc-file-list" to get the complete list.

/usr/share/vim/vim82/doc/tags
 The tags file used for finding information in the documentation files.

/usr/share/vim/vim82/syntax/syntax.vim
 System wide syntax initializations.

/usr/share/vim/vim82/syntax/*.vim
 Syntax files for various languages.

/usr/share/vim/vimrc
 System wide **Vim** initializations.

~/.vimrc Your personal **Vim** initializations.

/usr/share/vim/gvimrc
 System wide gvim initializations.

~/.gvimrc Your personal gvim initializations.

/usr/share/vim/vim82/optwin.vim
 Script used for the ":options" command, a nice way to view and set options.

/usr/share/vim/vim82/menu.vim
 System wide menu initializations for gvim.

/usr/share/vim/vim82/bugreport.vim
 Script to generate a bug report. See ":help bugs".

/usr/share/vim/vim82/filetype.vim
 Script to detect the type of a file by its name. See ":help 'filetype'".

/usr/share/vim/vim82/scripts.vim
 Script to detect the type of a file by its contents. See ":help 'filetype'".

/usr/share/vim/vim82/print/*.ps
 Files used for PostScript printing.

For recent info read the VIM home page:

SEE ALSO

[vimtutor\(1\)](#)

AUTHOR

Most of **Vim** was made by Bram Moolenaar, with a lot of help from others. See ":help credits" in **Vim**.
Vim is based on Stevie, worked on by: Tim Thompson, Tony Andrews and G.R. (Fred) Walter. Although hardly any of the original code remains.

BUGS

Probably. See ":help todo" for a list of known problems.

Note that a number of things that may be regarded as bugs by some, are in fact caused by a too-faithful reproduction of Vi's behaviour. And if you think other things are bugs "because Vi does it differently", you should take a closer look at the vi_diff.txt file (or type :help vi_diff.txt when in Vim). Also have a look at the 'compatible' and 'coptions' options.

NAME

vim – Vi IMproved, a programmer's text editor

SYNOPSIS

```
vim [options] [file ..]
vim [options] -
vim [options] -t tag
vim [options] -q [errorfile]

ex
view
gvim gview evim eview
rvim rview rgvim rgview
```

DESCRIPTION

Vim is a text editor that is upwards compatible to Vi. It can be used to edit all kinds of plain text. It is especially useful for editing programs.

There are a lot of enhancements above Vi: multi level undo, multi windows and buffers, syntax highlighting, command line editing, filename completion, on-line help, visual selection, etc.. See ":help vi_diff.txt" for a summary of the differences between **Vim** and Vi.

While running **Vim** a lot of help can be obtained from the on-line help system, with the ":help" command. See the ON-LINE HELP section below.

Most often **Vim** is started to edit a single file with the command

```
vim file
```

More generally **Vim** is started with:

```
vim [options] [filelist]
```

If the filelist is missing, the editor will start with an empty buffer. Otherwise exactly one out of the following four may be used to choose one or more files to be edited.

- | | |
|----------------|---|
| file .. | A list of filenames. The first one will be the current file and read into the buffer. The cursor will be positioned on the first line of the buffer. You can get to the other files with the ":next" command. To edit a file that starts with a dash, precede the filelist with "--". |
| - | The file to edit is read from stdin. Commands are read from stderr, which should be a tty. |
| -t {tag} | The file to edit and the initial cursor position depends on a "tag", a sort of goto label. {tag} is looked up in the tags file, the associated file becomes the current file and the associated command is executed. Mostly this is used for C programs, in which case {tag} could be a function name. The effect is that the file containing that function becomes the current file and the cursor is positioned on the start of the function. See ":help tag-commands". |
| -q [errorfile] | Start in quickFix mode. The file [errorfile] is read and the first error is displayed. If [errorfile] is omitted, the filename is obtained from the 'errorfile' option (defaults to "AztecC.Err" for the Amiga, "errors.err" on other systems). Further errors can be jumped to with the ":cn" command. See ":help quickfix". |

Vim behaves differently, depending on the name of the command (the executable may still be the same file).

- | | |
|------|---|
| vim | The "normal" way, everything is default. |
| ex | Start in Ex mode. Go to Normal mode with the ":vi" command. Can also be done with the "-e" argument. |
| view | Start in read-only mode. You will be protected from writing the files. Can also be done with the "-R" argument. |

gvim gview

The GUI version. Starts a new window. Can also be done with the "-g" argument.

evim eview

The GUI version in easy mode. Starts a new window. Can also be done with the "-y" argument.

rvim rview rgvim rgview

Like the above, but with restrictions. It will not be possible to start shell commands, or suspend **Vim**. Can also be done with the "-Z" argument.

OPTIONS

The options may be given in any order, before or after filenames. Options without an argument can be combined after a single dash.

- +[num] For the first file the cursor will be positioned on line "num". If "num" is missing, the cursor will be positioned on the last line.
- +/ {pat} For the first file the cursor will be positioned in the line with the first occurrence of {pat}. See ":help search-pattern" for the available search patterns.
- +{command}
- c {command} {command} will be executed after the first file has been read. {command} is interpreted as an Ex command. If the {command} contains spaces it must be enclosed in double quotes (this depends on the shell that is used). Example: vim "+set si" main.c
Note: You can use up to 10 "+" or "-c" commands.
- S {file} {file} will be sourced after the first file has been read. This is equivalent to -c "source {file} ". {file} cannot start with '-'. If {file} is omitted "Session.vim" is used (only works when -S is the last argument).
- cmd {command} Like using "-c", but the command is executed just before processing any vimrc file. You can use up to 10 of these commands, independently from "-c" commands.
- A If **Vim** has been compiled with ARABIC support for editing right-to-left oriented files and Arabic keyboard mapping, this option starts **Vim** in Arabic mode, i.e. 'arabic' is set. Otherwise an error message is given and **Vim** aborts.
- b Binary mode. A few options will be set that makes it possible to edit a binary or executable file.
- C Compatible. Set the 'compatible' option. This will make **Vim** behave mostly like Vi, even though a .vimrc file exists.
- d Start in diff mode. There should between two to eight file name arguments. **Vim** will open all the files and show differences between them. Works like vimdiff(1).
- d {device} Open {device} for use as a terminal. Only on the Amiga. Example: "-d con:20/30/600/150".
- D Debugging. Go to debugging mode when executing the first command from a script.
- e Start **Vim** in Ex mode, just like the executable was called "ex".
- E Start **Vim** in improved Ex mode, just like the executable was called "exim".
- f Foreground. For the GUI version, **Vim** will not fork and detach from the shell it was started in. On the Amiga, **Vim** is not restarted to open a new window. This option should be used when **Vim** is executed by a program that will wait for the edit session to finish (e.g. mail). On the Amiga the ":sh" and ":!" commands will not work.
- nofork Foreground. For the GUI version, **Vim** will not fork and detach from the shell it was started in.

- F If **Vim** has been compiled with FKMAP support for editing right-to-left oriented files and Farsi keyboard mapping, this option starts **Vim** in Farsi mode, i.e. 'fkmap' and 'rightleft' are set. Otherwise an error message is given and **Vim** aborts.
- g If **Vim** has been compiled with GUI support, this option enables the GUI. If no GUI support was compiled in, an error message is given and **Vim** aborts.
- h Give a bit of help about the command line arguments and options. After this **Vim** exits.
- H If **Vim** has been compiled with RIGHTLEFT support for editing right-to-left oriented files and Hebrew keyboard mapping, this option starts **Vim** in Hebrew mode, i.e. 'hkmap' and 'rightleft' are set. Otherwise an error message is given and **Vim** aborts.
- i {viminfo} Specifies the filename to use when reading or writing the viminfo file, instead of the default "~/viminfo". This can also be used to skip the use of the .viminfo file, by giving the name "NONE".
- L Same as -r.
- l Lisp mode. Sets the 'lisp' and 'showmatch' options on.
- m Modifying files is disabled. Resets the 'write' option. You can still modify the buffer, but writing a file is not possible.
- M Modifications not allowed. The 'modifiable' and 'write' options will be unset, so that changes are not allowed and files can not be written. Note that these options can be set to enable making modifications.
- N No-compatible mode. Resets the 'compatible' option. This will make **Vim** behave a bit better, but less Vi compatible, even though a .vimrc file does not exist.
- n No swap file will be used. Recovery after a crash will be impossible. Handy if you want to edit a file on a very slow medium (e.g. floppy). Can also be done with ":set uc=0". Can be undone with ":set uc=200".
- nb Become an editor server for NetBeans. See the docs for details.
- o[N] Open N windows stacked. When N is omitted, open one window for each file.
- O[N] Open N windows side by side. When N is omitted, open one window for each file.
- p[N] Open N tab pages. When N is omitted, open one tab page for each file.
- R Read-only mode. The 'readonly' option will be set. You can still edit the buffer, but will be prevented from accidentally overwriting a file. If you do want to overwrite a file, add an exclamation mark to the Ex command, as in ":w!". The -R option also implies the -n option (see above). The 'readonly' option can be reset with ":set noro". See ":help 'readonly'".
- r List swap files, with information about using them for recovery.
- r {file} Recovery mode. The swap file is used to recover a crashed editing session. The swap file is a file with the same filename as the text file with ".swp" appended. See ":help recovery".
- s Silent mode. Only when started as "Ex" or when the "-e" option was given before the "-s" option.
- s {scriptin} The script file {scriptin} is read. The characters in the file are interpreted as if you had typed them. The same can be done with the command ":source! {scriptin}". If the end of the file is reached before the editor exits, further characters are read from the keyboard.
- T {terminal} Tells **Vim** the name of the terminal you are using. Only required when the automatic way doesn't work. Should be a terminal known to **Vim** (builtin) or defined in the termcap or terminfo file.
- u {vimrc} Use the commands in the file {vimrc} for initializations. All the other initializations are skipped. Use this to edit a special kind of files. It can also be used to skip all initializations

by giving the name "NONE". See ":help initialization" within vim for more details.

- U {gvimrc} Use the commands in the file {gvimrc} for GUI initializations. All the other GUI initializations are skipped. It can also be used to skip all GUI initializations by giving the name "NONE". See ":help gui-init" within vim for more details.
- V[N] Verbose. Give messages about which files are sourced and for reading and writing a viminfo file. The optional number N is the value for 'verbose'. Default is 10.
- v Start **Vim** in Vi mode, just like the executable was called "vi". This only has effect when the executable is called "ex".
- w {scriptout} All the characters that you type are recorded in the file {scriptout}, until you exit **Vim**. This is useful if you want to create a script file to be used with "vim -s" or ":source!". If the {scriptout} file exists, characters are appended.
- W {scriptout} Like -w, but an existing file is overwritten.
- x Use encryption when writing files. Will prompt for a crypt key.
- X Don't connect to the X server. Shortens startup time in a terminal, but the window title and clipboard will not be used.
- y Start **Vim** in easy mode, just like the executable was called "evim" or "eview". Makes **Vim** behave like a click-and-type editor.
- Z Restricted mode. Works like the executable starts with "r".
- Denotes the end of the options. Arguments after this will be handled as a file name. This can be used to edit a filename that starts with a '-'.
- clean Do not use any personal configuration (vimrc, plugins, etc.). Useful to see if a problem reproduces with a clean Vim setup.
- echo-wid GTK GUI only: Echo the Window ID on stdout.
- help Give a help message and exit, just like "-h".
- literal Take file name arguments literally, do not expand wildcards. This has no effect on Unix where the shell expands wildcards.
- nopugin Skip loading plugins. Implied by -u NONE.
- remote Connect to a Vim server and make it edit the files given in the rest of the arguments. If no server is found a warning is given and the files are edited in the current Vim.
- remote-expr {expr} Connect to a Vim server, evaluate {expr} in it and print the result on stdout.
- remote-send {keys} Connect to a Vim server and send {keys} to it.
- remote-silent As --remote, but without the warning when no server is found.
- remote-wait As --remote, but Vim does not exit until the files have been edited.
- remote-wait-silent As --remote-wait, but without the warning when no server is found.
- serverlist List the names of all Vim servers that can be found.
- servername {name} Use {name} as the server name. Used for the current Vim, unless used with a --remote argument, then it's the name of the server to connect to.

--socketid {id}
 GTK GUI only: Use the GtkPlug mechanism to run gvim in another window.
 --startuptime {file}
 During startup write timing messages to the file {fname}.
 --version Print version information and exit.

ON-LINE HELP

Type ":help" in **Vim** to get started. Type ":help subject" to get help on a specific subject. For example: ":help ZZ" to get help for the "ZZ" command. Use <Tab> and CTRL-D to complete subjects ("help cmd-line-completion"). Tags are present to jump from one place to another (sort of hypertext links, see ":help"). All documentation files can be viewed in this way, for example ":help syntax.txt".

FILES

/usr/share/vim/vim82/doc/*.txt
 The **Vim** documentation files. Use ":help doc-file-list" to get the complete list.
 /usr/share/vim/vim82/doc/tags
 The tags file used for finding information in the documentation files.
 /usr/share/vim/vim82/syntax/syntax.vim
 System wide syntax initializations.
 /usr/share/vim/vim82/syntax/*.vim
 Syntax files for various languages.
 /usr/share/vim/vimrc
 System wide **Vim** initializations.
 ~/.vimrc Your personal **Vim** initializations.
 /usr/share/vim/gvimrc
 System wide gvim initializations.
 ~/.gvimrc Your personal gvim initializations.
 /usr/share/vim/vim82/optwin.vim
 Script used for the ":options" command, a nice way to view and set options.
 /usr/share/vim/vim82/menu.vim
 System wide menu initializations for gvim.
 /usr/share/vim/vim82/bugreport.vim
 Script to generate a bug report. See ":help bugs".
 /usr/share/vim/vim82/filetype.vim
 Script to detect the type of a file by its name. See ":help 'filetype'".
 /usr/share/vim/vim82/scripts.vim
 Script to detect the type of a file by its contents. See ":help 'filetype'".
 /usr/share/vim/vim82/print/*.ps
 Files used for PostScript printing.

Vim is based on Stevie, worked on by: Tim Thompson, Tony Andrews and G.R. (Fred) Walter. Although hardly any of the original code remains.

BUGS

Probably. See ":help todo" for a list of known problems.

Note that a number of things that may be regarded as bugs by some, are in fact caused by a too-faithful reproduction of Vi's behaviour. And if you think other things are bugs "because Vi does it differently", you should take a closer look at the vi_diff.txt file (or type :help vi_diff.txt when in Vim). Also have a look at the 'compatible' and 'coptions' options.

NAME

watch – execute a program periodically, showing output fullscreen

SYNOPSIS

watch [*options*] *command*

DESCRIPTION

watch runs *command* repeatedly, displaying its output and errors (the first screenfull). This allows you to watch the program output change over time. By default, *command* is run every 2 seconds and **watch** will run until interrupted.

OPTIONS

-d, --differences[=permanent]

Highlight the differences between successive updates. If the optional *permanent* argument is specified then **watch** will show all changes since the first iteration.

-n, --interval seconds

Specify update interval. The command will not allow quicker than 0.1 second interval, in which the smaller values are converted. Both '.' and ',' work for any locales. The WATCH_INTERVAL environment can be used to persistently set a non-default interval (following the same rules and formatting).

-p, --precise

Make **watch** attempt to run *command* every --interval seconds. Try it with **ntpdate** (if present) and notice how the fractional seconds stays (nearly) the same, as opposed to normal mode where they continuously increase.

-t, --no-title

Turn off the header showing the interval, command, and current time at the top of the display, as well as the following blank line.

-b, --beep

Beep if command has a non-zero exit.

-e, --erexit

Freeze updates on command error, and exit after a key press.

-g, --chgexit

Exit when the output of *command* changes.

-c, --color

Interpret ANSI color and style sequences.

-x, --exec

Pass *command* to **exec(2)** instead of **sh -c** which reduces the need to use extra quoting to get the desired effect.

-w, --no-linewrap

Turn off line wrapping. Long lines will be truncated instead of wrapped to the next line.

-h, --help

Display help text and exit.

-v, --version

Display version information and exit.

EXIT STATUS

0 Success.

1 Various failures.

2 Forking the process to watch failed.

3 Replacing child process stdout with write side pipe failed.

4 Command execution failed.

- 5 Closing child process write pipe failed.
- 7 IPC pipe creation failed.
- 8 Getting child process return value with `waitpid(2)` failed, or command exited up on error.
- other The watch will propagate command exit status as child exit status.

ENVIRONMENT

The behaviour of **watch** is affected by the following environment variables.

WATCH_INTERVAL

Update interval, follows the same rules as the `--interval` command line option.

NOTES

POSIX option processing is used (i.e., option processing stops at the first non-option argument). This means that flags after *command* don't get interpreted by **watch** itself.

BUGS

Upon terminal resize, the screen will not be correctly repainted until the next scheduled update. All `--differences` highlighting is lost on that update as well.

Non-printing characters are stripped from program output. Use `cat -v` as part of the command pipeline if you want to see them.

Combining Characters that are supposed to display on the character at the last column on the screen may display one column early, or they may not display at all.

Combining Characters never count as different in `--differences` mode. Only the base character counts.

Blank lines directly after a line which ends in the last column do not display.

`--precise` mode doesn't yet have advanced temporal distortion technology to compensate for a *command* that takes more than `--interval` seconds to execute. **watch** also can get into a state where it rapid-fires as many executions of *command* as it can to catch up from a previous executions running longer than `--interval` (for example, `netstat` taking ages on a DNS lookup).

EXAMPLES

To watch for mail, you might do

```
watch -n 60 from
```

To watch the contents of a directory change, you could use

```
watch -d ls -l
```

If you're only interested in files owned by user joe, you might use

```
watch -d 'ls -l | fgrep joe'
```

To see the effects of quoting, try these out

```
watch echo $$  
watch echo '$$'  
watch echo "$$"$$"
```

To see the effect of precision time keeping, try adding `-p` to

```
watch -n 10 sleep 1
```

You can watch for your administrator to install the latest kernel with

```
watch uname -r
```

(Note that `-p` isn't guaranteed to work across reboots, especially in the face of `ntpdate` (if present) or other bootup time-changing mechanisms)

NAME

wc – print newline, word, and byte counts for each file

SYNOPSIS

wc [*OPTION*]... [*FILE*]...
wc [*OPTION*]... --files0-from=*F*

DESCRIPTION

Print newline, word, and byte counts for each FILE, and a total line if more than one FILE is specified. A word is a non-zero-length sequence of characters delimited by white space.

With no FILE, or when FILE is **-**, read standard input.

The options below may be used to select which counts are printed, always in the following order: newline, word, character, byte, maximum line length.

-c, --bytes

print the byte counts

-m, --chars

print the character counts

-l, --lines

print the newline counts

--files0-from=*F*

read input from the files specified by NUL-terminated names in file *F*; If *F* is **-** then read names from standard input

-L, --max-line-length

print the maximum display width

-w, --words

print the word counts

--help display this help and exit**--version**

output version information and exit

NAME

whatis – display one-line manual page descriptions

SYNOPSIS

```
whatis [ -dlv?V ] [ -r | -w ] [ -s list ] [ -m system [ ,... ] ] [ -M path ] [ -L locale ] [ -C file ] name ...
```

DESCRIPTION

Each manual page has a short description available within it. **whatis** searches the manual page names and displays the manual page descriptions of any *name* matched.

name may contain wildcards (**-w**) or be a regular expression (**-r**). Using these options, it may be necessary to quote the *name* or escape (\) the special characters to stop the shell from interpreting them.

index databases are used during the search, and are updated by the **mandb** program. Depending on your installation, this may be run by a periodic cron job, or may need to be run manually after new manual pages have been installed. To produce an old style text **whatis** database from the relative **index** database, issue the command:

```
whatis -M manpath -w '*' | sort > manpath/whatis
```

where *manpath* is a manual page hierarchy such as */usr/man*.

OPTIONS**-d, --debug**

Print debugging information.

-v, --verbose

Print verbose warning messages.

-r, --regex

Interpret each *name* as a regular expression. If *aname* matches any part of a page name, a match will be made. This option causes **whatis** to be somewhat slower due to the nature of database searches.

-w, --wildcard

Interpret each *name* as a pattern containing shell style wildcards. For a match to be made, an expanded *name* must match the entire page name. This option causes **whatis** to be somewhat slower due to the nature of database searches.

-l, --long

Do not trim output to the terminal width. Normally, output will be truncated to the terminal width to avoid ugly results from poorly-written **NAME** sections.

-s *list*, --sections=*list*, --section=*list*

Search only the given manual sections. *list* is a colon- or comma-separated list of sections. If an entry in *list* is a simple section, for example "3", then the displayed list of descriptions will include pages in sections "3", "3perl", "3x", and so on; while if an entry in *list* has an extension, for example "3perl", then the list will only include pages in that exact part of the manual section.

-m *system* [,...], --systems=*system* [,...]

If this system has access to other operating systems' manual page names, they can be accessed using this option. To search NewOS's manual page names, use the option **-m NewOS**.

The *system* specified can be a combination of comma delimited operating system names. To include a search of the native operating system's manual page names, include the system name **man** in the argument string. This option will override the **\$SYSTEM** environment variable.

-M *path*, --manpath=*path*

Specify an alternate set of colon-delimited manual page hierarchies to search. By default, **whatis** uses the **\$MANPATH** environment variable, unless it is empty or unset, in which case it will

determine an appropriate manpath based on your **\$PATH** environment variable. This option overrides the contents of **\$MANPATH**.

-L *locale*, **--locale**=*locale*

whatis will normally determine your current locale by a call to the C function **setlocale(3)** which interrogates various environment variables, possibly including **\$LC_MESSAGES** and **\$LANG**. To temporarily override the determined value, use this option to supply a *locale* string directly to **whatis**. Note that it will not take effect until the search for pages actually begins. Output such as the help message will always be displayed in the initially determined locale.

-C *file*, **--config-file**=*file*

Use this user configuration file rather than the default of **~/.manpath**.

-?, --help

Print a help message and exit.

--usage

Print a short usage message and exit.

-V, --version

Display version information.

EXIT STATUS

- 0** Successful program execution.
- 1** Usage, syntax or configuration file error.
- 2** Operational error.
- 16** Nothing was found that matched the criteria specified.

ENVIRONMENT

SYSTEM

If **\$SYSTEM** is set, it will have the same effect as if it had been specified as the argument to the **-m** option.

MANPATH

If **\$MANPATH** is set, its value is interpreted as the colon-delimited manual page hierarchy search path to use.

See the **SEARCH PATH** section of **manpath(5)** for the default behaviour and details of how this environment variable is handled.

MANWIDTH

If **\$MANWIDTH** is set, its value is used as the terminal width (see the **--long** option). If it is not set, the terminal width will be calculated using the value of **\$COLUMNS**, and **ioctl(2)** if available, or falling back to 80 characters if all else fails.

FILES

/usr/share/man/index.(bt/db/dir/pag)

A traditional global *index* database cache.

/var/cache/man/index.(bt/db/dir/pag)

An FHS compliant global *index* database cache.

/usr/share/man/.../whatis

A traditional **whatis** text database.

<https://savannah.nongnu.org/bugs/?group=man-db>

NAME

whereis – locate the binary, source, and manual page files for a command

SYNOPSIS

whereis [options] [**-BMS** *directory...* **-f**] *name...*

DESCRIPTION

whereis locates the binary, source and manual files for the specified command names. The supplied names are first stripped of leading pathname components. Prefixes of **s**, resulting from use of source code control are also dealt with. **whereis** then attempts to locate the desired program in the standard Linux places, and in the places specified by **\$PATH** and **\$MANPATH**.

The search restrictions (options **-b**, **-m** and **-s**) are cumulative and apply to the subsequent *name* patterns on the command line. Any new search restriction resets the search mask. For example,

whereis -bm ls tr -m gcc

searches for "ls" and "tr" binaries and man pages, and for "gcc" man pages only.

The options **-B**, **-M** and **-S** reset search paths for the subsequent *name* patterns. For example,

whereis -m ls -M /usr/share/man/man1 -f cal

searches for "ls" man pages in all default paths, but for "cal" in the */usr/share/man/man1* directory only.

OPTIONS**-b**

Search for binaries.

-m

Search for manuals.

-s

Search for sources.

-u

Only show the command names that have unusual entries. A command is said to be unusual if it does not have just one entry of each explicitly requested type. Thus '**whereis -m -u ***' asks for those files in the current directory which have no documentation file, or more than one.

-B *list*

Limit the places where **whereis** searches for binaries, by a whitespace-separated list of directories.

-M *list*

Limit the places where **whereis** searches for manuals and documentation in Info format, by a whitespace-separated list of directories.

-S *list*

Limit the places where **whereis** searches for sources, by a whitespace-separated list of directories.

-f

Terminates the directory list and signals the start of filenames. It *must* be used when any of the **-B**, **-M**, or **-S** options is used.

-l

Output the list of effective lookup paths that **whereis** is using. When none of **-B**, **-M**, or **-S** is

specified, the option will output the hard-coded paths that the command was able to find on the system.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

FILE SEARCH PATHS

By default **whereis** tries to find files from hard-coded paths, which are defined with glob patterns. The command attempts to use the contents of **\$PATH** and **\$MANPATH** environment variables as default search path. The easiest way to know what paths are in use is to add the **-l** listing option. Effects of the **-B**, **-M**, and **-S** are displayed with **-l**.

ENVIRONMENT**WHEREIS_DEBUG=all**

enables debug output.

EXAMPLES

To find all files in */usr/bin* which are not documented in */usr/man/man1* or have no source in */usr/src*:

```
cd /usr/bin whereis -u -ms -M /usr/man/man1 -S /usr/src -f *
```

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **whereis** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

who – show who is logged on

SYNOPSIS

who [*OPTION*]... [*FILE* / *ARG1 ARG2*]

DESCRIPTION

Print information about users who are currently logged in.

-a, --all

same as **-b -d --login -p -r -t -T -u**

-b, --boot

time of last system boot

-d, --dead

print dead processes

-H, --heading

print line of column headings

--ips print ips instead of hostnames. with **--lookup**, canonicalizes based on stored IP, if available, rather than stored hostname

-l, --login

print system login processes

--lookup

attempt to canonicalize hostnames via DNS

-m only hostname and user associated with stdin

-p, --process

print active processes spawned by init

-q, --count

all login names and number of users logged on

-r, --runlevel

print current runlevel

-s, --short

print only name, line, and time (default)

-t, --time

print last system clock change

-T, -w, --mesg

add user's message status as +, - or ?

-u, --users

list users logged in

--message

same as **-T**

--writable

same as **-T**

--help display this help and exit

--version

output version information and exit

If FILE is not specified, use */var/run/utmp*. */var/log/wtmp* as FILE is common. If ARG1 ARG2 given, **-m** presumed: 'am i' or 'mom likes' are usual.

NAME

xattr – Extended attributes

DESCRIPTION

Extended attributes are name:value pairs associated permanently with files and directories, similar to the environment strings associated with a process. An attribute may be defined or undefined. If it is defined, its value may be empty or non-empty.

Extended attributes are extensions to the normal attributes which are associated with all inodes in the system (i.e., the `stat(2)` data). They are often used to provide additional functionality to a filesystem—for example, additional security features such as Access Control Lists (ACLs) may be implemented using extended attributes.

Users with search access to a file or directory may use `listxattr(2)` to retrieve a list of attribute names defined for that file or directory.

Extended attributes are accessed as atomic objects. Reading (`getxattr(2)`) retrieves the whole value of an attribute and stores it in a buffer. Writing (`setxattr(2)`) replaces any previous value with the new value.

Space consumed for extended attributes may be counted towards the disk quotas of the file owner and file group.

Extended attribute namespaces

Attribute names are null-terminated strings. The attribute name is always specified in the fully qualified *namespace.attribute* form, for example, `user.mime_type`, `trusted.md5sum`, `system.posix_acl_access`, or `security.selinux`.

The namespace mechanism is used to define different classes of extended attributes. These different classes exist for several reasons; for example, the permissions and capabilities required for manipulating extended attributes of one namespace may differ to another.

Currently, the `security`, `system`, `trusted`, and `user` extended attribute classes are defined as described below. Additional classes may be added in the future.

Extended security attributes

The security attribute namespace is used by kernel security modules, such as Security Enhanced Linux, and also to implement file capabilities (see `capabilities(7)`). Read and write access permissions to security attributes depend on the policy implemented for each security attribute by the security module. When no security module is loaded, all processes have read access to extended security attributes, and write access is limited to processes that have the `CAP_SYS_ADMIN` capability.

System extended attributes

System extended attributes are used by the kernel to store system objects such as Access Control Lists. Read and write access permissions to system attributes depend on the policy implemented for each system attribute implemented by filesystems in the kernel.

Trusted extended attributes

Trusted extended attributes are visible and accessible only to processes that have the `CAP_SYS_ADMIN` capability. Attributes in this class are used to implement mechanisms in user space (i.e., outside the kernel) which keep information in extended attributes to which ordinary processes should not have access.

User extended attributes

User extended attributes may be assigned to files and directories for storing arbitrary additional information such as the mime type, character set or encoding of a file. The access permissions for user attributes are defined by the file permission bits: read permission is required to retrieve the attribute value, and writer permission is required to change it.

The file permission bits of regular files and directories are interpreted differently from the file permission bits of special files and symbolic links. For regular files and directories the file permission bits define access to the file's contents, while for device special files they define access to the device described by the special file. The file permissions of symbolic links are not used in access checks. These differences would allow users to consume filesystem resources in a way not controllable by disk quotas for group or world

writable special files and directories.

For this reason, user extended attributes are allowed only for regular files and directories, and access to user extended attributes is restricted to the owner and to users with appropriate capabilities for directories with the sticky bit set (see the **chmod(1)** manual page for an explanation of the sticky bit).

Filesystem differences

The kernel and the filesystem may place limits on the maximum number and size of extended attributes that can be associated with a file. The VFS-imposed limits on attribute names and values are 255 bytes and 64 kB, respectively. The list of attribute names that can be returned is also limited to 64 kB (see BUGS in **listxattr(2)**).

Some filesystems, such as Reiserfs (and, historically, ext2 and ext3), require the filesystem to be mounted with the **user_xattr** mount option in order for user extended attributes to be used.

In the current ext2, ext3, and ext4 filesystem implementations, the total bytes used by the names and values of all of a file's extended attributes must fit in a single filesystem block (1024, 2048 or 4096 bytes, depending on the block size specified when the filesystem was created).

In the Btrfs, XFS, and Reiserfs filesystem implementations, there is no practical limit on the number of extended attributes associated with a file, and the algorithms used to store extended attribute information on disk are scalable.

In the JFS, XFS, and Reiserfs filesystem implementations, the limit on bytes used in an EA value is the ceiling imposed by the VFS.

In the Btrfs filesystem implementation, the total bytes used for the name, value, and implementation overhead bytes is limited to the filesystem *nodesize* value (16 kB by default).

STANDARDS

Extended attributes are not specified in POSIX.1, but some other systems (e.g., the BSDs and Solaris) provide a similar feature.

NOTES

Since the filesystems on which extended attributes are stored might also be used on architectures with a different byte order and machine word size, care should be taken to store attribute values in an architecture-independent format.

This page was formerly named **attr(5)**.

NAME

xfs – layout, mount options, and supported file attributes for the XFS filesystem

DESCRIPTION

An XFS filesystem can reside on a regular disk partition or on a logical volume. An XFS filesystem has up to three parts: a data section, a log section, and a realtime section. Using the default **mkfs.xfs(8)** options, the realtime section is absent, and the log area is contained within the data section. The log section can be either separate from the data section or contained within it. The filesystem sections are divided into a certain number of *blocks*, whose size is specified at **mkfs.xfs(8)** time with the **-b** option.

The data section contains all the filesystem metadata (inodes, directories, indirect blocks) as well as the user file data for ordinary (non-realtime) files and the log area if the log is *internal* to the data section. The data section is divided into a number of *allocation groups*. The number and size of the allocation groups are chosen by **mkfs.xfs(8)** so that there is normally a small number of equal-sized groups. The number of allocation groups controls the amount of parallelism available in file and block allocation. It should be increased from the default if there is sufficient memory and a lot of allocation activity. The number of allocation groups should not be set very high, since this can cause large amounts of CPU time to be used by the filesystem, especially when the filesystem is nearly full. More allocation groups are added (of the original size) when **xfs_growfs(8)** is run.

The log section (or area, if it is internal to the data section) is used to store changes to filesystem metadata while the filesystem is running until those changes are made to the data section. It is written sequentially during normal operation and read only during mount. When mounting a filesystem after a crash, the log is read to complete operations that were in progress at the time of the crash.

The realtime section is used to store the data of realtime files. These files had an attribute bit set through **xfctl(3)** after file creation, before any data was written to the file. The realtime section is divided into a number of *extents* of fixed size (specified at **mkfs.xfs(8)** time). Each file in the realtime section has an extent size that is a multiple of the realtime section extent size.

Each allocation group contains several data structures. The first sector contains the superblock. For allocation groups after the first, the superblock is just a copy and is not updated after **mkfs.xfs(8)**. The next three sectors contain information for block and inode allocation within the allocation group. Also contained within each allocation group are data structures to locate free blocks and inodes; these are located through the header structures.

Each XFS filesystem is labeled with a Universal Unique Identifier (UUID). The UUID is stored in every allocation group header and is used to help distinguish one XFS filesystem from another, therefore you should avoid using **dd(1)** or other block-by-block copying programs to copy XFS filesystems. If two XFS filesystems on the same machine have the same UUID, **xfsdump(8)** may become confused when doing incremental and resumed dumps. **xfsdump(8)** and **xfs_r estore(8)** are recommended for making copies of XFS filesystems.

OPERATIONS

Some functionality specific to the XFS filesystem is accessible to applications through the **xfctl(3)** and by-handle (see **open_by_handle(3)**) interfaces.

MOUNT OPTIONS

The following XFS-specific mount options may be used when mounting an XFS filesystem. Other generic options may be used as well; refer to the **mount(8)** manual page for more details.

allocsize=size

Sets the buffered I/O end-of-file preallocation size when doing delayed allocation writeout. Valid values for this option are page size (typically 4KiB) through to 1GiB, inclusive, in power-of-2 increments.

The default behavior is for dynamic end-of-file preallocation size, which uses a set of heuristics to optimise the preallocation size based on the current allocation patterns within the file and the access patterns to the file. Specifying a fixed allocsize value turns off the dynamic behavior.

attr2|noattr2

Note: These options have been **deprecated** as of kernel v5.10; The noattr2 option will be removed no earlier than in September 2025 and attr2 option will be immutable default.

The options enable/disable an "opportunistic" improvement to be made in the way inline extended attributes are stored on-disk. When the new form is used for the first time when attr2 is selected (either when setting or removing extended attributes) the on-disk superblock feature bit field will be updated to reflect this format being in use.

The default behavior is determined by the on-disk feature bit indicating that attr2 behavior is active. If either mount option is set, then that becomes the new default used by the filesystem.

CRC enabled filesystems always use the attr2 format, and so will reject the noattr2 mount option if it is set.

dax=value

Set CPU direct access (DAX) behavior for the current filesystem. This mount option accepts the following values:

"dax=inode" DAX will be enabled only on regular files with FS_XFLAG_DAX applied.

"dax=never" DAX will not be enabled for any files. FS_XFLAG_DAX will be ignored.

"dax=always" DAX will be enabled for all regular files, regardless of the FS_XFLAG_DAX state.

If no option is used when mounting a filesystem stored on a DAX capable device, dax=inode will be used as default.

For details regarding DAX behavior in kernel, please refer to kernel's documentation at filesystems/dax.txt

discard|nodiscard

Enable/disable the issuing of commands to let the block device reclaim space freed by the filesystem. This is useful for SSD devices, thinly provisioned LUNs and virtual machine images, but may have a performance impact.

Note: It is currently recommended that you use the fstrim application to discard unused blocks rather than the discard mount option because the performance impact of this option is quite severe. For this reason, nodiscard is the default.

grpid|bsdgroups|nogrp|sysvgroups

These options define what group ID a newly created file gets. When grpid is set, it takes the group ID of the directory in which it is created; otherwise it takes the fsgid of the current process, unless the directory has the setgid bit set, in which case it takes the gid from the parent directory, and also gets the setgid bit set if it is a directory itself.

filestreams

Make the data allocator use the filestreams allocation mode across the entire filesystem rather than just on directories configured to use it.

ikeep|noikeep

Note: These options have been **deprecated** as of kernel v5.10; The noikeep option will be removed no earlier than in September 2025 and ikeep option will be immutable default.

When ikeep is specified, XFS does not delete empty inode clusters and keeps them around on disk. When noikeep is specified, empty inode clusters are returned to the free space pool. noikeep is the

default.

inode32|inode64

When inode32 is specified, it indicates that XFS limits inode creation to locations which will not result in inode numbers with more than 32 bits of significance.

When inode64 is specified, it indicates that XFS is allowed to create inodes at any location in the filesystem, including those which will result in inode numbers occupying more than 32 bits of significance.

inode32 is provided for backwards compatibility with older systems and applications, since 64 bits inode numbers might cause problems for some applications that cannot handle large inode numbers. If applications are in use which do not handle inode numbers bigger than 32 bits, the inode32 option should be specified.

For kernel v3.7 and later, inode64 is the default.

largeio|nolargeio

If "nolargeio" is specified, the optimal I/O reported in st_blksize by stat(2) will be as small as possible to allow user applications to avoid inefficient read/modify/write I/O. This is typically the page size of the machine, as this is the granularity of the page cache.

If "largeio" specified, a filesystem that was created with a "swidth" specified will return the "swidth" value (in bytes) in st_blksize. If the filesystem does not have a "swidth" specified but does specify an "allocsize" then "allocsize" (in bytes) will be returned instead. Otherwise the behavior is the same as if "nolargeio" was specified. nolargeio is the default.

logbufs=value

Set the number of in-memory log buffers. Valid numbers range from 2–8 inclusive.

The default value is 8 buffers.

If the memory cost of 8 log buffers is too high on small systems, then it may be reduced at some cost to performance on metadata intensive workloads. The logsize option below controls the size of each buffer and so is also relevant to this case.

logsize=value

Set the size of each in-memory log buffer. The size may be specified in bytes, or in kibibytes (KiB) with a "k" suffix. Valid sizes for version 1 and version 2 logs are 16384 (value=16k) and 32768 (value=32k). Valid sizes for version 2 logs also include 65536 (value=64k), 131072 (value=128k) and 262144 (value=256k). The logsize must be an integer multiple of the log stripe unit configured at mkfs time.

The default value for version 1 logs is 32768, while the default value for version 2 logs is max(32768, log_sunit).

logdev=device and rtdev=device

Use an external log (metadata journal) and/or real-time device. An XFS filesystem has up to three parts: a data section, a log section, and a real-time section. The real-time section is optional, and the log section can be separate from the data section or contained within it.

noalign

Data allocations will not be aligned at stripe unit boundaries. This is only relevant to filesystems created with non-zero data alignment parameters (sunit, swidth) by mkfs.

norecovery

The filesystem will be mounted without running log recovery. If the filesystem was not cleanly unmounted, it is likely to be inconsistent when mounted in "norecovery" mode. Some files or directories may not be accessible because of this. Filesystems mounted "norecovery" must be

mounted read-only or the mount will fail.

nouuid Don't check for double mounted file systems using the file system uuid. This is useful to mount LVM snapshot volumes, and often used in combination with "norecovery" for mounting read-only snapshots.

noquota

Forcibly turns off all quota accounting and enforcement within the filesystem.

uquota/usrquota/quota/uqnoenforce/qnoenforce

User disk quota accounting enabled, and limits (optionally) enforced. Refer to xfs_quota(8) for further details.

gquota/grpquota/gqnoenforce

Group disk quota accounting enabled and limits (optionally) enforced. Refer to xfs_quota(8) for further details.

pquota/prjquota/pqnoenforce

Project disk quota accounting enabled and limits (optionally) enforced. Refer to xfs_quota(8) for further details.

sunit=value and swidth=value

Used to specify the stripe unit and width for a RAID device or a stripe volume. "value" must be specified in 512-byte block units. These options are only relevant to filesystems that were created with non-zero data alignment parameters.

The sunit and swidth parameters specified must be compatible with the existing filesystem alignment characteristics. In general, that means the only valid changes to sunit are increasing it by a power-of-2 multiple. Valid swidth values are any integer multiple of a valid sunit value.

Typically the only time these mount options are necessary if after an underlying RAID device has had its geometry modified, such as adding a new disk to a RAID5 lun and reshaping it.

swalloc

Data allocations will be rounded up to stripe width boundaries when the current end of file is being extended and the file size is larger than the stripe width size.

wsync When specified, all filesystem namespace operations are executed synchronously. This ensures that when the namespace operation (create, unlink, etc) completes, the change to the namespace is on stable storage. This is useful in HA setups where failover must not result in clients seeing inconsistent namespace presentation during or after a failover event.

REMOVED MOUNT OPTIONS

The following mount options have been removed from the kernel, and will yield mount failures if specified. Mount options are deprecated for a significant period time prior to removal.

Name	Removed
---	-----
delaylog/nodelaylog	v4.0
ihashsize	v4.0
irixsgid	v4.0
osyncisdsync/osyncisosync	v4.0
barrier/nobarrier	v4.19

FILE ATTRIBUTES

The XFS filesystem supports setting the following file attributes on Linux systems using the chattr(1) utility:

a - append only

A - no atime updates

d - no dump

i - immutable

S - synchronous updates

For descriptions of these attribute flags, please refer to the **chattr(1)** man page.

SEE ALSO

chattr(1), **xfsctl(3)**, **mount(8)**, **mkfs.xfs(8)**, **xfs_info(8)**, **xfs_admin(8)**, **xfsdump(8)**, **xfsrestore(8)**.

NAME

xkill - kill a client by its X resource

SYNOPSIS

xkill [**-display** *displayname*] [**-id** *resource*] [**-button** *number*] [**-frame**] [**-all**] [**-version**]

DESCRIPTION

Xkill is a utility for forcing the X server to close connections to clients. This program is very dangerous, but is useful for aborting programs that have displayed undesired windows on a user's screen. If no resource identifier is given with **-id**, *xkill* will display a special cursor as a prompt for the user to select a window to be killed. If a pointer button is pressed over a non-root window, the server will close its connection to the client that created the window.

OPTIONS

-display *displayname*

This option specifies the name of the X server to contact.

-id *resource*

This option specifies the X identifier for the resource whose creator is to be aborted. If no resource is specified, *xkill* will display a special cursor with which you should select a window to be kill.

-button *number*

This option specifies the number of pointer button that should be used in selecting a window to kill. If the word "any" is specified, any button on the pointer may be used. By default, the first button in the pointer map (which is usually the leftmost button) is used.

-all This option indicates that all clients with top-level windows on the screen should be killed. *Xkill* will ask you to select the root window with each of the currently defined buttons to give you several chances to abort. Use of this option is highly discouraged.

-frame This option indicates that *xkill* should ignore the standard conventions for finding top-level client windows (which are typically nested inside a window manager window), and simply believe that you want to kill direct children of the root.

-version

This option makes *xkill* print its version and exit without killing anything.

CAVEATS

This command does not provide any warranty that the application whose connection to the X server is closed will abort nicely, or even abort at all. All this command does is to close the connection to the X server. Many existing applications do indeed abort when their connection to the X server is closed, but some can choose to continue.

XDEFUALTS

Button Specifies a specific pointer button number or the word "any" to use when selecting windows.

yum(8) - Linux man page

Name

yum - Yellowdog Updater Modified

Synopsis

yum [options] [command] [package ...]

Description

yum is an interactive, rpm based, package manager. It can automatically perform system updates, including dependency analysis and obsolete processing based on "repository" metadata. It can also perform installation of new packages, removal of old packages and perform queries on the installed and/or available packages among many other commands/services (see below). **yum** is similar to other high level package managers like apt-get and smart.

While there are some graphical interfaces directly to the **yum** code, more recent graphical interface development is happening with PackageKit and the gnome-packagekit application.

command is one of:

- * install package1 [package2] [...]
- * update [package1] [package2] [...]
- * update-to [package1] [package2] [...]
- * check-update
- * upgrade [package1] [package2] [...]
- * upgrade-to [package1] [package2] [...]
- * distribution-synchronization [package1] [package2] [...]
- * remove | erase package1 [package2] [...]
- * list [...]

```

Unless the --help or -h option is given, one of the above commands must be present.

Repository configuration is honored in all operations.

install

Is used to install the latest version of a package or group of packages while ensuring that all dependencies are satisfied. (See **Specifying package names** for more information) If no package matches the given package **name(s)**, they are assumed to be a shell glob and any matches are then installed. If the name starts with an @ character the rest of the name is used as though passed to the groupinstall command. If the name starts with a - character, then a search is done within the transaction and any matches are removed. If the name is a file, then install works like localinstall. If the name doesn't match a package, then package "provides" are searched (e.g. "_sqlitecache.so()(64bit)") as are filelists (Eg. "/usr/bin/yum"). Also note that for filelists, wildcards will match multiple packages.

update

If run without any packages, update will update every currently installed package. If one or more packages or package globs are specified, Yum will only update the listed packages. While updating packages, **yum** will ensure that all dependencies are satisfied. (See **Specifying package names** for more information) If the packages or globs specified match to packages which are not currently installed then update will not install them. update operates on groups, files, provides and filelists just like the "install" command.

If the main obsoletes configure option is true (default) or the --obsoletes flag is present **yum** will include package obsoletes in its calculations - this makes it better for distro-version changes, for example: upgrading from somelinux 8.0 to somelinux 9.

Note that "**update**" works on installed packages first, and only if there are no matches does it look for available packages. The difference is most noticeable when you do "**update** foo-1-2" which will act exactly as "**update** foo" if foo-1-2 is installed. You can use the "**update-to**" if you'd prefer that nothing happen in the above case.

update-to

This command works like "**update**" but always specifies the version of the package we want to update to.

check-update

Implemented so you could know if your machine had any updates that needed to be applied without running it interactively. Returns exit value of 100 if there are packages available for an update. Also returns a list of the packages to be updated in list format. Returns 0 if no packages are available for update. Returns 1 if an error occurred. Running in verbose mode also shows obsoletes.

upgrade

Is the same as the update command with the --obsoletes flag set. See update for more details.

upgrade-to

This command works like "**upgrade**" but always specifies the version of the package we want to update to.

distribution-synchronization or distro-sync

Synchronizes the installed package set with the latest packages available, this is done by either obsoleting, upgrading or downgrading as appropriate. This will "normally" do the same thing as the upgrade command however if you have the package FOO installed at version 4, and the latest available is only version 3, then this command will **downgrade** FOO to version 3.

This command does not perform operations on groups, local packages or negative selections.

remove or erase

Are used to remove the specified packages from the system as well as removing any packages which depend on the package being removed. remove operates on groups, files, provides and filelists just like the "install" command.(See **Specifying package names** for more information)

Note that "yum" is included in the protected_packages configuration, by default. So you can't accidentally remove yum itself.

list

Is used to list various information about available packages; more complete details are available in the *List Options* section below.

provides or whatprovides

Is used to find out which package provides some feature or file. Just use a specific name or a file-glob-syntax wildcards to list the packages available or installed that provide that feature or file.

search

This is used to find packages when you know something about the package but aren't sure of it's name. By default search will try searching just package names and summaries, but if that "fails" it will then try descriptions and url.

Yum search orders the results so that those packages matching more terms will appear first.

You can force searching everything by specifying "all" as the first argument.

info

Is used to list a description and summary information about available packages; takes the same arguments as in the *List Options* section below.

clean

Is used to clean up various things which accumulate in the **yum** cache directory over time. More complete details can be found in the *Clean Options* section below.

makecache

Is used to download and make usable all the metadata for the currently enabled **yum** repos.

groupinstall

Is used to install all of the individual packages in a group, of the specified types (this works as if you'd taken each of those package names and put them on the command line for a "yum install" command). The group_package_types configuration option specifies which types will be installed.

groupupdate

Is just an alias for groupinstall, which will do the right thing because "yum install X" and "yum update X" do the same thing, when X is already installed.

grouplist

Is used to list the available groups from all **yum** repos. Groups are marked as "installed" if all mandatory packages are installed, or if a group doesn't have any mandatory packages then it is installed if any of the optional or default package are installed. The optional "hidden" argument will also list groups marked as not being "user visible". If you pass the -v option, to enable verbose mode, then the groupids are displayed.

groupremove

Is used to remove all of the packages in a group, unlike "groupinstall" this will remove everything regardless of group_package_types. It is worth pointing out that packages can be in more than one group, so "groupinstall X Y" followed by "groupremove Y" does not do give you the same result as "groupinstall X".

The groupremove_leaf_only configuration changes the behaviour of this command to only remove packages which aren't required by something else.

groupinfo

Is used to give the description and package list of a group (and which type those packages are marked as). Note that you can use the yum-filter-data and yum-list-data plugins to get/use the data the other way around (Ie. what groups own packages need updating). If you pass the -v option, to enable verbose mode, then the package names are matched against installed/available packages similar to the list command.

shell

Is used to enter the 'yum shell', when a filename is specified the contents of that file is executed in yum shell mode. See **yum-shell(8)** for more info

resolvedep

Is used to list packages providing the specified dependencies, at most one package is listed per dependency.

localinstall

Is used to install a set of local rpm files. If required the enabled repositories will be used to resolve dependencies. Note that the install command will do a local install, if given a filename. This option is maintained for legacy reasons only.

localupdate

Is used to update the system by specifying local rpm files. Only the specified rpm files of which an older version is already installed will be installed, the remaining specified packages will be ignored. If required the enabled repositories will be used to resolve dependencies. Note that the update command will do a local update, if given a filename. This option is maintained for legacy reasons only.

reinstall

Will reinstall the identically versioned package as is currently installed. This does not work for "installonly" packages, like Kernels. reinstall operates on groups, files, provides and filelists just like the "install" command.

downgrade

Will try and downgrade a package from the version currently installed to the previously highest version (or the specified version). The depsolver will not necessarily work, but if you specify all the packages it should work (and thus. all the simple cases will work). Also this does not work

for "installonly" packages, like Kernels. downgrade operates on groups, files, provides, filelists and rpm files just like the "install" command.

deplist

Produces a list of all dependencies and what packages provide those dependencies for the given packages.

repolist

Produces a list of configured repositories. The default is to list all enabled repositories. If you pass -v, for verbose mode, more information is listed. If the first argument is 'enabled', 'disabled' or 'all' then the command will list those types of repos.

You can pass repo id or name arguments, or wildcards which to match against both of those. However if the id or name matches exactly then the repo will be listed even if you are listing enabled repos. and it is disabled.

In non-verbose mode the first column will start with a '*' if the repo. has metalink data and the latest metadata is not local. For non-verbose mode the last column will also display the number of packages in the repo. and (if there are any user specified excludes) the number of packages excluded.

One last special feature of repolist, is that if you are in non-verbose mode then yum will ignore any repo errors and output the information it can get (Eg. "yum clean all; yum -C repolist" will output something, although the package counts/etc. will be zeroed out).

version

Produces a "version" of the rpmbdb, and of the enabled repositories if "all" is given as the first argument. You can also specify version groups in the version-groups configuration file. If you pass -v, for verbose mode, more information is listed. The version is calculated by taking an SHA1 hash of the packages (in sorted order), and the checksum_type/checksum_data entries from the yumdb. Note that this rpmbdb version is now also used significantly within yum (esp. in yum history).

The version command will now show "groups" of packages as a separate version, and so takes sub-commands:

"version grouplist" - List the defined version groups.

"version groupinfo" - Get the complete list of packages within one or more version groups.

"version installed" - This is the default, only show the version information for installed packages.

"version available" - Only show the version information for available packages.

"version all" - Show the version information for installed and available packages.

"version nogroups | nogroups-*" - Just show the main version information.

"version group-*" - Just show the grouped version information, if more arguments are given then only show the data for those groups.

history

The history command allows the user to view what has happened in past transactions (assuming the history_record config. option is set). You can use info/list/packages-list/packages-info/summary to view what happened, undo/redo/rollback to act on that information and new to start a new history file.

The info/list/summary commands take either a transaction id or a package (with wildcards, as in **Specifying package names**), all three can also be passed no arguments. list can be passed the keyword "all" to list all the transactions.

The packages-list/packages-info commands takes a package (with wildcards, as in **Specifying package names**). And show data from the point of view of that package.

The undo/redo/rollback commands take either a single transaction id or the keyword last and an offset from the last transaction (Eg. if you've done 250 transactions, "last" refers to transaction 250, and "last-4" refers to transaction 246).

The undo/redo commands act on the specified transaction, undo'ing or repeating the work of that transaction. While the rollback command will undo all transactions up to the point of the specified transaction. For example, if you have 3 transactions, where package A; B and C were installed respectively. Then "undo 1" will try to remove package A, "redo 1" will try to install package A (if it is not still installed), and "rollback 1" will try to remove packages B and C. Note that after a "rollback 1" you will have a fourth transaction, although the ending rpmdb version (see: yum version) should be the same in transactions 1 and 4.

The addon-info command takes a transaction ID, and the packages-list command takes a package (with wildcards).

The stats command shows some statistics about the current history DB.

The sync commands allows you to change the rpmdb/yumdb data stored for any installed packages, to whatever is in the current rpmdb/yumdb (this is mostly useful when this data was not stored when the package went into the history DB).

In "history list" you can change the behaviour of the 2nd column via. the configuration option history_list_view.

In "history list" output the Altered column also gives some extra information if there was something not good with the transaction (this is also shown at the end of the package column in the packages-list command).

- > - The rpmdb was changed, outside yum, after the transaction.
- < - The rpmdb was changed, outside yum, before the transaction.
- * - The transaction aborted before completion.
- # - The transaction completed, but with a non-zero status.
- E - The transaction completed fine, but had warning/error output during the transaction.
- P - The transaction completed fine, but problems already existed in the rpmdb.
- s - The transaction completed fine, but --skip-broken was enabled and had to skip some packages.

load-transaction

This command will re-load a saved yum transaction file, this allows you to run a transaction on one machine and then use it on another. The two common ways to get a saved yum transaction file are from "yum -q history addon-info last saved_tx" or via. the automatic saves in \$TMPDIR/yum_save_tx.* when a transaction is solved but not run.

check

Checks the local rpmbdb and produces information on any problems it finds. You can pass the check command the arguments "dependencies" or "duplicates", to limit the checking that is performed (the default is "all" which does both).

The info command can also take ranges of transaction ids, of the form start..end, which will then display a merged history as if all the transactions in the range had happened at once. Eg. "history info 1..4" will merge the first four transactions and display them as a single transaction.

help

Produces help, either for all commands or if given a command name then the help for that particular command.

General Options

Most command line options can be set using the configuration file as well and the descriptions indicate the necessary configuration option to set.

-h, --help

Help; display a help message and then quit.

-y, --assumeyes

Assume yes; assume that the answer to any question which would be asked is yes.

Configuration Option: **assumeyes**

-c, --config=[config file]

Specifies the config file location - can take HTTP and FTP URLs and local file paths.

-q, --quiet

Run without output. Note that you likely also want to use -y.

-v, --verbose

Run with a lot of debugging output.

-d, --debuglevel=[number]

Sets the debugging level to [number] - turns up or down the amount of things that are printed.

Practical range: 0 - 10

Configuration Option: **debuglevel**

-e, --errorlevel=[number]

Sets the error level to [number] Practical range 0 - 10. 0 means print only critical errors about which you must be told. 1 means print all errors, even ones that are not overly important. 1+ means print more errors (if any) -e 0 is good for cron jobs.

Configuration Option: **errorlevel**

--rpmverbosity=[name]

Sets the debug level to [name] for rpm scriptlets. 'info' is the default, other options are: 'critical', 'emergency', 'error', 'warn' and 'debug'.

Configuration Option: **rpmverbosity**

-R, --randomwait=[time in minutes]

Sets the maximum amount of time yum will wait before performing a command - it randomizes over the time.

-C, --cacheonly

Tells yum to run entirely from system cache - does not download or update any headers unless it has to to perform the requested action. If you're using this as a user yum will not use the tempcache for the user but will only use the system cache in the system cachedir.

--version

Reports the **yum** version number and installed package versions for everything in history_record_packages (can be added to by plugins).

--showduplicates

Doesn't limit packages to their latest versions in the info, list and search commands (will also affect plugins which use the doPackageLists() API).

--installroot=root

Specifies an alternative installroot, relative to which all packages will be installed.

Configuration Option: **installroot**

--enablerepo=repoidglob

Enables specific repositories by id or glob that have been disabled in the configuration file using the enabled=0 option.

Configuration Option: **enabled**

--disablerepo=repoidglob

Disables specific repositories by id or glob.

Configuration Option: **enabled**

--obsoletes

This option only has affect for an update, it enables **yum**'s obsoletes processing logic. For more information see the **update** command above.

Configuration Option: **obsoletes**

-x, --exclude=package

Exclude a specific package by name or glob from updates on all repositories. Configuration Option: **exclude**

--color=[always|auto|never]

Display colorized output automatically, depending on the output terminal, always (using ANSI codes) or never. Note that some commands (Eg. list and info) will do a little extra work when color is enabled. Configuration Option: **color**

--disableexcludes=[all|main|repoid]

Disable the excludes defined in your config files. Takes one of three options:

all == disable all excludes

main == disable excludes defined in [main] in yum.conf

repoid == disable excludes defined for that repo

--disableplugin=plugin

Run with one or more plugins disabled, the argument is a comma separated list of wildcards to match against plugin names.

--nopugins

Run with all plugins disabled.

Configuration Option: **plugins**

--nogpgcheck

Run with GPG signature checking disabled.

Configuration Option: **gpgcheck**

--skip-broken

Resolve depolve problems by removing packages that are causing problems from the transaction.

Configuration Option: **skip_broken**

--releasever=version

Pretend the current release version is the given string. This is very useful when combined with --installroot. Note that with the default upstream cachedir, of /var/cache/yum, using this option will corrupt your cache (and you can use \$releasever in your cachedir configuration to stop this).

-t, --tolerant

This option currently does nothing.

--setopt=option=value

Set any config option in yum config or repo files. For options in the global config just use: --setopt=option=value for repo options use: --setopt=repoid.option=value

List Options

The following are the ways which you can invoke **yum** in list mode. Note that all **list** commands include information on the version of the package.

OUTPUT

The format of the output of yum list is:

name.arch [epoch:]version-release repo or @installed-from-repo

yum list [all | glob_exp1] [glob_exp2] [...]

List all available and installed packages.

yum list available [glob_exp1] [...]

List all packages in the yum repositories available to be installed.

yum list updates [glob_exp1] [...]

List all packages with updates available in the yum repositories.

yum list installed [glob_exp1] [...]

List the packages specified by *args*. If an argument does not match the name of an available package, it is assumed to be a shell-style glob and any matches are printed.

yum list extras [glob_exp1] [...]

List the packages installed on the system that are not available in any yum repository listed in the config file.

yum list obsoletes [glob_exp1] [...]

List the packages installed on the system that are obsoleted by packages in any yum repository listed in the config file.

yum list recent

List packages recently added into the repositories. This is often not helpful, but what you may really want to use is "yum list-updateinfo new" from the security yum plugin.

Specifying Package Names

A package can be referred to for install, update, remove, list, info etc with any of the following as well as globs of any of the following:

name

name.arch

name-ver
name-ver-rel
name-ver-rel.arch
name-epoch:ver-rel.arch
epoch:name-ver-rel.arch

For example: **yum remove kernel-2.4.1-10.i686**

this will remove this specific kernel-ver-rel.arch.

Or: **yum list available 'foo*'**

will list all available packages that match 'foo*'. (The single quotes will keep your shell from expanding the globs.)

Clean Options

The following are the ways which you can invoke **yum** in clean

mode. Note that "all files" in the commands below means "all files in currently enabled repositories". If you want to also clean any (temporarily) disabled repositories you need to use **-enablerepo='*' option.**

yum clean expire-cache

Eliminate the local data saying when the metadata and mirrorlists were downloaded for each repo. This means yum will revalidate the cache for each repo. next time it is used. However if the cache is still valid, nothing significant was deleted.

yum clean packages

Eliminate any cached packages from the system. Note that packages are not automatically deleted after they are downloaded.

yum clean headers

Eliminate all of the header files, which old versions of yum used for dependency resolution.

yum clean metadata

Eliminate all of the files which yum uses to determine the remote availability of packages. Using this option will force yum to download all the metadata the next time it is run.

yum clean dbcache

Eliminate the sqlite cache used for faster access to metadata. Using this option will force yum to download the sqlite metadata the next time it is run, or recreate the sqlite metadata if using an older repo.

yum clean rpmdb

Eliminate any cached data from the local rpmdb.

yum clean plugins

Tell any enabled plugins to eliminate their cached data.

yum clean all

Does all of the above.

Plugins

Yum can be extended through the use of plugins. A plugin is a Python ".py" file which is installed in one of the directories specified by the **pluginpath** option in yum.conf. For a plugin to work, the following conditions must be met:

1. The plugin module file must be installed in the plugin path as just described.
2. The global **plugins** option in /etc/yum.conf must be set to '1'.

3. A configuration file for the plugin must exist in /etc/yum/pluginconf.d/<plugin_name>.conf and the **enabled** setting in this file must set to '1'. The minimal content for such a configuration file is:

[main]

```
enabled = 1
```

See the **yum.conf(5)** man page for more information on plugin related configuration options.

Files

/etc/yum.conf
/etc/yum/version-groups.conf
/etc/yum.repos.d/
/etc/yum/pluginconf.d/
/var/cache/yum/

yum.conf(5) - Linux man page

Name

yum.conf - Configuration file for [yum\(8\)](#).

Description

Yum uses a configuration file at **/etc/yum.conf**.

Additional configuration files are also read from the directories set by the **reposdir** option (default is '/etc/yum.repos.d'). See the **reposdir** option below for further details.

Parameters

There are two types of sections in the yum configuration **file(s)**: main and repository. Main defines all global configuration options. There should be only one main section. The repository **section(s)** define the configuration for each repository/server. There should be one or more repository sections.

[main] OPTIONS

The [main] section must exist for yum to do anything. It consists of the following options:

cachedir Directory where yum should store its cache and db files. The default is '/var/cache/yum'.

persistdir Directory where yum should store information that should persist over multiple runs. The default is '/var/lib/yum'.

keepcache Either '1' or '0'. Determines whether or not yum keeps the cache of headers and packages after successful installation. Default is '1' (keep files)

reposdir A list of directories where yum should look for .repo files which define repositories to use. Default is '/etc/yum.repos.d'. Each file in this directory should contain one or more repository sections as documented in **[repository] options** below. These will be merged with the repositories defined in /etc/yum.conf to form the complete set of repositories that yum will use.

debuglevel Debug message output level. Practical range is 0-10. Default is '2'.

errorlevel Error message output level. Practical range is 0-10. Default is '2'.

rpmverbosity Debug scriptlet output level. 'info' is the default, other options are: 'critical', 'emergency', 'error', 'warn' and 'debug'.

protected_packages This is a list of packages that yum should never completely remove. They are protected via. Obsoletes as well as user/plugin removals.

The default is: yum glob:/etc/yum/protected.d/*.conf So any packages which should be protected can do so by including a file in /etc/yum/protected.d with their package name in it.

Also if this configuration is set to anything, then yum will protect the package corresponding to the running version of the kernel.

protected_multilib Either '1' or '0'. This tells yum whether or not it should perform a check to make sure that multilib packages are the same version. For example, if this option is off (rpm behaviour) pkgA-1.x86_64 and pkgA-2.i386 can be installed at the same time. However this is very rarely desired. install only packages, like the kernel, are exempt from this check. The default is '1'.

logfile Full directory and file name for where yum should write its log file.

gpgcheck Either '1' or '0'. This tells yum whether or not it should perform a GPG signature check on packages. When this is set in the [main] section it sets the default for all repositories. The default is '0'.

localpkg_gpgcheck Either '1' or '0'. This tells yum whether or not it should perform a GPG signature check on local packages (packages in a file, not in a repository). The default is '0'.

repo_gpgcheck Either '1' or '0'. This tells yum whether or not it should perform a GPG signature check on the repodata. When this is set in the [main] section it sets the default for all repositories. The default is '0'.

skip_broken Either '1' or '0'. Resolve dependency problems by removing packages that are causing problems from the transaction.

assumeyes Either '1' or '0'. Determines whether or not yum prompts for confirmation of critical actions. Default is '0' (do prompt).

Command-line option: **-y**

alwaysprompt Either '1' or '0'. Without this option, yum will not prompt for confirmation when the list of packages to be installed exactly matches those given on the command line. Unless **assumeyes** is enabled, it will still prompt for package removal, or when additional packages need to be installed to fulfill dependencies. Default is '1'.

tolerant Either '1' or '0'. If enabled, then yum will be tolerant of errors on the command line with regard to packages. For example: if you request to install foo, bar and baz and baz is installed; yum won't error out complaining that baz is already

installed. Default to '0' (not tolerant).

Command-line option: **-t**

exclude List of packages to exclude from updates or installs. This should be a space separated list. Shell globs using wildcards (eg. * and ?) are allowed.

exactarch Either '1' or '0'. Set to '1' to make yum update only update the architectures of packages that you have installed. ie: with this enabled yum will not install an i686 package to update an i386 package. Default is '1'.

installonlypkgs List of package provides that should only ever be installed, never updated. Kernels in particular fall into this category. Defaults to kernel, kernel-bigmem, kernel-enterprise, kernel-smp, kernel-debug, kernel-unsupported, kernel-source, kernel-devel, kernel-PAE, kernel-PAE-debug.

Note that because these are provides, and not just package names, kernel-devel will also apply to kernel-debug-devel, etc.

Note that "kernel-modules" is **not** in this list, in RHEL-6, and so anything providing that is updated like any other package.

installonly_limit Number of packages listed in installonlypkgs to keep installed at the same time. Setting to 0 disables this feature. Default is '3'. Note that this functionality used to be in the "installonly" plugin, where this option was altered via. tokeep. Note that as of version 3.2.24, yum will now look in the yumdb for a installonly attribute on installed packages. If that attribute is "keep", then they will never be removed.

kernelpkgnames List of package names that are kernels. This is really only here for the updating of kernel packages and should be removed out in the yum 2.1 series.

showduplicatesfromrepos Either '0' or '1'. Set to '1' if you wish to show any duplicate packages from any repository, from package listings like the info or list commands. Set to '0' if you want only to see the newest packages from any repository. Default is '0'.

obsoletes This option only has affect during an **update**. It enables yum's obsoletes processing logic. Useful when doing distribution level upgrades. See also the yum **upgrade** command documentation for more details ([yum\(8\)](#)). Default is 'true'.

Command-line option: **--obsoletes**

overwrite_groups Either '0' or '1'. Used to determine yum's behaviour if two or more repositories offer the package groups with the same name. If **overwrite_groups** is '1' then the group packages of the last matching repository will be used. If **overwrite_groups** is '0' then the groups from all matching repositories will be merged together as one large group.

groupremove_leaf_only Either '0' or '1'. Used to determine yum's behaviour when the groupremove command is run. If **groupremove_leaf_only** is '0' (default) then all packages in the group will be removed. If **groupremove_leaf_only** is '1' then only those packages in the group that aren't required by another package will be removed.

enable_group_conditionals Either '0' or '1'. Determines whether yum will allow the use of conditionals packages. Default is '1' (package conditionals are allowed).

group_package_types List of the following: optional, default, mandatory. Tells yum which type of packages in groups will be installed when 'groupinstall' is called. Default is: default, mandatory

installroot Specifies an alternative installroot, relative to which all packages will be installed.

Command-line option: **--installroot**

distroverpkg The package used by yum to determine the "version" of the distribution. This can be any installed package. Default is 'redhat-release'. You can see what provides this manually by using: "yum whatprovides redhat-release".

diskspacecheck Either '0' or '1'. Set this to '0' to disable the checking for sufficient diskspace before a RPM transaction is run. Default is '1' (perform the check).

tsflags Comma or space separated list of transaction flags to pass to the rpm transaction set. These include 'noscripts', 'notriggers', 'nodocs', 'test', 'justdb' and 'nocontexts'. 'repackage' is also available but that does nothing with newer rpm versions. You can set all/any of them. However, if you don't know what these do in the context of an rpm transaction set you're best leaving it alone. Default is an empty list.

recent Number of days back to look for 'recent' packages added to a repository. Used by the **list recent** command. Default is '7'.

retries Set the number of times any attempt to retrieve a file should retry before returning an error. Setting this to '0' makes yum try forever. Default is '10'.

keepalive Either '0' or '1'. Set whether HTTP keepalive should be used for HTTP/1.1 servers that support it. This can improve transfer speeds by using one connection when downloading multiple files from a repository. Default is '1'.

timeout Number of seconds to wait for a connection before timing out. Defaults to 30 seconds. This may be too short of a time for extremely overloaded sites.

http_caching Determines how upstream HTTP caches are instructed to handle any HTTP downloads that Yum does. This option can take the following values:

'all' means that all HTTP downloads should be cached.

'packages' means that only RPM package downloads should be cached (but not repository metadata downloads).

'none' means that no HTTP downloads should be cached.

The default is 'all'. This is recommended unless you are experiencing caching related issues. Try to at least use 'packages' to minimize load on repository servers.

throttle Enable bandwidth throttling for downloads. This option can be expressed as a absolute data rate in bytes/sec. An SI prefix (k, M or G) may be appended to the bandwidth value (eg. '5.5k' is 5.5 kilobytes/sec, '2M' is 2 Megabytes/sec).

Alternatively, this option can specify the percentage of total bandwidth to use (eg. '60%'). In this case the **bandwidth** option should be used to specify the maximum available bandwidth.

Set to '0' to disable bandwidth throttling. This is the default.

bandwidth Use to specify the maximum available network bandwidth in bytes/second. Used with the **throttle** option (above). If **throttle** is a percentage and **bandwidth** is '0' then bandwidth throttling will be disabled. If **throttle** is expressed as a data rate (bytes/sec) then this option is ignored. Default is '0' (no bandwidth throttling).

sslcacert Path to the directory containing the databases of the certificate authorities yum should use to verify SSL certificates. Defaults to none - uses system default

sslvverify Boolean - should yum verify SSL certificates/hosts at all. Defaults to True.

Note that the plugin yum-rhn-plugin will force this value to true, and may alter other ssl settings (like hostname checking), even if it the machine is not registered.

sslclientcert Path to the SSL client certificate yum should use to connect to repos/remote sites Defaults to none.

Note that if you are using curl compiled against NSS (default in Fedora/RHEL), curl treats sslclientcert values with the same basename as _identical_. This version of yum will check that this isn't true and output an error when the repositories "foo" and "bar" violate this, like so:

sslclientcert basename shared between foo and bar

sslclientkey Path to the SSL client key yum should use to connect to repos/remote sites Defaults to none.

ssl_check_cert_permissions Boolean - Whether yum should check the permissions on the paths for the certificates on the repository (both remote and local). If we can't

read any of the files then yum will force `skip_if_unavailable` to be true. This is most useful for non-root processes which use yum on repos. that have client cert files which are readable only by root. Defaults to True.

history_record Boolean - should yum record history entries for transactions. This takes some disk space, and some extra time in the transactions. But it allows how to know a lot of information about what has happened before, and display it to the user with the history info/list/summary commands. yum also provides the history undo/redo commands. Defaults to True.

Note that if history is recorded, yum uses that information to see if any modifications to the rpmbdb have been done outside of yum. These are always bad, from yum's point of view, and so yum will issue a warning and automatically run some of "yum check" to try and find some of the worst problems altering the rpmbdb might have caused.

This means that turning this option off will stop yum from being able to detect when the rpmbdb has changed and thus. it will never warn you or automatically run "yum check". The problems will likely still be there, and yumdb etc. will still be wrong but yum will not warn you about it.

history_record_packages This is a list of package names that should be recorded as having helped the transaction. yum plugins have an API to add themselves to this, so it should not normally be necessary to add packages here. Note that this is also used for the packages to look for in --version. Defaults to rpm, yum, yum-metadata-parser.

history_list_view Which column of information to display in the "yum history list" command. There are currently three options: users, cmd (or commands), single-user-commands.

Older versions of yum acted like "users", which always outputs the user who initiated the yum transaction. You can now specify "commands" which will instead always output the command line of the transaction. You can also specify "single-user-commands" which will display the users if there are more than one, otherwise it will display the command line.

You can also specify "default" which currently selects "users".

commands List of functional commands to run if no functional commands are specified on the command line (eg. "update foo bar baz quux"). None of the short options (eg. -y, -e, -d) are accepted for this option.

syslog_ident Identification (program name) for syslog messages.

syslog_facility Facility name for syslog messages, see [syslog\(3\)](#). Default is 'LOG_USER'.

syslog_device Where to log syslog messages. Can be a local device (path) or a host:port string to use a remote syslog. If empty or points to a nonexistent device, syslog logging is disabled. Default is '/dev/log'.

proxy URL to the proxy server that yum should use.

proxy_username username to use for proxy

proxy_password password for this proxy

username username to use for basic authentication to a repo or really any url.

password password to use with the username for basic authentication.

plugins Either '0' or '1'. Global switch to enable or disable yum plugins. Default is '0' (plugins disabled). See the **PLUGINS** section of the [yum\(8\)](#) man for more information on installing yum plugins.

pluginpath A list of directories where yum should look for plugin modules. Default is '/usr/share/yum-plugins' and '/usr/lib/yum-plugins'.

pluginconfpath A list of directories where yum should look for plugin configuration files. Default is '/etc/yum/pluginconf.d'.

metadata_expire Time (in seconds) after which the metadata will expire. So that if the current metadata downloaded is less than this many seconds old then yum will not update the metadata against the repository. If you find that yum is not downloading information on updates as often as you would like lower the value of this option. You can also change from the default of using seconds to using days, hours or minutes by appending a d, h or m respectively. The default is 6 hours, to compliment yum-updatesd running once an hour. It's also possible to use the word "never", meaning that the metadata will never expire. Note that when using a metalink file the metalink must always be newer than the metadata for the repository, due to the validation, so this timeout also applies to the metalink file.

mirrorlist_expire Time (in seconds) after which the mirrorlist locally cached will expire. If the current mirrorlist is less than this many seconds old then yum will not download another copy of the mirrorlist, it has the same extra format as metadata_expire. If you find that yum is not downloading the mirrorlists as often as you would like lower the value of this option.

mdpolicy You can select from different metadata download policies depending on how much data you want to download with the main repository metadata index. The advantages of downloading more metadata with the index is that you can't get into situations where you need to use that metadata later and the versions available aren't

compatible (or the user lacks privileges) and that if the metadata is corrupt in any way yum will revert to the previous metadata.

'instant' - Just download the new metadata index, this is roughly what yum always did, however it now does some checking on the index and reverts if it classifies it as bad.

'group:primary' - Download the primary metadata with the index. This contains most of the package information and so is almost always required anyway. This is the default.

'group:small' - With the primary also download the updateinfo metadata, this is required for yum-security operations and it also used in the graphical clients. This file also tends to be significantly smaller than most others.

'group:main' - With the primary and updateinfo download the filelists metadata and the group metadata. The filelists data is required for operations like "yum install /bin/bash", and also some dependency resolutions require it. The group data is used in some graphical clients and for group operations like "yum grouplist Base".

'group:all' - Download all metadata listed in the index, currently the only one not listed above is the other metadata, which contains the changelog information which is used by yum-changelog. This is what "yum makecache" uses.

multilib_policy Can be set to 'all' or 'best'. All means install all possible arches for any package you want to install. Therefore yum install foo will install foo.i386 and foo.x86_64 on x86_64, if it is available. Best means install the best arch for this platform, only.

bugtracker_url URL where bugs should be filed for yum. Configurable for local versions or distro-specific bugtrackers.

color Display colorized output automatically, depending on the output terminal, always (using ANSI codes) or never. Command-line option: **--color**

color_list_installed_older The colorization/highlighting for packages in list/info installed which are older than the latest available package with the same name and arch. Default is 'bold'. Possible values are a comma separated list containing: bold, blink, dim, reverse, underline, fg:black, fg:red, fg:green, fg:yellow, fg:blue, fg:magenta, fg:cyan, fg:white, bg:black, bg:red, bg:green, bg:yellow, bg:blue, bg:magenta, bg:cyan, bg:white.

color_list_installed_newer The colorization/highlighting for packages in list/info installed which are newer than the latest available package with the same name and arch. Default is 'bold,yellow'. See **color_list_installed_older** for possible values.

color_list_installed_reinstall The colorization/highlighting for packages in list/info installed which is the same version as the latest available package with the same name and arch. Default is 'normal'. See color_list_installed_older for possible values.

color_list_installed_extra The colorization/highlighting for packages in list/info installed which has no available package with the same name and arch. Default is 'bold,red'. See color_list_installed_older for possible values.

color_list_available_upgrade The colorization/highlighting for packages in list/info available which is an upgrade for the latest installed package with the same name and arch. Default is 'bold,blue'. See color_list_installed_older for possible values.

color_list_available_downgrade The colorization/highlighting for packages in list/info available which is a downgrade for the latest installed package with the same name and arch. Default is 'dim,cyan'. See color_list_installed_older for possible values.

color_list_available_install The colorization/highlighting for packages in list/info available which has no installed package with the same name and arch. Default is 'normal'. See color_list_installed_older for possible values.

color_list_available_reinstall The colorization/highlighting for packages in list/info available which is the same version as the installed package with the same name and arch. Default is 'bold,underline,green'. See color_list_installed_older for possible values.

color_search_match The colorization/highlighting for text matches in search. Default is 'bold'. See color_list_installed_older for possible values.

color_update_installed The colorization/highlighting for packages in the "updates list" which are installed. The updates list is what is printed when you run "yum update", "yum list updates", "yum list obsoletes" and "yum check-update". Default is 'normal'. See color_list_installed_older for possible values.

color_update_local The colorization/highlighting for packages in the "updates list" which are already downloaded. The updates list is what is printed when you run "yum update", "yum list updates", "yum list obsoletes" and "yum check-update". Default is 'bold'. See color_list_installed_older for possible values.

color_update_remote The colorization/highlighting for packages in the "updates list" which need to be downloaded. The updates list is what is printed when you run "yum update", "yum list updates", "yum list obsoletes" and "yum check-update". Default is 'normal'. See color_list_installed_older for possible values.

clean_requirements_on_remove When removing packages (by removal, update or obsolescence) go through each package's dependencies. If any of them are no longer

required by any other package then also mark them to be removed. Boolean (1, 0, True, False, yes,no) Defaults to False

reset_nice If set to true then yum will try to reset the nice value to zero, before running an rpm transaction. Defaults to True.

[repository] OPTIONS

The repository **section**(s) take the following form:

Example: [repositoryid]

name=Some name for this repository

baseurl=url://path/to/repository/

repositoryid Must be a unique name for each repository, one word.

name A human readable string describing the repository.

baseurl Must be a URL to the directory where the yum repository's 'repodata' directory lives. Can be an http://, ftp:// or file:// URL. You can specify multiple URLs in one baseurl statement. The best way to do this is like this:

[repositoryid]

name=Some name for this repository

baseurl=url://server1/path/to/repository/

url://server2/path/to/repository/

url://server3/path/to/repository/

If you list more than one baseurl= statement in a repository you will find yum will ignore the earlier ones and probably act bizarrely. Don't do this, you've been warned.

You can use HTTP basic auth by prepending "user:password@" to the server name in the baseurl line. For example: "baseurl=http://user:passwd@example.com/".

metalink Specifies a URL to a metalink file for the repomd.xml, a list of mirrors for the entire repository are generated by converting the mirrors for the repomd.xml file to a baseurl. The metalink file also contains the latest timestamp from the data in the repomd.xml, the length of the repomd.xml and checksum data. This data is checked against any downloaded repomd.xml file and all of the information from the metalink file must match. This can be used instead of or with the **baseurl** option. Substitution variables, described below, can be used with this option. This option disables the mirrorlist option. As a special hack if the mirrorlist URL contains the word "metalink" then the value of mirrorlist is copied to metalink (if metalink is not set).

mirrorlist Specifies a URL to a file containing a list of baseurls. This can be used instead of or with the **baseurl** option. Substitution variables, described below, can be

used with this option. As a special hack is the mirrorlist URL contains the word "metalink" then the value of mirrorlist is copied to metalink (if metalink is not set).

enabled Either '1' or '0'. This tells yum whether or not use this repository.

gpgcheck Either '1' or '0'. This tells yum whether or not it should perform a GPG signature check on the packages gotten from this repository.

repo_gpgcheck Either '1' or '0'. This tells yum whether or not it should perform a GPG signature check on the repodata from this repository.

gpgkey A URL pointing to the ASCII-armored GPG key file for the repository. This option is used if yum needs a public key to verify a package and the required key hasn't been imported into the RPM database. If this option is set, yum will automatically import the key from the specified URL. You will be prompted before the key is installed unless the **assumeyes** option is set.

Multiple URLs may be specified here in the same manner as the **baseurl** option (above). If a GPG key is required to install a package from a repository, all keys specified for that repository will be installed.

gpgcakey A URL pointing to the ASCII-armored CA key file for the repository. This is a normal gpg public key - but this key will be used to validate detached signatures of all other keys. The idea is you are asked to confirm import for this key. After that any other gpg key needed for package or repository verification, if it has a detached signature which matches this key will be automatically imported without user confirmation.

exclude Same as the [main] **exclude** option but only for this repository. Substitution variables, described below, are honored here.

includepkgs Inverse of exclude. This is a list of packages you want to use from a repository. If this option lists only one package then that is all yum will ever see from the repository. Defaults to an empty list. Substitution variables, described below, are honored here.

enablegroups Either '0' or '1'. Determines whether yum will allow the use of package groups for this repository. Default is '1' (package groups are allowed).

failovermethod Either 'roundrobin' or 'priority'.

'roundrobin' randomly selects a URL out of the list of URLs to start with and proceeds through each of them as it encounters a failure contacting the host.

'priority' starts from the first baseurl listed and reads through them sequentially.

failovermethod defaults to 'roundrobin' if not specified.

keepalive Either '1' or '0'. This tells yum whether or not HTTP/1.1 keepalive should be used with this repository. See the global option in the [main] section above for more information.

timeout Overrides the **timeout** option from the [main] section for this repository.

http_caching Overrides the **http_caching** option from the [main] section for this repository.

retries Overrides the **retries** option from the [main] section for this repository.

throttle Overrides the **throttle** option from the [main] section for this repository.

bandwidth Overrides the **bandwidth** option from the [main] section for this repository.

sslcacert Overrides the **sslcacert** option from the [main] section for this repository.

sslverify Overrides the **sslverify** option from the [main] section for this repository.

sslclientcert Overrides the **sslclientcert** option from the [main] section for this repository.

sslclientkey Overrides the **sslclientkey** option from the [main] section for this repository.

ssl_check_cert_permissions Overrides the **ssl_check_cert_permissions** option from the [main] section for this repository.

metadata_expire Overrides the **metadata_expire** option from the [main] section for this repository.

mirrorlist_expire Overrides the **mirrorlist_expire** option from the [main] section for this repository.

proxy URL to the proxy server for this repository. Set to '_none_' to disable the global proxy setting for this repository. If this is unset it inherits it from the global setting

proxy_username username to use for proxy. If this is unset it inherits it from the global setting

proxy_password password for this proxy. If this is unset it inherits it from the global setting

username username to use for basic authentication to a repo or really any url. If this is unset it inherits it from the global setting

password password to use with the username for basic authentication. If this is unset it inherits it from the global setting

cost relative cost of accessing this repository. Useful for weighing one repo's packages as greater/less than any other. defaults to 1000

skip_if_unavailable If set to True yum will continue running if this repository cannot be contacted for any reason. This should be set carefully as all repos are consulted for any given command. Defaults to False.

Url Include Syntax

The inclusion of external configuration files is supported for /etc/yum.conf and the .repo files in the /etc/yum.repos.d directory. To include a URL, use a line of the following format:

```
include=url://to/some/location
```

The configuration file will be inserted at the position of the "include=" line. Included files may contain further include lines. Yum will abort with an error if an inclusion loop is detected.

GLOB: FOR LIST OPTIONS

Any of the configurations options which are a list of items can be specified using the glob syntax: **glob:/etc/path/somewhere.d/*.conf**. This will read in all files matching that glob and include all lines in each file (excluding comments and blank lines) as items in the list.

Variables

There are a number of variables you can use to ease maintenance of yum's configuration files. They are available in the values of several options including **name**, **baseurl** and **commands**.

\$releasever This will be replaced with the value of the version of the package listed in **distroverpkg**. This defaults to the version of 'redhat-release' package.

\$arch This will be replaced with your architecture as listed by os.uname()[4] in Python.

\$basearch This will be replaced with your base architecture in yum. For example, if your \$arch is i686 your \$basearch will be i386.

\$uuid This will be replaced with a unique but persistent uuid for this machine. The value that is first generated will be stored in /var/lib/yum/uuid and reused until this file is deleted.

\$YUM0-\$YUM9 These will be replaced with the value of the shell environment variable of the same name. If the shell environment variable does not exist then the configuration file variable will not be replaced.

As of 3.2.28, any file in /etc/yum/vars is turned into a variable named after the filename (or overrides any of the above variables).

Note that no warnings/errors are given if the files are unreadable, so creating files that only root can read may be confusing for users.

Also note that only the first line will be read and all new line characters are removed, as a convenience. However, no other checking is performed on the data. This means it is possible to have bad character data in any value.

Files

/etc/yum.conf
/etc/yum.repos.d/
/etc/yum/pluginconf.d/
/etc/yum/protected.d
/etc/yum/vars

NAME

`zsh` – the Z shell

OVERVIEW

Because `zsh` contains many features, the `zsh` manual has been split into a number of sections:

`zsh` Zsh overview (this section)
`zshroadmap` Informal introduction to the manual
`zshmisc` Anything not fitting into the other sections
`zshexpn` Zsh command and parameter expansion
`zshparam` Zsh parameters
`zshoptions` Zsh options
`zshbuiltins` Zsh built-in functions
`zshzle` Zsh command line editing
`zshcompwid` Zsh completion widgets
`zshcompsys` Zsh completion system
`zshcompctl` Zsh completion control
`zshmodules` Zsh loadable modules
`zshcalsys` Zsh built-in calendar functions
`zshtcp sys` Zsh built-in TCP functions
`zshzftpsys` Zsh built-in FTP client
`zshcontrib` Additional zsh functions and utilities
`zshall` Meta-man page containing all of the above

DESCRIPTION

Zsh is a UNIX command interpreter (shell) usable as an interactive login shell and as a shell script command processor. Of the standard shells, `zsh` most closely resembles `ksh` but includes many enhancements. It does not provide compatibility with POSIX or other shells in its default operating mode: see the section Compatibility below.

Zsh has command line editing, builtin spelling correction, programmable command completion, shell functions (with autoloading), a history mechanism, and a host of other features.

AUTHOR

Zsh was originally written by Paul Falstad <pf@zsh.org>. Zsh is now maintained by the members of the zsh-workers mailing list <zsh-workers@zsh.org>. The development is currently coordinated by Peter Stephenson <pws@zsh.org>. The coordinator can be contacted at<coordinator@zsh.org>, but matters relating to the code should generally go to the mailing list.

AVAILABILITY

Zsh is available from the following HTTP and anonymous FTP site.

<ftp://ftp.zsh.org/pub/>
<https://www.zsh.org/pub/>
)

The up-to-date source code is available via Git from Sourceforge. See<https://sourceforge.net/projects/zsh/> for details. A summary of instructions for the archive can be found at <http://zsh.sourceforge.net/>.

MAILING LISTS

Zsh has 3 mailing lists:

<zsh-announce@zsh.org>

Announcements about releases, major changes in the shell and the monthly posting of the Zsh FAQ. (moderated)

<zsh-users@zsh.org>

User discussions.

<zsh-workers@zsh.org>

Hacking, development, bug reports and patches.

To subscribe or unsubscribe, send mail to the associated administrative address for the mailing list.

<zsh-announce-subscribe@zsh.org>

<zsh-users-subscribe@zsh.org>

<zsh-workers-subscribe@zsh.org>

<zsh-announce-unsubscribe@zsh.org>

<zsh-users-unsubscribe@zsh.org>

<zsh-workers-unsubscribe@zsh.org>

YOU ONLY NEED TO JOIN ONE OF THE MAILING LISTS AS THEY ARE NESTED. All submissions to **zsh-announce** are automatically forwarded to **zsh-users**. All submissions to **zsh-users** are automatically forwarded to **zsh-workers**.

If you have problems subscribing/unsubscribing to any of the mailing lists, send mail to **<listmaster@zsh.org>**. The mailing lists are maintained by Karsten Thygesen **<kathy@kom.auc.dk>**.

The mailing lists are archived; the archives can be accessed via the administrative addresses listed above. There is also a hypertext archive, maintained by Geoff Wing **<gew@zsh.org>**, available at <https://www.zsh.org/mla/>.

THE ZSH FAQ

Zsh has a list of Frequently Asked Questions (FAQ), maintained by Peter Stephenson **<pws@zsh.org>**. It is regularly posted to the newsgroup **comp.unix.shell** and the **zsh-announce** mailing list. The latest version can be found at any of the Zsh FTP sites, or at <http://www.zsh.org/FAQ/>. The contact address for FAQ-related matters is **<faqmaster@zsh.org>**.

THE ZSH WEB PAGE

Zsh has a web page which is located at <https://www.zsh.org/>. This is maintained by Karsten Thygesen **<kathy@zsh.org>**, of SunSITE Denmark. The contact address for web-related matters is **<webmaster@zsh.org>**.

THE ZSH USERGUIDE

A userguide is currently in preparation. It is intended to complement the manual, with explanations and hints on issues where the manual can be cabballistic, hierographic, or downright mystifying (for example, the word ‘hierographic’ does not exist). It can be viewed in its current state at <http://zsh.sourceforge.net/Guide/>. At the time of writing, chapters dealing with startup files and their contents and the new completion system were essentially complete.

INVOCATION

The following flags are interpreted by the shell when invoked to determine where the shell will read commands from:

- c Take the first argument as a command to execute, rather than reading commands from a script or standard input. If any further arguments are given, the first one is assigned to \$0, rather than being used as a positional parameter.
- i Force shell to be interactive. It is still possible to specify a script to execute.
- s Force shell to read commands from the standard input. If the -s flag is not present and an argument is given, the first argument is taken to be the pathname of a script to execute.

If there are any remaining arguments after option processing, and neither of the options -c or -s was supplied, the first argument is taken as the file name of a script containing shell commands to be executed. If the option **PATH_SCRIPT** is set, and the file name does not contain a directory path (i.e. there is no ‘/’ in the name), first the current directory and then the command path given by the variable **PATH** are searched for the script. If the option is not set or the file name contains a ‘/’ it is used directly.

After the first one or two arguments have been appropriated as described above, the remaining arguments are assigned to the positional parameters.

For further options, which are common to invocation and the **set** builtin, see *zshoptions(1)*.

The long option ‘**--emulate**’ followed (in a separate word) by an emulation mode may be passed to the shell. The emulation modes are those described for the **emulate** builtin, see *zshbuiltins(1)*. The ‘**--emulate**’ option must precede any other options (which might otherwise be overridden), but following options are honoured, so may be used to modify the requested emulation mode. Note that certain extra steps are taken to ensure a smooth emulation when this option is used compared with the **emulate** command within the shell: for example, variables that conflict with POSIX usage such as **path** are not defined within the shell.

Options may be specified by name using the **-o** option. **-o** acts like a single-letter option, but takes a following string as the option name. For example,

```
zsh -x -o shwordsplit scr
```

runs the script **scr**, setting the **XTRACE** option by the corresponding letter ‘**-x**’ and the **SH_WORD_SPLIT** option by name. Options may be turned *off* by name by using **+o** instead of **-o**. **-o** can be stacked up with preceding single-letter options, so for example ‘**-xo shwordsplit**’ or ‘**-xoshword-split**’ is equivalent to ‘**-x -o shwordsplit**’.

Options may also be specified by name in GNU long option style, ‘**--option-name**’. When this is done, ‘**-**’ characters in the option name are permitted: they are translated into ‘**_**’, and thus ignored. So, for example, ‘**zsh --sh-word-split**’ invokes zsh with the **SH_WORD_SPLIT** option turned on. Like other option syntaxes, options can be turned off by replacing the initial ‘**-**’ with a ‘**+**’; thus ‘**+sh-word-split**’ is equivalent to ‘**--no-sh-word-split**’. Unlike other option syntaxes, GNU-style long options cannot be stacked with any other options, so for example ‘**-x-shwordsplit**’ is an error, rather than being treated like ‘**-x --shwordsplit**’.

The special GNU-style option ‘**--version**’ is handled; it sends to standard output the shell’s version information, then exits successfully. ‘**--help**’ is also handled; it sends to standard output a list of options that can be used when invoking the shell, then exits successfully.

Option processing may be finished, allowing following arguments that start with ‘**-**’ or ‘**+**’ to be treated as normal arguments, in two ways. Firstly, a lone ‘**-**’ (or ‘**+**’) as an argument by itself ends option processing. Secondly, a special option ‘**--**’ (or ‘**+--**’), which may be specified on its own (which is the standard POSIX usage) or may be stacked with preceding options (so ‘**-x--**’ is equivalent to ‘**-x --**’). Options are not permitted to be stacked after ‘**--**’ (so ‘**-x-f**’ is an error), but note the GNU-style option form discussed above, where ‘**--shwordsplit**’ is permitted and does not end option processing.

Except when the **sh/ksh** emulation single-letter options are in effect, the option ‘**-b**’ (or ‘**+b**’) ends option processing. ‘**-b**’ is like ‘**--**’, except that further single-letter options can be stacked after the ‘**-b**’ and will take effect as normal.

COMPATIBILITY

Zsh tries to emulate **sh** or **ksh** when it is invoked as **sh** or **ksh** respectively; more precisely, it looks at the first letter of the name by which it was invoked, excluding any initial ‘**r**’ (assumed to stand for ‘restricted’), and if that is ‘**b**’, ‘**s**’ or ‘**k**’ it will emulate **sh** or **ksh**. Furthermore, if invoked as **su** (which happens on certain systems when the shell is executed by the **su** command), the shell will try to find an alternative name from the **SHELL** environment variable and perform emulation based on that.

In **sh** and **ksh** compatibility modes the following parameters are not special and not initialized by the shell: **ARGC**, **argv**, **cdpath**, **fignore**, **fpath**, **HISTCHARS**, **mailpath**, **MANPATH**, **manpath**, **path**, **prompt**, **PROMPT**, **PROMPT2**, **PROMPT3**, **PROMPT4**, **psvar**, **status**, **watch**.

The usual zsh startup/shutdown scripts are not executed. Login shells source **/etc/pr file** followed by **\$HOME/.profile**. If the **ENV** environment variable is set on invocation, **\$ENV** is sourced after the profile scripts. The value of **ENV** is subjected to parameter expansion, command substitution, and arithmetic expansion before being interpreted as a pathname. Note that the **PRIVILEGED** option also affects the execution of startup files.

The following options are set if the shell is invoked as **sh** or **ksh**: **NO_BAD_PATTERN**, **NO_BANG_HIST**, **NO_BG_NICE**, **NO_EQUALS**, **NO_FUNCTION_ARGZERO**, **GLOB_SUBST**,

NO_GLOBAL_EXPORT, **NO_HUP**, **INTERACTIVE_COMMENTS**, **KSH_ARRAYS**, **NO_MULTIOS**, **NO_NOMATCH**, **NO_NOTIFY**, **POSIX_BUILTINS**, **NO_PROMPT_PERCENT**, **RM_STAR_SILENT**, **SH_FILE_EXPANSION**, **SH_GLOB**, **SH_OPTION LETTERS**, **SH_WORD_SPLIT**. Additionally the **BSD_ECHO** and **IGNORE_BRA CES** options are set if zsh is invoked as **sh**. Also, the **KSH_OPTION_PRINT**, **LOCAL_OPTIONS**, **PR OMPT_BANG**, **PROMPT_SUBST** and **SINGLE_LINE_ZLE** options are set if zsh is invoked as **ksh**.

RESTRICTED SHELL

When the basename of the command used to invoke zsh starts with the letter ‘r’ or the ‘-r’ command line option is supplied at invocation, the shell becomes restricted. Emulation mode is determined after stripping the letter ‘r’ from the invocation name. The following are disabled in restricted mode:

- changing directories with the **cd** builtin
- changing or unsetting the **EGID**, **EUID**, **GID**, **HISTFILE**, **HISTSIZE**, **IFS**, **LD_AOUT_LIBRARY_PATH**, **LD_AOUT_PRELOAD**, **LD_LIBRARY_PATH**, **LD_PRELOAD**, **MODULE_PATH**, **module_path**, **PATH**, **path**, **SHELL**, **UID** and **USERNAME** parameters
- specifying command names containing /
- specifying command pathnames using **hash**
- redirecting output to files
- using the **exec** builtin command to replace the shell with another command
- using **jobs -Z** to overwrite the shell process’ argument and environment space
- using the **ARGV0** parameter to override **argv[0]** for external commands
- turning off restricted mode with **set +r** or **unsetopt RESTRICTED**

These restrictions are enforced after processing the startup files. The startup files should set up **PATH** to point to a directory of commands which can be safely invoked in the restricted environment. They may also add further restrictions by disabling selected builtins.

Restricted mode can also be activated any time by setting the **RESTRICTED** option. This immediately enables all the restrictions described above even if the shell still has not processed all startup files.

A shell *Restricted Mode* is an outdated way to restrict what users may do: modern systems have better, safer and more reliable ways to confine user actions, such as *chroot jails*, *containers* and *zones*.

A restricted shell is very difficult to implement safely. The feature may be removed in a future version of zsh.

It is important to realise that the restrictions only apply to the shell, not to the commands it runs (except for some shell builtins). While a restricted shell can only run the restricted list of commands accessible via the predefined ‘**PATH**’ variable, it does not prevent those commands from running any other command.

As an example, if ‘**env**’ is among the list of *allowed* commands, then it allows the user to run any command as ‘**env**’ is not a shell builtin command and can run arbitrary executables.

So when implementing a restricted shell framework it is important to be fully aware of what actions each of the *allowed* commands or features (which may be regarded as *modules*) can perform.

Many commands can have their behaviour affected by environment variables. Except for the few listed above, zsh does not restrict the setting of environment variables.

If a ‘**perl**’, ‘**python**’, ‘**bash**’, or other general purpose interpreted script is treated as a restricted command, the user can work around the restriction by setting specially crafted ‘**PERL5LIB**’, ‘**PYTHONPATH**’, ‘**BASHENV**’ (etc.) environment variables. On GNU systems, any command can be made to run arbitrary code when performing character set conversion (including zsh itself) by setting a ‘**GCONV_PATH**’ environment variable. Those are only a few examples.

Bear in mind that, contrary to some other shells, ‘**readonly**’ is not a security feature in zsh as it can be undone and so cannot be used to mitigate the above.

A restricted shell only works if the allowed commands are few and carefully written so as not to grant more access to users than intended. It is also important to restrict what zsh module the user may load as some of them, such as ‘zsh/system’, ‘zsh/mapfile’ and ‘zsh/files’, allow bypassing most of the restrictions.

STARTUP/SHUTDOWN FILES

Commands are first read from `/etc/zsh/zshenv`; this cannot be overridden. Subsequent behaviour is modified by the **RCS** and **GLOBAL_RCS** options; the former affects all startup files, while the second only affects global startup files (those shown here with a `/`). If one of the options is unset at any point, any subsequent startup file(s) of the corresponding type will not be read. It is also possible for a file in `$ZDOTDIR` to re-enable **GLOBAL_RCS**. Both **RCS** and **GLOBAL_RCS** are set by default.

Commands are then read from `$ZDOTDIR/.zshenv`. If the shell is a login shell, commands are read from `/etc/zsh/zprofile` and then `$ZDOTDIR/.zprofile`. Then, if the shell is interactive, commands are read from `/etc/zsh/zshrc` and then `$ZDOTDIR/.zshrc`. Finally, if the shell is a login shell, `/etc/zsh/zlogin` and `$ZDOTDIR/.zlogin` are read.

When a login shell exits, the files `$ZDOTDIR/.zlogout` and then `/etc/zsh/zlogout` are read. This happens with either an explicit exit via the **exit** or **logout** commands, or an implicit exit by reading end-of-file from the terminal. However, if the shell terminates due to **exec**'ing another process, the logout files are not read. These are also affected by the **RCS** and **GLOBAL_RCS** options. Note also that the **RCS** option affects the saving of history files, i.e. if **RCS** is unset when the shell exits, no history file will be saved.

If **ZDOTDIR** is unset, **HOME** is used instead. Files listed above as being in `/etc` may be in another directory, depending on the installation.

As `/etc/zsh/zshenv` is run for all instances of zsh, it is important that it be kept as small as possible. In particular, it is a good idea to put code that does not need to be run for every single shell behind a test of the form ‘**if [[-o rcs]]; then ...**’ so that it will not be executed when zsh is invoked with the ‘**-f**’ option.

Any of these files may be pre-compiled with the **zcompile** builtin command (see *zshbuiltins(1)*). If a compiled file exists (named for the original file plus the `.zwc` extension) and it is newer than the original file, the compiled file will be used instead.

FILES

```
$ZDOTDIR/.zshenv
$ZDOTDIR/.zprofile
$ZDOTDIR/.zshrc
$ZDOTDIR/.zlogin
$ZDOTDIR/.zlogout
${TMPPREFIX}* (default is /tmp/zsh*)
/etc/zsh/zshenv
/etc/zsh/zprofile
/etc/zsh/zshrc
/etc/zsh/zlogin
/etc/zsh/zlogout (installation-specific – /etc is the default)
```

NAME

`zshbuiltins` – zsh built-in commands

SHELL BUILTIN COMMANDS

Some shell builtin commands take options as described in individual entries; these are often referred to in the list below as ‘**flags**’ to avoid confusion with shell options, which may also have an effect on the behaviour of builtin commands. In this introductory section, ‘**option**’ always has the meaning of an option to a command that should be familiar to most command line users.

Typically, options are single letters preceded by a hyphen (–). Options that take an argument accept it either immediately following the option letter or after white space, for example ‘**print –C3 {1..9}**’ or ‘**print –C 3 {1..9}**’ are equivalent. Arguments to options are not the same as arguments to the command; the documentation indicates which is which. Options that do not take an argument may be combined in a single word, for example ‘**print –rca -- ***’ and ‘**print –r –c –a -- ***’ are equivalent.

Some shell builtin commands also take options that begin with ‘+’ instead of ‘–’. The list below makes clear which commands these are.

Options (together with their individual arguments, if any) must appear in a group before any non-option arguments; once the first non-option argument has been found, option processing is terminated.

All builtin commands other than ‘**echo**’ and precommand modifiers, even those that have no options, can be given the argument ‘**--**’ to terminate option processing. This indicates that the following words are non-option arguments, but is otherwise ignored. This is useful in cases where arguments to the command may begin with ‘–’. For historical reasons, most builtin commands (including ‘**echo**’) also recognize a single ‘–’ in a separate word for this purpose; note that this is less standard and use of ‘**--**’ is recommended.

– simple command

See the section ‘Precommand Modifiers’ in *zshmisc(1)*.

.file [arg ...]

Read commands from *file* and execute them in the current shell environment.

If *file* does not contain a slash, or if **PATH_DIRS** is set, the shell looks in the components of **\$path** to find the directory containing *file*. Files in the current directory are not read unless ‘.’ appears somewhere in **\$path**. If a file named ‘*file.zwc*’ is found, is newer than *file*, and is the compiled form (created with the **zcompile** builtin) of *file*, then commands are read from that file instead of *file*.

If any arguments *arg* are given, they become the positional parameters; the old positional parameters are restored when the *file* is done executing. However, if no arguments are given, the positional parameters remain those of the calling context, and no restoring is done.

If *file* was not found the return status is 127; if *file* was found but contained a syntax error the return status is 126; else the return status is the exit status of the last command executed.

: [arg ...]

This command does nothing, although normal argument expansions is performed which may have effects on shell parameters. A zero exit status is returned.

alias [{+|-}gmrsL] [name[=value] ...]

For each *name* with a corresponding *value*, define an alias with that value. A trailing space in *value* causes the next word to be checked for alias expansion. If the **-g** flag is present, define a global alias; global aliases are expanded even if they do not occur in command position.

If the **-s** flag is present, define a suffix alias: if the command word on a command line is in the form ‘*text.name*’, where *text* is any non-empty string, it is replaced by the text ‘*value text.name*’. Note that *name* is treated as a literal string, not a pattern. A trailing space in *value* is not special in this case. For example,

```
alias -s ps='gv --'
```

will cause the command ‘*.ps’ to be expanded to ‘gv -- *.ps’. As alias expansion is carried out

earlier than globbing, the ‘*.ps’ will then be expanded. Suffix aliases constitute a different name space from other aliases (so in the above example it is still possible to create an alias for the command **ps**) and the two sets are never listed together.

For each *name* with no *value*, print the value of *name*, if any. With no arguments, print all currently defined aliases other than suffix aliases. If the **-m** flag is given the arguments are taken as patterns (they should be quoted to preserve them from being interpreted as glob patterns), and the aliases matching these patterns are printed. When printing aliases and one of the **-g**, **-r** or **-s** flags is present, restrict the printing to global, regular or suffix aliases, respectively; a regular alias is one which is neither a global nor a suffix alias. Using ‘+’ instead of ‘-’, or ending the option list with a single ‘+’, prevents the values of the aliases from being printed.

If the **-L** flag is present, then print each alias in a manner suitable for putting in a startup script. The exit status is nonzero if a *name* (with no *value*) is given for which no alias has been defined.

For more on aliases, include common problems, see the section ALIASING in *zshmisc(1)*.

autoload [{+|-}RTUXdkmrtWz] [-w] [*name* ...]

See the section ‘Autoloading Functions’ in *zshmisc(1)* for full details. The **fpath** parameter will be searched to find the function definition when the function is first referenced.

If *name* consists of an absolute path, the function is defined to load from the file given (searching as usual for dump files in the given location). The name of the function is the basename (non-directory part) of the file. It is normally an error if the function is not found in the given location; however, if the option **-d** is given, searching for the function defaults to **\$fpath**. If a function is loaded by absolute path, any functions loaded from it that are marked for **autoload** without an absolute path have the load path of the parent function temporarily prepended to **\$fpath**.

If the option **-r** or **-R** is given, the function is searched for immediately and the location is recorded internally for use when the function is executed; a relative path is expanded using the value of **\$PWD**. This protects against a change to **\$fpath** after the call to **autoload**. With **-r**, if the function is not found, it is silently left unresolved until execution; with **-R**, an error message is printed and command processing aborted immediately the search fails, i.e. at the **autoload** command rather than at function execution..

The flag **-X** may be used only inside a shell function. It causes the calling function to be marked for autoloading and then immediately loaded and executed, with the current array of positional parameters as arguments. This replaces the previous definition of the function. If no function definition is found, an error is printed and the function remains undefined and marked for autoloading. If an argument is given, it is used as a directory (i.e. it does not include the name of the function) in which the function is to be found; this may be combined with the **-d** option to allow the function search to default to **\$fpath** if it is not in the given location.

The flag **+X** attempts to load each *name* as an autoloaded function, but does *not* execute it. The exit status is zero (success) if the function was not previously defined *and* a definition for it was found. This *does not* replace any existing definition of the function. The exit status is nonzero (failure) if the function was already defined or when no definition was found. In the latter case the function remains undefined and marked for autoloading. If ksh-style autoloading is enabled, the function created will contain the contents of the file plus a call to the function itself appended to it, thus giving normal ksh autoloading behaviour on the first call to the function. If the **-m** flag is also given each *name* is treated as a pattern and all functions already marked for autoload that match the pattern are loaded.

With the **-t** flag, turn on execution tracing; with **-T**, turn on execution tracing only for the current function, turning it off on entry to any called functions that do not also have tracing enabled.

With the **-U** flag, alias expansion is suppressed when the function is loaded.

With the **-w** flag, the *names* are taken as names of files compiled with the **zcompile** builtin, and all functions defined in them are marked for autoloading.

The flags **-z** and **-k** mark the function to be autoloaded using the zsh or ksh style, as if the option

KSH_AUTOLOAD were unset or were set, respectively. The flags override the setting of the option at the time the function is loaded.

Note that the **autoload** command makes no attempt to ensure the shell options set during the loading or execution of the file have any particular value. For this, the **emulate** command can be used:

```
emulate zsh -c 'autoload -Uz func'
```

arranges that when *func* is loaded the shell is in native **zsh** emulation, and this emulation is also applied when *func* is run.

Some of the functions of **autoload** are also provided by **functions -u** or **functions -U**, but **autoload** is a more comprehensive interface.

bg [*job* ...]

job ... &

Put each specified *job* in the background, or the current job if none is specified.

bindkey

See the section ‘Zle Builtins’ in *zshzle(1)*.

break [*n*]

Exit from an enclosing **for**, **while**, **until**, **select** or **repeat** loop. If an arithmetic expression *n* is specified, then break *n* levels instead of just one.

builtin *name* [*args* ...]

Executes the builtin *name*, with the given *args*.

bye Same as **exit**.

cap See the section ‘The zsh/cap Module’ in *zshmodules(1)*.

cd [**-qsLP**] [*arg*]

cd [**-qsLP**] *old new*

cd [**-qsLP**] {+|-}n

Change the current directory. In the first form, change the current directory to *arg*, or to the value of **\$HOME** if *arg* is not specified. If *arg* is ‘-’, change to the previous directory.

Otherwise, if *arg* begins with a slash, attempt to change to the directory given by *arg*.

If *arg* does not begin with a slash, the behaviour depends on whether the current directory ‘.’ occurs in the list of directories contained in the shell parameter **cdpath**. If it does not, first attempt to change to the directory *arg* under the current directory, and if that fails but **cdpath** is set and contains at least one element attempt to change to the directory *arg* under each component of **cdpath** in turn until successful. If ‘.’ occurs in **cdpath**, then **cdpath** is searched strictly in order so that ‘.’ is only tried at the appropriate point.

The order of testing **cdpath** is modified if the option **POSIX_CD** is set, as described in the documentation for the option.

If no directory is found, the option **CDABLE_VARS** is set, and a parameter named *arg* exists whose value begins with a slash, treat its value as the directory. In that case, the parameter is added to the named directory hash table.

The second form of **cd** substitutes the string *new* for the string *old* in the name of the current directory, and tries to change to this new directory.

The third form of **cd** extracts an entry from the directory stack, and changes to that directory. An argument of the form ‘+*n*’ identifies a stack entry by counting from the left of the list shown by the **dirs** command, starting with zero. An argument of the form ‘-*n*’ counts from the right. If the **PUSHD_MINUS** option is set, the meanings of ‘+’ and ‘-’ in this context are swapped. If the **POSIX_CD** option is set, this form of **cd** is not recognised and will be interpreted as the first form.

If the **-q** (quiet) option is specified, the hook function **chpwd** and the functions in the array

chpwd_functions are not called. This is useful for calls to **cd** that do not change the environment seen by an interactive user.

If the **-s** option is specified, **cd** refuses to change the current directory if the given pathname contains symlinks. If the **-P** option is given or the **CHASE_LINKS** option is set, symbolic links are resolved to their true values. If the **-L** option is given symbolic links are retained in the directory (and not resolved) regardless of the state of the **CHASE_LINKS** option.

chdir Same as **cd**.

clone See the section ‘The zsh/clone Module’ in *zshmodules(1)*.

command [**-pvV**] *simple command*

The simple command argument is taken as an external command instead of a function or builtin and is executed. If the **POSIX_BUILTINS** option is set, builtins will also be executed but certain special properties of them are suppressed. The **-p** flag causes a default path to be searched instead of that in **\$path**. With the **-v** flag, **command** is similar to **whence** and with **-V**, it is equivalent to **whence -v**.

See also the section ‘Precommand Modifiers’ in *zshmisc(1)*.

comparguments

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

compcall

See the section ‘The zsh/comptcl Module’ in *zshmodules(1)*.

compctl

See the section ‘The zsh/comptcl Module’ in *zshmodules(1)*.

compdescribe

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

compfiles

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

compgroups

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

compquote

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

comptags

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

comptrry

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

compvalues

See the section ‘The zsh/computil Module’ in *zshmodules(1)*.

continue [*n*]

Resume the next iteration of the enclosing **for**, **while**, **until**, **select** or **repeat** loop. If an arithmetic expression *n* is specified, break out of *n*–1 loops and resume at the *n*th enclosing loop.

declare Same as **typeset**.

dirs [**-c**] [*arg* ...]

dirs [**-lpv**]

With no arguments, print the contents of the directory stack. Directories are added to this stack with the **pushd** command, and removed with the **cd** or **popd** commands. If arguments are specified, load them onto the directory stack, replacing anything that was there, and push the current directory onto the stack.

-c clear the directory stack.

- l** print directory names in full instead of using of using `~` expressions (see *Dynamic* and *Static named directories* in *zshexpn(1)*).
- p** print directory entries one per line.
- v** number the directories in the stack when printing.

disable [**-afmprs**] *name* ...

Temporarily disable the *named* hash table elements or patterns. The default is to disable builtin commands. This allows you to use an external command with the same name as a builtin command. The **-a** option causes **disable** to act on regular or global aliases. The **-s** option causes **disable** to act on suffix aliases. The **-f** option causes **disable** to act on shell functions. The **-r** options causes **disable** to act on reserved words. Without arguments all disabled hash table elements from the corresponding hash table are printed. With the **-m** flag the arguments are taken as patterns (which should be quoted to prevent them from undergoing filename expansion), and all hash table elements from the corresponding hash table matching these patterns are disabled. Disabled objects can be enabled with the **enable** command.

With the option **-p**, *name* ... refer to elements of the shell's pattern syntax as described in the section 'Filename Generation'. Certain elements can be disabled separately, as given below.

Note that patterns not allowed by the current settings for the options **EXTENDED_GLOB**, **KSH_GLOB** and **SH_GLOB** are never enabled, regardless of the setting here. For example, if **EXTENDED_GLOB** is not active, the pattern `^` is ineffective even if '**disable -p "^"**' has not been issued. The list below indicates any option settings that restrict the use of the pattern. It should be noted that setting **SH_GLOB** has a wider effect than merely disabling patterns as certain expressions, in particular those involving parentheses, are parsed differently.

The following patterns may be disabled; all the strings need quoting on the command line to prevent them from being interpreted immediately as patterns and the patterns are shown below in single quotes as a reminder.

- '?'** The pattern character `?` wherever it occurs, including when preceding a parenthesis with **KSH_GLOB**.
- '*'** The pattern character `*` wherever it occurs, including recursive globbing and when preceding a parenthesis with **KSH_GLOB**.
- '['** Character classes.
- '<' (NO_SH_GLOB)**
Numeric ranges.
- '|' (NO_SH_GLOB)**
Alternation in grouped patterns, case statements, or **KSH_GLOB** parenthesised expressions.
- '(' (NO_SH_GLOB)**
Grouping using single parentheses. Disabling this does not disable the use of parentheses for **KSH_GLOB** where they are introduced by a special character, nor for glob qualifiers (use '**setopt NO_BARE_GLOB_QUAL**' to disable glob qualifiers that use parentheses only).
- '~' (EXTENDED_GLOB)**
Exclusion in the form `A~B`.
- '^' (EXTENDED_GLOB)**
Exclusion in the form `A^B`.
- '#' (EXTENDED_GLOB)**
The pattern character `#` wherever it occurs, both for repetition of a previous pattern and for indicating globbing flags.

'?' (KSH_GLOB)

The grouping form ?(...). Note this is also disabled if '*' is disabled.

'*' (KSH_GLOB)

The grouping form *(...). Note this is also disabled if '*' is disabled.

'+' (KSH_GLOB)

The grouping form +(...).

'!' (KSH_GLOB)

The grouping form !(...).

'@' (KSH_GLOB)

The grouping form @(...).

disown [job ...]

job ... &|

job ... &!

Remove the specified *jobs* from the job table; the shell will no longer report their status, and will not complain if you try to exit an interactive shell with them running or stopped. If no *job* is specified, disown the current job.

If the *jobs* are currently stopped and the **AUTO_CONTINUE** option is not set, a warning is printed containing information about how to make them running after they have been disowned. If one of the latter two forms is used, the *jobs* will automatically be made running, independent of the setting of the **AUTO_CONTINUE** option.

echo [-neE] [arg ...]

Write each *arg* on the standard output, with a space separating each one. If the **-n** flag is not present, print a newline at the end. **echo** recognizes the following escape sequences:

\a	bell character
\b	backspace
\c	suppress subsequent characters and final newline
\e	escape
\f	form feed
\n	linefeed (newline)
\r	carriage return
\t	horizontal tab
\v	vertical tab
\\\	backslash
\0NNN	character code in octal
\xNN	character code in hexadecimal
\uNNNN	unicode character code in hexadecimal
\UNNNNNNNNN	unicode character code in hexadecimal

The **-E** flag, or the **BSD_ECHO** option, can be used to disable these escape sequences. In the latter case, **-e** flag can be used to enable them.

Note that for standards compliance a double dash does not terminate option processing; instead, it is printed directly. However, a single dash does terminate option processing, so the first dash, possibly following options, is not printed, but everything following it is printed as an argument. The single dash behaviour is different from other shells. For a more portable way of printing text, see **printf**, and for a more controllable way of printing text within zsh, see **print**.

echotc See the section ‘The zsh/termcap Module’ in *zshmodules(1)*.

echoti See the section ‘The zsh/terminfo Module’ in *zshmodules(1)*.

emulate [**-ILR**] [{**zsh|sh|ksh|csh**} [*flags* ...]]

Without any argument print current emulation mode.

With single argument set up zsh options to emulate the specified shell as much as possible. **csh** will never be fully emulated. If the argument is not one of the shells listed above, **zsh** will be used as a default; more precisely, the tests performed on the argument are the same as those used to determine the emulation at startup based on the shell name, see the section COMPATIBILITY in *zsh(1)*. In addition to setting shell options, the command also restores the pristine state of pattern enables, as if all patterns had been enabled using **enable -p**.

If the **emulate** command occurs inside a function that has been marked for execution tracing with **functions -t** then the **xtrace** option will be turned on regardless of emulation mode or other options. Note that code executed inside the function by the **..**, **source**, or **eval** commands is not considered to be running directly from the function, hence does not provoke this behaviour.

If the **-R** switch is given, all settable options are reset to their default value corresponding to the specified emulation mode, except for certain options describing the interactive environment; otherwise, only those options likely to cause portability problems in scripts and functions are altered. If the **-L** switch is given, the options **LOCAL_OPTIONS**, **LOCAL_PATTERNS** and **LOCAL_TRAPS** will be set as well, causing the effects of the **emulate** command and any **setopt**, **disable -p** or **enable -p**, and **trap** commands to be local to the immediately surrounding shell function, if any; normally these options are turned off in all emulation modes except **ksh**. The **-L** switch is mutually exclusive with the use of **-c** in *flags*.

If there is a single argument and the **-I** switch is given, the options that would be set or unset (the latter indicated with the prefix ‘**no**’) are listed. **-I** can be combined with **-L** or **-R** and the list will be modified in the appropriate way. Note the list does not depend on the current setting of options, i.e. it includes all options that may in principle change, not just those that would actually change.

The *flags* may be any of the invocation-time flags described in the section INVOCATION in *zsh(1)*, except that ‘**-o EMACS**’ and ‘**-o VI**’ may not be used. Flags such as ‘**+r**’/‘**+o RESTRICTED**’ may be prohibited in some circumstances.

If **-c arg** appears in *flags*, *arg* is evaluated while the requested emulation is temporarily in effect. In this case the emulation mode and all options are restored to their previous values before **emulate** returns. The **-R** switch may precede the name of the shell to emulate; note this has a meaning distinct from including **-R** in *flags*.

Use of **-c** enables ‘sticky’ emulation mode for functions defined within the evaluated expression: the emulation mode is associated thereafter with the function so that whenever the function is executed the emulation (respecting the **-R** switch, if present) and all options are set (and pattern disables cleared) before entry to the function, and the state is restored after exit. If the function is called when the sticky emulation is already in effect, either within an ‘**emulate shell -c**’ expression or within another function with the same sticky emulation, entry and exit from the function do not cause options to be altered (except due to standard processing such as the **LOCAL_OPTIONS** option). This also applies to functions marked for autoload within the sticky emulation; the appropriate set of options will be applied at the point the function is loaded as well as when it is run.

For example:

```
emulate sh -c 'fni() { setopt cshnullglob; }
fno() { fni; }
fno
```

The two functions **fni** and **fno** are defined with sticky **sh** emulation. **fno** is then executed, causing options associated with emulations to be set to their values in **sh**. **fno** then calls **fni**; because **fni** is also marked for sticky **sh** emulation, no option changes take place on entry to or exit from it. Hence the option **cshnullglob**, turned off by **sh** emulation, will be turned on within **fni** and remain on return to **fno**. On exit from **fno**, the emulation mode and all options will be restored to the state

they were in before entry to the temporary emulation.

The documentation above is typically sufficient for the intended purpose of executing code designed for other shells in a suitable environment. More detailed rules follow.

1. The sticky emulation environment provided by ‘**emulate shell -c**’ is identical to that provided by entry to a function marked for sticky emulation as a consequence of being defined in such an environment. Hence, for example, the sticky emulation is inherited by subfunctions defined within functions with sticky emulation.
2. No change of options takes place on entry to or exit from functions that are not marked for sticky emulation, other than those that would normally take place, even if those functions are called within sticky emulation.
3. No special handling is provided for functions marked for **autoload** nor for functions present in wordcode created by the **zcompile** command.
4. The presence or absence of the **-R** switch to **emulate** corresponds to different sticky emulation modes, so for example ‘**emulate sh -c**’, ‘**emulate -R sh -c**’ and ‘**emulate csh -c**’ are treated as three distinct sticky emulations.
5. Difference in shell options supplied in addition to the basic emulation also mean the sticky emulations are different, so for example ‘**emulate zsh -c**’ and ‘**emulate zsh -o cbases -c**’ are treated as distinct sticky emulations.

enable [**-afmprs**] *name* ...

Enable the *named* hash table elements, presumably disabled earlier with **disable**. The default is to enable builtin commands. The **-a** option causes **enable** to act on regular or global aliases. The **-s** option causes **enable** to act on suffix aliases. The **-f** option causes **enable** to act on shell functions. The **-r** option causes **enable** to act on reserved words. Without arguments all enabled hash table elements from the corresponding hash table are printed. With the **-m** flag the arguments are taken as patterns (should be quoted) and all hash table elements from the corresponding hash table matching these patterns are enabled. Enabled objects can be disabled with the **disable** builtin command.

enable -p reenables patterns disabled with **disable -p**. Note that it does not override globbing options; for example, ‘**enable -p "~~"**’ does not cause the pattern character **~** to be active unless the **EXTENDED_GLOB** option is also set. To enable all possible patterns (so that they may be individually disabled with **disable -p**), use ‘**setopt EXTENDED_GLOB KSH_GLOB NO_SH_GLOB**’.

eval [*arg* ...]

Read the arguments as input to the shell and execute the resulting command(s) in the current shell process. The return status is the same as if the commands had been executed directly by the shell; if there are no *args* or they contain no commands (i.e. are an empty string or whitespace) the return status is zero.

exec [**-cl**] [**-a** *argv0*] [*command* [*arg* ...]]

Replace the current shell with *command* rather than forking. If *command* is a shell builtin command or a shell function, the shell executes it, and exits when the command is complete.

With **-c** clear the environment; with **-l** prepend **-** to the **argv[0]** string of the command executed (to simulate a login shell); with **-a** *argv0* set the **argv[0]** string of the command executed. See the section ‘Precommand Modifiers’ in *zshmisc(1)*.

If the option **POSIX_BUILTINS** is set, *command* is never interpreted as a shell builtin command or shell function. This means further precommand modifiers such as **builtin** and **noglob** are also not interpreted within the shell. Hence *command* is always found by searching the command path.

If *command* is omitted but any redirections are specified, then the redirections will take effect in the current shell.

exit [*n*]

Exit the shell with the exit status specified by an arithmetic expression *n*; if none is specified, use the exit status from the last command executed. An EOF condition will also cause the shell to

exit, unless the **IGNORE_EOF** option is set.

See notes at the end of the section JOBS in *zshmisc(1)* for some possibly unexpected interactions of the **exit** command with jobs.

export [*name[=value]* ...]

The specified *names* are marked for automatic export to the environment of subsequently executed commands. Equivalent to **typeset -gx**. If a parameter specified does not already exist, it is created in the global scope.

false [*arg* ...]

Do nothing and return an exit status of 1.

fc [**-e** *ename*] [**-LI**] [**-m** *match*] [*old=new* ...] [*first* [*last*]]

fc **-l** [**-LI**] [**-nrdfEiD**] [**-t** *timefmt*] [**-m** *match*]

[*old=new* ...] [*first* [*last*]]

fc **-p** [**-a**] [*filename* [*histsize* [*savehistsize*]]]

fc **-P**

fc **-ARWI** [*filename*]

The **fc** command controls the interactive history mechanism. Note that reading and writing of history options is only performed if the shell is interactive. Usually this is detected automatically, but it can be forced by setting the **interactive** option when starting the shell.

The first two forms of this command select a range of events from *first* to *last* from the history list. The arguments *first* and *last* may be specified as a number or as a string. A negative number is used as an offset to the current history event number. A string specifies the most recent event beginning with the given string. All substitutions *old=new*, if any, are then performed on the text of the events.

In addition to the number range,

-I restricts to only internal events (not from **\$HISTFILE**)

-L restricts to only local events (not from other shells, see **SHARE_HISTORY** in *zshoptions(1)* — note that **\$HISTFILE** is considered local when read at startup)

-m takes the first argument as a pattern (should be quoted) and only the history events matching this pattern are considered

If *first* is not specified, it will be set to -1 (the most recent event), or to -16 if the **-I** flag is given. If *last* is not specified, it will be set to *first*, or to -1 if the **-I** flag is given. However, if the current event has added entries to the history with '**print -s**' or '**fc -R**', then the default *last* for **-I** includes all new history entries since the current event began.

When the **-I** flag is given, the resulting events are listed on standard output. Otherwise the editor program specified by **-e** *ename* is invoked on a file containing these history events. If **-e** is not given, the value of the parameter **FCEDIT** is used; if that is not set the value of the parameter **EDITOR** is used; if that is not set a builtin default, usually '**vi**' is used. If *ename* is ' $-$ ', no editor is invoked. When editing is complete, the edited command is executed.

The flag **-r** reverses the order of the events and the flag **-n** suppresses event numbers when listing.

Also when listing,

-d prints timestamps for each event

-f prints full time–date stamps in the US '*MM/DD/YY hh:mm*' format

-E prints full time–date stamps in the European '*dd.mm.yyyy hh:mm*' format

-i prints full time–date stamps in ISO8601 '*yyyy-mm-dd hh:mm*' format

-t *fmt* prints time and date stamps in the given format; *fmt* is formatted with the `strftime` function with the zsh extensions described for the **%D{string}** prompt format in the section EXPANSION OF PROMPT SEQUENCES in *zshmisc(1)*. The resulting formatted string must be no more than 256 characters or will not be printed

-D prints elapsed times; may be combined with one of the options above

‘**fc -p**’ pushes the current history list onto a stack and switches to a new history list. If the **-a** option is also specified, this history list will be automatically popped when the current function scope is exited, which is a much better solution than creating a trap function to call ‘**fc -P**’ manually. If no arguments are specified, the history list is left empty, **\$HISTFILE** is unset, and **\$HISTSIZE** & **\$SAVEHIST** are set to their default values. If one argument is given, **\$HISTFILE** is set to that filename, **\$HISTSIZE** & **\$SAVEHIST** are left unchanged, and the history file is read in (if it exists) to initialize the new list. If a second argument is specified, **\$HISTSIZE** & **\$SAVEHIST** are instead set to the single specified numeric value. Finally, if a third argument is specified, **\$SAVEHIST** is set to a separate value from **\$HISTSIZE**. You are free to change these environment values for the new history list however you desire in order to manipulate the new history list.

‘**fc -P**’ pops the history list back to an older list saved by ‘**fc -p**’. The current list is saved to its **\$HISTFILE** before it is destroyed (assuming that **\$HISTFILE** and **\$SAVEHIST** are set appropriately, of course). The values of **\$HISTFILE**, **\$HISTSIZE**, and **\$SAVEHIST** are restored to the values they had when ‘**fc -p**’ was called. Note that this restoration can conflict with making these variables “local”, so your best bet is to avoid local declarations for these variables in functions that use ‘**fc -p**’. The one other guaranteed-safe combination is declaring these variables to be local at the top of your function and using the automatic option (**-a**) with ‘**fc -p**’. Finally, note that it is legal to manually pop a push marked for automatic popping if you need to do so before the function exits.

‘**fc -R**’ reads the history from the given file, ‘**fc -W**’ writes the history out to the given file, and ‘**fc -A**’ appends the history out to the given file. If no filename is specified, the **\$HISTFILE** is assumed. If the **-I** option is added to **-R**, only those events that are not already contained within the internal history list are added. If the **-I** option is added to **-A** or **-W**, only those events that are new since last incremental append/write to the history file are appended/written. In any case, the created file will have no more than **\$SAVEHIST** entries.

fg [job ...]

job ... Bring each specified *job* in turn to the foreground. If no *job* is specified, resume the current job.

float [{+|-}Hghlprtux] [{+|-}EFLRZ [*n*]] [*name[=value]* ...]

Equivalent to **typeset -E**, except that options irrelevant to floating point numbers are not permitted.

functions [{+|-}UkmtTuWz] [-x *num*] [*name* ...]

functions -c *oldfn newfn*

functions -M [-s] *mathfn* [*min* [*max* [*shellfn*]]]

functions -M [-m *pattern* ...]

functions +M [-m] *mathfn* ...

Equivalent to **typeset -f**, with the exception of the **-c**, **-x**, **-M** and **-W** options. For **functions -u** and **functions -U**, see **autoload**, which provides additional options.

The **-x** option indicates that any functions output will have each leading tab for indentation, added by the shell to show syntactic structure, expanded to the given number *num* of spaces. *num* can also be 0 to suppress all indentation.

The **-W** option turns on the option **WARN_NESTED_VAR** for the named function or functions only. The option is turned off at the start of nested functions (apart from anonymous functions) unless the called function also has the **-W** attribute.

The **-c** option causes *oldfn* to be copied to *newfn*. The copy is efficiently handled internally by reference counting. If *oldfn* was marked for autoload it is first loaded and if this fails the copy fails. Either function may subsequently be redefined without affecting the other. A typical idiom is that *oldfn* is the name of a library shell function which is then redefined to call **newfn**, thereby installing a modified version of the function.

Use of the **-M** option may not be combined with any of the options handled by **typeset -f**.

functions -M *mathfn* defines *mathfn* as the name of a mathematical function recognised in all forms of arithmetical expressions; see the section ‘Arithmetic Evaluation’ in *zshmisc(1)*. By default *mathfn* may take any number of comma-separated arguments. If *min* is given, it must have exactly *min* args; if *min* and *max* are both given, it must have at least *min* and at most *max* args. *max* may be -1 to indicate that there is no upper limit.

By default the function is implemented by a shell function of the same name; if *shellfn* is specified it gives the name of the corresponding shell function while *mathfn* remains the name used in arithmetical expressions. The name of the function in **\$0** is *mathfn* (not *shellfn* as would usually be the case), provided the option **FUNCTION_ARGZERO** is in effect. The positional parameters in the shell function correspond to the arguments of the mathematical function call. The result of the last arithmetical expression evaluated inside the shell function (even if it is a form that normally only returns a status) gives the result of the mathematical function.

If the additional option **-s** is given to **functions -M**, the argument to the function is a single string: anything between the opening and matching closing parenthesis is passed to the function as a single argument, even if it includes commas or white space. The minimum and maximum argument specifiers must therefore be 1 if given. An empty argument list is passed as a zero-length string.

functions -M with no arguments lists all such user-defined functions in the same form as a definition. With the additional option **-m** and a list of arguments, all functions whose *mathfn* matches one of the pattern arguments are listed.

function +M removes the list of mathematical functions; with the additional option **-m** the arguments are treated as patterns and all functions whose *mathfn* matches the pattern are removed. Note that the shell function implementing the behaviour is not removed (regardless of whether its name coincides with *mathfn*).

For example, the following prints the cube of 3 :

```
zmath_cube() { (( $1 * $1 * $1 )) }
functions -M cube 1 1 zmath_cube
print $(( cube(3) ))
```

The following string function takes a single argument, including the commas, so prints 11 :

```
stringfn() { (( $#1 )) }
functions -Ms stringfn
print $(( stringfn(foo,bar,rod) ))
```

getcap See the section ‘The zsh/cap Module’ in *zshmodules(1)*.

getln [**-AclneE**] *name* ...

Read the top value from the buffer stack and put it in the shell parameter *name*. Equivalent to **read -zr**.

getopts *optstring name [arg ...]*

Checks the *args* for legal options. If the *args* are omitted, use the positional parameters. A valid option argument begins with a $+$ or a $-$. An argument not beginning with a $+$ or a $-$, or the argument $--$, ends the options. Note that a single $-$ is not considered a valid option argument. *optstring* contains the letters that **getopts** recognizes. If a letter is followed by a $:$, that option requires an argument. The options can be separated from the argument by blanks.

Each time it is invoked, **getopts** places the option letter it finds in the shell parameter *name*, prepended with a $+$ when *arg* begins with a $+$. The index of the next *arg* is stored in **OPTIND**. The option argument, if any, is stored in **OPTARG**.

The first option to be examined may be changed by explicitly assigning to **OPTIND**. **OPTIND** has an initial value of **1**, and is normally set to **1** upon entry to a shell function and restored upon exit (this is disabled by the **POSIX_BUILTINS** option). **OPTARG** is not reset and retains its value from the most recent call to **getopts**. If either of **OPTIND** or **OPTARG** is explicitly unset,

it remains unset, and the index or option argument is not stored. The option itself is still stored in *name* in this case.

A leading ‘:’ in *optstring* causes **getopts** to store the letter of any invalid option in **OPTARG**, and to set *name* to ‘?’ for an unknown option and to ‘:’ when a required argument is missing. Otherwise, **getopts** sets *name* to ‘?’ and prints an error message when an option is invalid. The exit status is nonzero when there are no more options.

hash [**-LdfmrV**] [*name[=value]*] ...

hash can be used to directly modify the contents of the command hash table, and the named directory hash table. Normally one would modify these tables by modifying one’s **PATH** (for the command hash table) or by creating appropriate shell parameters (for the named directory hash table). The choice of hash table to work on is determined by the **-d** option; without the option the command hash table is used, and with the option the named directory hash table is used.

A command *name* starting with a / is never hashed, whether by explicit use of the **hash** command or otherwise. Such a command is always found by direct look up in the file system.

Given no arguments, and neither the **-r** or **-f** options, the selected hash table will be listed in full.

The **-r** option causes the selected hash table to be emptied. It will be subsequently rebuilt in the normal fashion. The **-f** option causes the selected hash table to be fully rebuilt immediately. For the command hash table this hashes all the absolute directories in the **PATH**, and for the named directory hash table this adds all users’ home directories. These two options cannot be used with any arguments.

The **-m** option causes the arguments to be taken as patterns (which should be quoted) and the elements of the hash table matching those patterns are printed. This is the only way to display a limited selection of hash table elements.

For each *name* with a corresponding *value*, put ‘*name*’ in the selected hash table, associating it with the pathname ‘*value*’. In the command hash table, this means that whenever ‘*name*’ is used as a command argument, the shell will try to execute the file given by ‘*value*’. In the named directory hash table, this means that ‘*value*’ may be referred to as ‘~*name*’.

For each *name* with no corresponding *value*, attempt to add *name* to the hash table, checking what the appropriate **value** is in the normal manner for that hash table. If an appropriate **value** can’t be found, then the hash table will be unchanged.

The **-v** option causes hash table entries to be listed as they are added by explicit specification. If has no effect if used with **-f**.

If the **-L** flag is present, then each hash table entry is printed in the form of a call to **hash**.

history Same as **fc -l**.

integer [{+|-}Hghlpertux] [{+|-}LRZi [*n*]] [*name[=value]*] ...]

Equivalent to **typeset -i**, except that options irrelevant to integers are not permitted.

jobs [**-dlprs**] [*job* ...]

jobs **-Z** *string*

Lists information about each given job, or all jobs if *job* is omitted. The **-l** flag lists process IDs, and the **-p** flag lists process groups. If the **-r** flag is specified only running jobs will be listed and if the **-s** flag is given only stopped jobs are shown. If the **-d** flag is given, the directory from which the job was started (which may not be the current directory of the job) will also be shown.

The **-Z** option replaces the shell’s argument and environment space with the given string, truncated if necessary to fit. This will normally be visible in **ps** (*ps(1)*) listings. This feature is typically used by daemons, to indicate their state.

kill [**-s** *signal_name* | **-n** *signal_number* | **-sig**] *job* ...

kill -l [*sig* ...]

Sends either **SIGTERM** or the specified signal to the given jobs or processes. Signals are given by number or by names, with or without the ‘**SIG**’ prefix. If the signal being sent is not ‘**KILL**’ or ‘**CONT**’, then the job will be sent a ‘**CONT**’ signal if it is stopped. The argument *job* can be the process ID of a job not in the job list. In the second form, **kill -l**, if *sig* is not specified the signal names are listed. Otherwise, for each *sig* that is a name, the corresponding signal number is listed. For each *sig* that is a signal number or a number representing the exit status of a process which was terminated or stopped by a signal the name of the signal is printed.

On some systems, alternative signal names are allowed for a few signals. Typical examples are **SIGCHLD** and **SIGCLD** or **SIGPOLL** and **SIGIO**, assuming they correspond to the same signal number. **kill -l** will only list the preferred form, however **kill -l alt** will show if the alternative form corresponds to a signal number. For example, under Linux **kill -l IO** and **kill -l POLL** both output 29, hence **kill -IO** and **kill -POLL** have the same effect.

Many systems will allow process IDs to be negative to kill a process group or zero to kill the current process group.

let *arg* ...

Evaluate each *arg* as an arithmetic expression. See the section ‘Arithmetic Evaluation’ in *zshmisc(1)* for a description of arithmetic expressions. The exit status is 0 if the value of the last expression is nonzero, 1 if it is zero, and 2 if an error occurred.

limit [-hs] [*resource* [*limit*]] ...

Set or display resource limits. Unless the **-s** flag is given, the limit applies only the children of the shell. If **-s** is given without other arguments, the resource limits of the current shell is set to the previously set resource limits of the children.

If *limit* is not specified, print the current limit placed on *resource*, otherwise set the limit to the specified value. If the **-h** flag is given, use hard limits instead of soft limits. If no *resource* is given, print all limits.

When looping over multiple resources, the shell will abort immediately if it detects a badly formed argument. However, if it fails to set a limit for some other reason it will continue trying to set the remaining limits.

resource can be one of:

addressspace

Maximum amount of address space used.

aiomemorylocked

Maximum amount of memory locked in RAM for AIO operations.

aiooperations

Maximum number of AIO operations.

cachedthreads

Maximum number of cached threads.

coredumpsize

Maximum size of a core dump.

cputime

Maximum CPU seconds per process.

datasize

Maximum data size (including stack) for each process.

descriptors

Maximum value for a file descriptor.

filesize

Largest single file allowed.

kqueues

Maximum number of kqueues allocated.

maxproc

Maximum number of processes.

maxthreads

Maximum number of threads per process.

memorylocked

Maximum amount of memory locked in RAM.

memoryuse

Maximum resident set size.

msgqueue

Maximum number of bytes in POSIX message queues.

posixlocks

Maximum number of POSIX locks per user.

pseudoterminals

Maximum number of pseudo-terminals.

resident

Maximum resident set size.

sigpending

Maximum number of pending signals.

sockbufsize

Maximum size of all socket buffers.

stacksize

Maximum stack size for each process.

swapsize

Maximum amount of swap used.

vmemorysize

Maximum amount of virtual memory.

Which of these resource limits are available depends on the system. *resource* can be abbreviated to any unambiguous prefix. It can also be an integer, which corresponds to the integer defined for the resource by the operating system.

If argument corresponds to a number which is out of the range of the resources configured into the shell, the shell will try to read or write the limit anyway, and will report an error if this fails. As the shell does not store such resources internally, an attempt to set the limit will fail unless the **-s** option is present.

limit is a number, with an optional scaling factor, as follows:

n h	hours
n k	kilobytes (default)
n m	megabytes or minutes
n g	gigabytes
[m m :] s	minutes and seconds

The **limit** command is not made available by default when the shell starts in a mode emulating another shell. It can be made available with the command ‘**zmodload -F zsh/rlimits b:limit**’.

local [{+|-}A{HUhlp}rtux] [{+|-}EFLRZi [*n*]] [*name*[=value] ...]

Same as **typeset**, except that the options **-g**, and **-f** are not permitted. In this case the **-x** option does not force the use of **-g**, i.e. exported variables will be local to functions.

log List all users currently logged in who are affected by the current setting of the **watch** parameter.

logout [*n*]

Same as **exit**, except that it only works in a login shell.

noglob *simple command*

See the section ‘Precommand Modifiers’ in *zshmisc*(1).

popd [**-q**] [{+|-}n]

Remove an entry from the directory stack, and perform a **cd** to the new top directory. With no argument, the current top entry is removed. An argument of the form '+n' identifies a stack entry by counting from the left of the list shown by the **dirs** command, starting with zero. An argument of the form '-n' counts from the right. If the **PUSHD_MINUS** option is set, the meanings of '+' and '-' in this context are swapped.

If the **-q** (quiet) option is specified, the hook function **chpwd** and the functions in the array **\$chpwd_functions** are not called, and the new directory stack is not printed. This is useful for calls to **popd** that do not change the environment seen by an interactive user.

print [**-abcDilmnNoOpPrsSz**] [**-u n**] [**-f format**] [**-C cols**]
[**-v name**] [**-xX tabstop**] [**-R** [**-en**]] [**arg ...**]

With the '**-f**' option the arguments are printed as described by **printf**. With no flags or with the flag '**-**', the arguments are printed on the standard output as described by **echo**, with the following differences: the escape sequence '**\M-x**' (or '**\Mx**') metafies the character *x* (sets the highest bit), '**\C-x**' (or '**\Cx**') produces a control character ('**\C-@**' and '**\C-?**' give the characters NULL and delete), a character code in octal is represented by '**\NNN**' (instead of '**\0NNN**'), and '**\E**' is a synonym for '**\e**'. Finally, if not in an escape sequence, '****' escapes the following character and is not printed.

-a Print arguments with the column incrementing first. Only useful with the **-c** and **-C** options.

-b Recognize all the escape sequences defined for the **bindkey** command, see the section 'Zle Builtins' in *zshzle(1)*.

-c Print the arguments in columns. Unless **-a** is also given, arguments are printed with the row incrementing first.

-C cols

Print the arguments in *cols* columns. Unless **-a** is also given, arguments are printed with the row incrementing first.

-D Treat the arguments as paths, replacing directory prefixes with **~** expressions corresponding to directory names, as appropriate.

-i If given together with **-o** or **-O**, sorting is performed case-independently.

-l Print the arguments separated by newlines instead of spaces. Note: if the list of arguments is empty, **print -l** will still output one empty line. To print a possibly-empty list of arguments one per line, use **print -C1**, as in '**print -rC1 -- "\$list[@]"**'.

-m Take the first argument as a pattern (should be quoted), and remove it from the argument list together with subsequent arguments that do not match this pattern.

-n Do not add a newline to the output.

-N Print the arguments separated and terminated by nulls. Again, **print -rNC1 -- "\$list[@]"** is a canonical way to print an arbitrary list as null-delimited records.

-o Print the arguments sorted in ascending order.

-O Print the arguments sorted in descending order.

-p Print the arguments to the input of the coprocess.

-P Perform prompt expansion (see EXPANSION OF PROMPT SEQUENCES in *zshmisc(1)*). In combination with '**-f**', prompt escape sequences are parsed only within interpolated arguments, not within the format string.

-r Ignore the escape conventions of **echo**.

-R Emulate the BSD **echo** command, which does not process escape sequences unless the **-e** flag is given. The **-n** flag suppresses the trailing newline. Only the **-e** and **-n** flags are

recognized after **-R**; all other arguments and options are printed.

- s** Place the results in the history list instead of on the standard output. Each argument to the **print** command is treated as a single word in the history, regardless of its content.
- S** Place the results in the history list instead of on the standard output. In this case only a single argument is allowed; it will be split into words as if it were a full shell command line. The effect is similar to reading the line from a history file with the **HIST_LEX_WORDS** option active.
- u n** Print the arguments to file descriptor *n*.
- v name** Store the printed arguments as the value of the parameter *name*.
- x tab-stop** Expand leading tabs on each line of output in the printed string assuming a tab stop every *tab-stop* characters. This is appropriate for formatting code that may be indented with tabs. Note that leading tabs of any argument to print, not just the first, are expanded, even if **print** is using spaces to separate arguments (the column count is maintained across arguments but may be incorrect on output owing to previous unexpanded tabs).
The start of the output of each **print** command is assumed to be aligned with a tab stop. Widths of multibyte characters are handled if the option **MULTIBYTE** is in effect. This option is ignored if other formatting options are in effect, namely column alignment or **printf** style, or if output is to a special location such as shell history or the command line editor.
- X tab-stop** This is similar to **-x**, except that all tabs in the printed string are expanded. This is appropriate if tabs in the arguments are being used to produce a table format.
- z** Push the arguments onto the editing buffer stack, separated by spaces.
If any of '**-m**', '**-o**' or '**-O**' are used in combination with '**-f**' and there are no arguments (after the removal process in the case of '**-m**') then nothing is printed.

printf [**-v** *name*] *format* [*arg ...*]

Print the arguments according to the format specification. Formatting rules are the same as used in C. The same escape sequences as for **echo** are recognised in the format. All C conversion specifications ending in one of **cstdiouxXeEfgGn** are handled. In addition to this, '**%b**' can be used instead of '**%s**' to cause escape sequences in the argument to be recognised and '**%q**' can be used to quote the argument in such a way that allows it to be reused as shell input. With the numeric format specifiers, if the corresponding argument starts with a quote character, the numeric value of the following character is used as the number to print; otherwise the argument is evaluated as an arithmetic expression. See the section 'Arithmetic Evaluation' in *zshmisc(1)* for a description of arithmetic expressions. With '**%n**', the corresponding argument is taken as an identifier which is created as an integer parameter.

Normally, conversion specifications are applied to each argument in order but they can explicitly specify the *n*th argument is to be used by replacing '**%**' by '**%on\$**' and '*****' by '***n\$**'. It is recommended that you do not mix references of this explicit style with the normal style and the handling of such mixed styles may be subject to future change.

If arguments remain unused after formatting, the format string is reused until all arguments have been consumed. With the **print** builtin, this can be suppressed by using the **-r** option. If more arguments are required by the format than have been specified, the behaviour is as if zero or an empty string had been specified as the argument.

The **-v** option causes the output to be stored as the value of the parameter *name*, instead of printed. If *name* is an array and the format string is reused when consuming arguments then one array element will be used for each use of the format string.

pushd [**-qsLP**] [*arg*]
pushd [**-qsLP**] *old new*
pushd [**-qsLP**] {+|-}n

Change the current directory, and push the old current directory onto the directory stack. In the first form, change the current directory to *arg*. If *arg* is not specified, change to the second directory on the stack (that is, exchange the top two entries), or change to **\$HOME** if the **PUSHD_TO_HOME** option is set or if there is only one entry on the stack. Otherwise, *arg* is interpreted as it would be by **cd**. The meaning of *old* and *new* in the second form is also the same as for **cd**.

The third form of **pushd** changes directory by rotating the directory list. An argument of the form ‘+n’ identifies a stack entry by counting from the left of the list shown by the **dirs** command, starting with zero. An argument of the form ‘-n’ counts from the right. If the **PUSHD_MINUS** option is set, the meanings of ‘+’ and ‘-’ in this context are swapped.

If the **-q** (quiet) option is specified, the hook function **chpwd** and the functions in the array **\$chpwd_functions** are not called, and the new directory stack is not printed. This is useful for calls to **pushd** that do not change the environment seen by an interactive user.

If the option **-q** is not specified and the shell option **PUSHD_SILENT** is not set, the directory stack will be printed after a **pushd** is performed.

The options **-s**, **-L** and **-P** have the same meanings as for the **cd** builtin.

pushln [*arg ...*]

Equivalent to **print -nz**.

pwd [**-rLP**]

Print the absolute pathname of the current working directory. If the **-r** or the **-P** flag is specified, or the **CHASE_LINKS** option is set and the **-L** flag is not given, the printed path will not contain symbolic links.

r Same as **fc -e -**.

read [**-rszpqAclnE**] [**-t** [*num*]] [**-k** [*num*]] [**-d** *delim*]
[**-u** *n*] [*name*[?*prompt*]] [*name ...*]

Read one line and break it into fields using the characters in **\$IFS** as separators, except as noted below. The first field is assigned to the *firstname*, the second field to the second *name*, etc., with leftover fields assigned to the last *name*. If *name* is omitted then **REPLY** is used for scalars and **reply** for arrays.

-r Raw mode: a ‘\’ at the end of a line does not signify line continuation and backslashes in the line don’t quote the following character and are not removed.

-s Don’t echo back characters if reading from the terminal.

-q Read only one character from the terminal and set *name* to ‘y’ if this character was ‘y’ or ‘Y’ and to ‘n’ otherwise. With this flag set the return status is zero only if the character was ‘y’ or ‘Y’. This option may be used with a timeout (see **-t**); if the read times out, or encounters end of file, status 2 is returned. Input is read from the terminal unless one of **-u** or **-p** is present. This option may also be used within zle widgets.

-k [*num*]

Read only one (or *num*) characters. All are assigned to the first *name*, without word splitting. This flag is ignored when **-q** is present. Input is read from the terminal unless one of **-u** or **-p** is present. This option may also be used within zle widgets.

Note that despite the mnemonic ‘key’ this option does read full characters, which may consist of multiple bytes if the option **MULTIBYTE** is set.

-z Read one entry from the editor buffer stack and assign it to the first *name*, without word splitting. Text is pushed onto the stack with ‘**print -z**’ or with **push-line** from the line

editor (see *zshzle(1)*). This flag is ignored when the **-k** or **-q** flags are present.

- e**
- E** The input read is printed (echoed) to the standard output. If the **-e** flag is used, no input is assigned to the parameters.
- A** The first *name* is taken as the name of an array and all words are assigned to it.
- c**
- l** These flags are allowed only if called inside a function used for completion (specified with the **-K** flag to **compctl**). If the **-c** flag is given, the words of the current command are read. If the **-l** flag is given, the whole line is assigned as a scalar. If both flags are present, **-l** is used and **-c** is ignored.
- n** Together with **-c**, the number of the word the cursor is on is read. With **-l**, the index of the character the cursor is on is read. Note that the command name is word number 1, not word 0, and that when the cursor is at the end of the line, its character index is the length of the line plus one.
- u** *n* Input is read from file descriptor *n*.
- p** Input is read from the coprocess.
- d** *delim* Input is terminated by the first character of *delim* instead of by newline.
- t** [*num*] Test if input is available before attempting to read. If *num* is present, it must begin with a digit and will be evaluated to give a number of seconds, which may be a floating point number; in this case the read times out if input is not available within this time. If *num* is not present, it is taken to be zero, so that **read** returns immediately if no input is available. If no input is available, return status 1 and do not set any variables.

This option is not available when reading from the editor buffer with **-z**, when called from within completion with **-c** or **-l**, with **-q** which clears the input queue before reading, or within zle where other mechanisms should be used to test for input.

Note that **read** does not attempt to alter the input processing mode. The default mode is canonical input, in which an entire line is read at a time, so usually ‘**read -t**’ will not read anything until an entire line has been typed. However, when reading from the terminal with **-k** input is processed one key at a time; in this case, only availability of the first character is tested, so that e.g. ‘**read -t -k 2**’ can still block on the second character. Use two instances of ‘**read -t -k**’ if this is not what is wanted.

If the first argument contains a ‘?’ , the remainder of this word is used as a *prompt* on standard error when the shell is interactive.

The value (exit status) of **read** is 1 when an end-of-file is encountered, or when **-c** or **-l** is present and the command is not called from a **compctl** function, or as described for **-q**. Otherwise the value is 0.

The behavior of some combinations of the **-k**, **-p**, **-q**, **-u** and **-z** flags is undefined. Presently **-q** cancels all the others, **-p** cancels **-u**, **-k** cancels **-z**, and otherwise **-z** cancels both **-p** and **-u**.

The **-c** or **-l** flags cancel any and all of **-kpquz**.

readonly

Same as **typeset -r**. With the **POSIX_BUILTINS** option set, same as **typeset -gr**.

rehash

Same as **hash -r**.

return [*n*]

Causes a shell function or ‘.’ script to return to the invoking script with the return status specified by an arithmetic expression *n*. If *n* is omitted, the return status is that of the last command executed.

If **return** was executed from a trap in a **TRAPNAL** function, the effect is different for zero and non-zero return status. With zero status (or after an implicit return at the end of the trap), the shell will return to whatever it was previously processing; with a non-zero status, the shell will behave as interrupted except that the return status of the trap is retained. Note that the numeric value of the signal which caused the trap is passed as the first argument, so the statement ‘**return \$((128+\$1))**’ will return the same status as if the signal had not been trapped.

sched See the section ‘The zsh/sched Module’ in *zshmodules(1)*.

set [{+|-}options | {+|-}o [*option_name*]] ... [{+|-}A [*name*]]
[*arg* ...]

Set the options for the shell and/or set the positional parameters, or declare and set an array. If the **-s** option is given, it causes the specified arguments to be sorted before assigning them to the positional parameters (or to the array *name* if **-A** is used). With **+s** sort arguments in descending order. For the meaning of the other flags, see *zshoptions(1)*. Flags may be specified by name using the **-o** option. If no option name is supplied with **-o**, the current option states are printed: see the description of **setopt** below for more information on the format. With **+o** they are printed in a form that can be used as input to the shell.

If the **-A** flag is specified, *name* is set to an array containing the given *args*; if no *name* is specified, all arrays are printed together with their values.

If **+A** is used and *name* is an array, the given arguments will replace the initial elements of that array; if no *name* is specified, all arrays are printed without their values.

The behaviour of arguments after **-A** *name* or **+A** *name* depends on whether the option **KSH_ARRAYS** is set. If it is not set, all arguments following *name* are treated as values for the array, regardless of their form. If the option is set, normal option processing continues at that point; only regular arguments are treated as values for the array. This means that

set -A array -x -- foo

sets **array** to ‘**-x -- foo**’ if **KSH_ARRAYS** is not set, but sets the array to **foo** and turns on the option ‘**-x**’ if it is set.

If the **-A** flag is not present, but there are arguments beyond the options, the positional parameters are set. If the option list (if any) is terminated by ‘**--**’, and there are no further arguments, the positional parameters will be unset.

If no arguments and no ‘**--**’ are given, then the names and values of all parameters are printed on the standard output. If the only argument is ‘**+**’, the names of all parameters are printed.

For historical reasons, ‘**set -**’ is treated as ‘**set +xv**’ and ‘**set - args**’ as ‘**set +xv -- args**’ when in any other emulation mode than zsh’s native mode.

setcap See the section ‘The zsh/cap Module’ in *zshmodules(1)*.

setopt [{+|-}options | {+|-}o *option_name*] [**-m**] [*name* ...]

Set the options for the shell. All options specified either with flags or by name are set.

If no arguments are supplied, the names of all options currently set are printed. The form is chosen so as to minimize the differences from the default options for the current emulation (the default emulation being native **zsh**, shown as **<Z>** in *zshoptions(1)*). Options that are on by default for the emulation are shown with the prefix **no** only if they are off, while other options are shown without the prefix **no** and only if they are on. In addition to options changed from the default state by the user, any options activated automatically by the shell (for example, **SHIN_STDIN** or **INTERACTIVE**) will be shown in the list. The format is further modified by the option

KSH_OPTION_PRINT, however the rationale for choosing options with or without the **no** prefix remains the same in this case.

If the **-m** flag is given the arguments are taken as patterns (which should be quoted to protect them from filename expansion), and all options with names matching these patterns are set.

Note that a bad option name does not cause execution of subsequent shell code to be aborted; this behaviour is different from that of '**set -o**'. This is because **set** is regarded as a special builtin by the POSIX standard, but **setopt** is not.

shift [**-p**] [*n*] [*name ...*]

The positional parameters $\${n+1} \dots$ are renamed to **\$1** ..., where *n* is an arithmetic expression that defaults to 1. If any *names* are given then the arrays with these names are shifted instead of the positional parameters.

If the option **-p** is given arguments are instead removed (popped) from the end rather than the start of the array.

source *file* [*arg ...*]

Same as '.', except that the current directory is always searched and is always searched first, before directories in **\$path**.

stat See the section 'The zsh/stat Module' in *zshmodules*(1).

suspend [**-f**]

Suspend the execution of the shell (send it a **SIGTSTP**) until it receives a **SIGCONT**. Unless the **-f** option is given, this will refuse to suspend a login shell.

test [*arg ...*]

[[*arg ...*]]

Like the system version of **test**. Added for compatibility; use conditional expressions instead (see the section 'Conditional Expressions'). The main differences between the conditional expression syntax and the **test** and [builtins are: these commands are not handled syntactically, so for example an empty variable expansion may cause an argument to be omitted; syntax errors cause status 2 to be returned instead of a shell error; and arithmetic operators expect integer arguments rather than arithmetic expressions.

The command attempts to implement POSIX and its extensions where these are specified. Unfortunately there are intrinsic ambiguities in the syntax; in particular there is no distinction between test operators and strings that resemble them. The standard attempts to resolve these for small numbers of arguments (up to four); for five or more arguments compatibility cannot be relied on. Users are urged wherever possible to use the '[[...]]' test syntax which does not have these ambiguities.

times Print the accumulated user and system times for the shell and for processes run from the shell.

trap [*arg*] [*sig ...*]

arg is a series of commands (usually quoted to protect it from immediate evaluation by the shell) to be read and executed when the shell receives any of the signals specified by one or more *sig* args. Each *sig* can be given as a number, or as the name of a signal either with or without the string **SIG** in front (e.g. 1, HUP, and SIGHUP are all the same signal).

If *arg* is '−', then the specified signals are reset to their defaults, or, if no *sig* args are present, all traps are reset.

If *arg* is an empty string, then the specified signals are ignored by the shell (and by the commands it invokes).

If *arg* is omitted but one or more *sig* args are provided (i.e. the first argument is a valid signal number or name), the effect is the same as if *arg* had been specified as '−'.

The **trap** command with no arguments prints a list of commands associated with each signal.

If *sig* is **ZERR** then *arg* will be executed after each command with a nonzero exit status. **ERR** is

an alias for **ZERR** on systems that have no **SIGERR** signal (this is the usual case).

If *sig* is **DEBUG** then *arg* will be executed before each command if the option **DEBUG_BEFORE_CMD** is set (as it is by default), else after each command. Here, a ‘command’ is what is described as a ‘sublist’ in the shell grammar, see the section SIMPLE COMMANDS & PIPELINES in *zshmisc(1)*. If **DEBUG_BEFORE_CMD** is set various additional features are available. First, it is possible to skip the next command by setting the option **ERR_EXIT**; see the description of the **ERR_EXIT** option in *zshoptions(1)*. Also, the shell parameter **ZSH_DEBUG_CMD** is set to the string corresponding to the command to be executed following the trap. Note that this string is reconstructed from the internal format and may not be formatted the same way as the original text. The parameter is unset after the trap is executed.

If *sig* is **0** or **EXIT** and the **trap** statement is executed inside the body of a function, then the command *arg* is executed after the function completes. The value of **\$?** at the start of execution is the exit status of the shell or the return status of the function exiting. If *sig* is **0** or **EXIT** and the **trap** statement is not executed inside the body of a function, then the command *arg* is executed when the shell terminates; the trap runs before any **zshexit** hook functions.

ZERR, **DEBUG**, and **EXIT** traps are not executed inside other traps. **ZERR** and **DEBUG** traps are kept within subshells, while other traps are reset.

Note that traps defined with the **trap** builtin are slightly different from those defined as ‘**TRAP-NAL () { ... }**’, as the latter have their own function environment (line numbers, local variables, etc.) while the former use the environment of the command in which they were called. For example,

```
trap 'print $LINENO' DEBUG
```

will print the line number of a command executed after it has run, while

```
TRAPDEBUG() { print $LINENO; }
```

will always print the number zero.

Alternative signal names are allowed as described under **kill** above. Defining a trap under either name causes any trap under an alternative name to be removed. However, it is recommended that for consistency users stick exclusively to one name or another.

true [*arg* ...]

Do nothing and return an exit status of 0.

ttyctl [**-fu**]

The **-f** option freezes the tty (i.e. terminal or terminal emulator), and **-u** unfreezes it. When the tty is frozen, no changes made to the tty settings by external programs will be honored by the shell, except for changes in the size of the screen; the shell will simply reset the settings to their previous values as soon as each command exits or is suspended. Thus, **stty** and similar programs have no effect when the tty is frozen. Freezing the tty does not cause the current state to be remembered: instead, it causes future changes to the state to be blocked.

Without options it reports whether the terminal is frozen or not.

Note that, regardless of whether the tty is frozen or not, the shell needs to change the settings when the line editor starts, so unfreezing the tty does not guarantee settings made on the command line are preserved. Strings of commands run between editing the command line will see a consistent tty state. See also the shell variable **STTY** for a means of initialising the tty before running external commands.

type [**-wfpamsS**] *name* ...

Equivalent to **whence -v**.

```
typeset [ {+|-}AHUaghlmrtux ] [ {+|-}EFLRZip [ n ] ]
```

```
[ + ] [ name[=value] ... ]
```

```
typeset -T [ {+|-}Uglrx ] [ {+|-}LRZp [ n ] ]
```

```
[ + | SCALAR[=value] array[=(value ...)] [ sep ] ]
```

```
typeset -f [ {+|-}TUKmtuz ] [ + ] [ name ... ]
```

Set or display attributes and values for shell parameters.

Except as noted below for control flags that change the behavior, a parameter is created for each *name* that does not already refer to one. When inside a function, a new parameter is created for every *name* (even those that already exist), and is unset again when the function completes. See ‘Local Parameters’ in *zshparam(1)*. The same rules apply to special shell parameters, which retain their special attributes when made local.

For each *name*=*value* assignment, the parameter *name* is set to *value*.

If the shell option **TYPESET_SILENT** is not set, for each remaining *name* that refers to a parameter that is already set, the name and value of the parameter are printed in the form of an assignment. Nothing is printed for newly-created parameters, or when any attribute flags listed below are given along with the *name*. Using ‘+’ instead of minus to introduce an attribute turns it off.

If no *name* is present, the names and values of all parameters are printed. In this case the attribute flags restrict the display to only those parameters that have the specified attributes, and using ‘+’ rather than ‘-’ to introduce the flag suppresses printing of the values of parameters when there is no parameter name.

All forms of the command handle scalar assignment. Array assignment is possible if any of the reserved words **declare**, **export**, **float**, **integer**, **local**, **readonly** or **typeset** is matched when the line is parsed (N.B. not when it is executed). In this case the arguments are parsed as assignments, except that the ‘+=’ syntax and the **GLOB_ASSIGN** option are not supported, and scalar values after = are *not* split further into words, even if expanded (regardless of the setting of the **KSH_TYPESET** option; this option is obsolete).

Examples of the differences between command and reserved word parsing:

```
# Reserved word parsing
typeset svar=$(echo one word) avar=(several words)
```

The above creates a scalar parameter **svar** and an array parameter **avar** as if the assignments had been

```
svar="one word"
avar=(several words)
```

On the other hand:

```
# Normal builtin interface
builtin typeset svar=$(echo two words)
```

The **builtin** keyword causes the above to use the standard builtin interface to **typeset** in which argument parsing is performed in the same way as for other commands. This example creates a scalar **svar** containing the value **two** and another scalar parameter **words** with no value. An array value in this case would either cause an error or be treated as an obscure set of glob qualifiers.

Arbitrary arguments are allowed if they take the form of assignments after command line expansion; however, these only perform scalar assignment:

```
var='svar=val'
typeset $var
```

The above sets the scalar parameter **svar** to the value **val**. Parentheses around the value within **var** would not cause array assignment as they will be treated as ordinary characters when **\$var** is substituted. Any non-trivial expansion in the name part of the assignment causes the argument to be treated in this fashion:

typeset {var1,var2,var3}=name

The above syntax is valid, and has the expected effect of setting the three parameters to the same value, but the command line is parsed as a set of three normal command line arguments to **typeset** after expansion. Hence it is not possible to assign to multiple arrays by this means.

Note that each interface to any of the commands may be disabled separately. For example, ‘**disable -r typeset**’ disables the reserved word interface to **typeset**, exposing the builtin interface, while ‘**disable typeset**’ disables the builtin. Note that disabling the reserved word interface for **typeset** may cause problems with the output of ‘**typeset -p**’, which assumes the reserved word interface is available in order to restore array and associative array values.

Unlike parameter assignment statements, **typeset**’s exit status on an assignment that involves a command substitution does not reflect the exit status of the command substitution. Therefore, to test for an error in a command substitution, separate the declaration of the parameter from its initialization:

```
# WRONG
typeset var1=$(exit 1) || echo "Trouble with var1"
```

```
# RIGHT
typeset var1 && var1=$(exit 1) || echo "Trouble with var1"
```

To initialize a parameter *param* to a command output and mark it readonly, use **typeset -r param** or **readonly param** after the parameter assignment statement.

If no attribute flags are given, and either no *name* arguments are present or the flag **+m** is used, then each parameter name printed is preceded by a list of the attributes of that parameter (**array**, **association**, **exported**, **float**, **integer**, **readonly**, or **undefined** for autoloaded parameters not yet loaded). If **+m** is used with attrib ute flags, and all those flags are introduced with **+**, the matching parameter names are printed but their values are not.

The following control flags change the behavior of **typeset**:

- +** If ‘**+**’ appears by itself in a separate word as the last option, then the names of all parameters (functions with **-f**) are printed, but the values (function bodies) are not. No *name* arguments may appear, and it is an error for any other options to follow ‘**+**’. The effect of ‘**+**’ is as if all attribute flags which precede it were given with a ‘**+**’ prefix. For example, ‘**typeset -U +**’ is equivalent to ‘**typeset +U**’ and displays the names of all arrays having the uniqueness attribute, whereas ‘**typeset -f -U +**’ displays the names of all autoloadable functions. If **+** is the only option, then type information (array, readonly, etc.) is also printed for each parameter, in the same manner as ‘**typeset +m ".*"**’.

- g** The **-g** (global) means that any resulting parameter will not be restricted to local scope. Note that this does not necessarily mean that the parameter will be global, as the flag will apply to any existing parameter (even if unset) from an enclosing function. This flag does not affect the parameter after creation, hence it has no effect when listing existing parameters, nor does the flag **+g** have any effect except in combination with **-m** (see below).

- m** If the **-m** flag is given the *name* arguments are taken as patterns (use quoting to prevent these from being interpreted as file patterns). With no attribute flags, all parameters (or functions with the **-f** flag) with matching names are printed (the shell option **TYPESET_SILENT** is not used in this case).

If the **+g** flag is combined with **-m**, a new local parameter is created for every matching parameter that is not already local. Otherwise **-m** applies all other flags or assignments to the existing parameters.

Except when assignments are made with *name=value*, using **+m** forces the matching parameters and their attributes to be printed, even inside a function. Note that **-m** is ignored if no patterns are given, so ‘**typeset -m**’ displays attributes but ‘**typeset -a +m**’ does not.

-p [n] If the **-p** option is given, parameters and values are printed in the form of a typeset command with an assignment, regardless of other flags and options. Note that the **-H** flag on parameters is respected; no value will be shown for these parameters.

-p may be followed by an optional integer argument. Currently only the value **1** is supported. In this case arrays and associative arrays are printed with newlines between indented elements for readability.

-T [scalar[=value] array[=(value ...)] [sep]]

This flag has a different meaning when used with **-f**; see below. Otherwise the **-T** option requires zero, two, or three arguments to be present. With no arguments, the list of parameters created in this fashion is shown. With two or three arguments, the first two are the name of a scalar and of an array parameter (in that order) that will be tied together in the manner of **\$PATH** and **\$path**. The optional third argument is a single-character separator which will be used to join the elements of the array to form the scalar; if absent, a colon is used, as with **\$PATH**. Only the first character of the separator is significant; any remaining characters are ignored. Multibyte characters are not yet supported.

Only one of the scalar and array parameters may be assigned an initial value (the restrictions on assignment forms described above also apply).

Both the scalar and the array may be manipulated as normal. If one is unset, the other will automatically be unset too. There is no way of untying the variables without unsetting them, nor of converting the type of one of them with another **typeset** command; **+T** does not work, assigning an array to *scalar* is an error, and assigning a scalar to *array* sets it to be a single-element array.

Note that both ‘**typeset -xT ...**’ and ‘**export -T ...**’ work, but only the scalar will be marked for export. Setting the value using the scalar version causes a split on all separators (which cannot be quoted). It is possible to apply **-T** to two previously tied variables but with a different separator character, in which case the variables remain joined as before but the separator is changed.

When an existing scalar is tied to a new array, the value of the scalar is preserved but no attribute other than **export** will be preserved.

Attribute flags that transform the final value (**-L**, **-R**, **-Z**, **-I**, **-u**) are only applied to the expanded value at the point of a parameter expansion expression using ‘\$’. They are not applied when a parameter is retrieved internally by the shell for any purpose.

The following attribute flags may be specified:

-A The names refer to associative array parameters; see ‘Array Parameters’ in *zshparam(1)*.

-L [n]

Left justify and remove leading blanks from the value when the parameter is expanded. If *n* is nonzero, it defines the width of the field. If *n* is zero, the width is determined by the width of the value of the first assignment. In the case of numeric parameters, the length of the complete value assigned to the parameter is used to determine the width, not the value that would be output.

The width is the count of characters, which may be multibyte characters if the **MULTIBYTE** option is in effect. Note that the screen width of the character is not taken into account; if this is required, use padding with parameter expansion flags **\$(ml...)** as described in ‘Parameter Expansion Flags’ in *zshexpn(1)*.

When the parameter is expanded, it is filled on the right with blanks or truncated if necessary to fit the field. Note truncation can lead to unexpected results with numeric parameters. Leading zeros are removed if the **-Z** flag is also set.

-R [n]

Similar to **-L**, except that right justification is used; when the parameter is expanded, the field is left filled with blanks or truncated from the end. May not be combined with the **-Z** flag.

-U

For arrays (but not for associative arrays), keep only the first occurrence of each duplicated value. This may also be set for tied parameters (see **-T**) or colon-separated special parameters like **PATH** or **IGNORE**, etc. Note the flag takes effect on assignment, and the type of the variable being assigned to is determinative; for variables with shared values it is therefore recommended to set the flag for all interfaces, e.g. ‘**typeset -U PATH path**’.

This flag has a different meaning when used with **-f**; see below.

-Z [n]

Specially handled if set along with the **-L** flag. Otherwise, similar to **-R**, except that leading zeros are used for padding instead of blanks if the first non-blank character is a digit. Numeric parameters are specially handled: they are always eligible for padding with zeroes, and the zeroes are inserted at an appropriate place in the output.

-a

The names refer to array parameters. An array parameter may be created this way, but it may be assigned to in the **typeset** statement only if the reserved word form of **typeset** is enabled (as it is by default). When displaying, both normal and associative arrays are shown.

-f

The names refer to functions rather than parameters. No assignments can be made, and the only other valid flags are **-t**, **-T**, **-k**, **-u**, **-U** and **-z**. The flag **-t** turns on execution tracing for this function; the flag **-T** does the same, but turns off tracing for any named (not anonymous) function called from the present one, unless that function also has the **-t** or **-T** flag. The **-u** and **-U** flags cause the function to be marked for autoloading; **-U** also causes alias expansion to be suppressed when the function is loaded. See the description of the ‘**autoload**’ builtin for details.

Note that the builtin **functions** provides the same basic capabilities as **typeset -f** but gives access to a few extra options; **autoload** gives further additional options for the case **typeset -fu** and **typeset -fU**.

-h

Hide: only useful for special parameters (those marked ‘<S>’ in the table in *zsh-param(1)*), and for local parameters with the same name as a special parameter, though harmless for others. A special parameter with this attribute will not retain its special effect when made local. Thus after ‘**typeset -h PATH**’, a function containing ‘**typeset PATH**’ will create an ordinary local parameter without the usual behaviour of **PATH**. Alternatively, the local parameter may itself be given this attribute; hence inside a function ‘**typeset -h PATH**’ creates an ordinary local parameter and the special **PATH** parameter is not altered in any way. It is also possible to create a local parameter using ‘**typeset +h special**’, where the local copy of *special* will retain its special properties regardless of having the **-h** attribute. Global special parameters loaded from shell modules (currently those in **zsh/mapfile** and **zsh/parameter**) are automatically given the **-h** attribute to avoid name clashes.

-H

Hide value: specifies that **typeset** will not display the value of the parameter when listing parameters; the display for such parameters is always as if the ‘+’ flag had been given. Use of the parameter is in other respects normal, and the option does not apply if the parameter is specified by name, or by pattern with the **-m** option. This is on by default for the parameters in the **zsh/parameter** and **zsh/mapfile** modules. Note, however, that unlike the **-h** flag this is also useful for non-special parameters.

-i [n]

Use an internal integer representation. If *n* is nonzero it defines the output arithmetic base, otherwise it is determined by the first assignment. Bases from 2 to 36 inclusive are allowed.

-E [n]

Use an internal double-precision floating point representation. On output the variable will be converted to scientific notation. If *n* is nonzero it defines the number of significant figures to display; the default is ten.

-F [n] Use an internal double-precision floating point representation. On output the variable will be converted to fixed-point decimal notation. If *n* is nonzero it defines the number of digits to display after the decimal point; the default is ten.

-l Convert the result to lower case whenever the parameter is expanded. The value is *not* converted when assigned.

-r The given *names* are marked readonly. Note that if *name* is a special parameter, the readonly attribute can be turned on, but cannot then be turned off.

If the **POSIX_BUILTINS** option is set, the readonly attribute is more restrictive: unset variables can be marked readonly and cannot then be set; furthermore, the readonly attribute cannot be removed from any variable.

It is still possible to change other attributes of the variable though, some of which like **-U** or **-Z** would affect the value. More generally, the readonly attribute should not be relied on as a security mechanism.

Note that in zsh (like in pdksh but unlike most other shells) it is still possible to create a local variable of the same name as this is considered a different variable (though this variable, too, can be marked readonly). Special variables that have been made readonly retain their value and readonly attribute when made local.

-t Tags the named parameters. Tags have no special meaning to the shell. This flag has a different meaning when used with **-f**; see above.

-u Convert the result to upper case whenever the parameter is expanded. The value is *not* converted when assigned. This flag has a different meaning when used with **-f**; see above.

-x Mark for automatic export to the environment of subsequently executed commands. If the option **GLOBAL_EXPORT** is set, this implies the option **-g**, unless **+g** is also explicitly given; in other words the parameter is not made local to the enclosing function. This is for compatibility with previous versions of zsh.

ulimit [-HSa] [{ -bcdflmnpqrsTtvwx | -N resource } [limit] ...]

Set or display resource limits of the shell and the processes started by the shell. The value of *limit* can be a number in the unit specified below or one of the values '**unlimited**', which removes the limit on the resource, or '**hard**', which uses the current value of the hard limit on the resource.

By default, only soft limits are manipulated. If the **-H** flag is given use hard limits instead of soft limits. If the **-S** flag is given together with the **-H** flag set both hard and soft limits.

If no options are used, the file size limit (**-f**) is assumed.

If *limit* is omitted the current value of the specified resources are printed. When more than one resource value is printed, the limit name and unit is printed before each value.

When looping over multiple resources, the shell will abort immediately if it detects a badly formed argument. However, if it fails to set a limit for some other reason it will continue trying to set the remaining limits.

Not all the following resources are supported on all systems. Running **ulimit -a** will show which are supported.

-a Lists all of the current resource limits.

-b Socket buffer size in bytes (N.B. not kilobytes)

-c 512-byte blocks on the size of core dumps.

-d	Kilobytes on the size of the data segment.
-f	512-byte blocks on the size of files written.
-i	The number of pending signals.
-k	The number of kqueues allocated.
-l	Kilobytes on the size of locked-in memory.
-m	Kilobytes on the size of physical memory.
-n	open file descriptors.
-p	The number of pseudo-terminals.
-q	Bytes in POSIX message queues.
-r	Maximum real time priority. On some systems where this is not available, such as NetBSD, this has the same effect as -T for compatibility with sh .
-s	Kilobytes on the size of the stack.
-T	The number of simultaneous threads available to the user.
-t	CPU seconds to be used.
-u	The number of processes available to the user.
-v	Kilobytes on the size of virtual memory. On some systems this refers to the limit called ‘address space’.
-w	Kilobytes on the size of swapped out memory.
-x	The number of locks on files.

A resource may also be specified by integer in the form ‘**-N resource**’, where *resource* corresponds to the integer defined for the resource by the operating system. This may be used to set the limits for resources known to the shell which do not correspond to option letters. Such limits will be shown by number in the output of ‘**ulimit -a**’.

The number may alternatively be out of the range of limits compiled into the shell. The shell will try to read or write the limit anyway, and will report an error if this fails.

umask [-S] [mask]

The umask is set to *mask*. *mask* can be either an octal number or a symbolic value as described in *chmod(1)*. If *mask* is omitted, the current value is printed. The **-S** option causes the mask to be printed as a symbolic value. Otherwise, the mask is printed as an octal number. Note that in the symbolic form the permissions you specify are those which are to be allowed (not denied) to the users specified.

unalias [-ams] name ...

Removes aliases. This command works the same as **unhash -a**, except that the **-a** option removes all regular or global aliases, or with **-s** all suffix aliases: in this case no *name* arguments may appear. The options **-m** (remove by pattern) and **-s** without **-a** (remove listed suffix aliases) behave as for **unhash -a**. Note that the meaning of **-a** is different between **unalias** and **unhash**.

unfunction

Same as **unhash -f**.

unhash [-adfms] name ...

Remove the element named *name* from an internal hash table. The default is remove elements from the command hash table. The **-a** option causes **unhash** to remove regular or global aliases; note when removing a global aliases that the argument must be quoted to prevent it from being expanded before being passed to the command. The **-s** option causes **unhash** to remove suffix aliases. The **-f** option causes **unhash** to remove shell functions. The **-d** option causes **unhash** to remove named directories. If the **-m** flag is given the arguments are taken as patterns (should be quoted) and all elements of the corresponding hash table with matching names will be removed.

unlimit [-hs] resource ...

The resource limit for each *resource* is set to the hard limit. If the **-h** flag is given and the shell has appropriate privileges, the hard resource limit for each *resource* is removed. The resources of the shell process are only changed if the **-s** flag is given.

The **unlimit** command is not made available by default when the shell starts in a mode emulating

another shell. It can be made available with the command ‘**zmodload -F zsh/rlimits b:unlimit**’.

unset [**-fmv**] *name* ...

Each named parameter is unset. Local parameters remain local even if unset; they appear unset within scope, but the previous value will still reappear when the scope ends.

Individual elements of associative array parameters may be unset by using subscript syntax on *name*, which should be quoted (or the entire command prefixed with **noglob**) to protect the subscript from filename generation.

If the **-m** flag is specified the arguments are taken as patterns (should be quoted) and all parameters with matching names are unset. Note that this cannot be used when unsetting associative array elements, as the subscript will be treated as part of the pattern.

The **-v** flag specifies that *name* refers to parameters. This is the default behaviour.

unset -f is equivalent to **unfunction**.

unsetopt [{+|-}options | {+|-}o *option_name*] [*name* ...]

Unset the options for the shell. All options specified either with flags or by name are unset. If no arguments are supplied, the names of all options currently unset are printed. If the **-m** flag is given the arguments are taken as patterns (which should be quoted to preserve them from being interpreted as glob patterns), and all options with names matching these patterns are unset.

vared See the section ‘Zle Builtins’ in *zshzle(1)*.

wait [*job* ...]

Wait for the specified jobs or processes. If *job* is not given then all currently active child processes are waited for. Each *job* can be either a job specification or the process ID of a job in the job table. The exit status from this command is that of the job waited for. If *job* represents an unknown job or process ID, a warning is printed (unless the **POSIX_BUILTINS** option is set) and the exit status is 127.

It is possible to wait for recent processes (specified by process ID, not by job) that were running in the background even if the process has exited. Typically the process ID will be recorded by capturing the value of the variable **\$!** immediately after the process has been started. There is a limit on the number of process IDs remembered by the shell; this is given by the value of the system configuration parameter **CHILD_MAX**. When this limit is reached, older process IDs are discarded, least recently started processes first.

Note there is no protection against the process ID wrapping, i.e. if the wait is not executed soon enough there is a chance the process waited for is the wrong one. A conflict implies both process IDs have been generated by the shell, as other processes are not recorded, and that the user is potentially interested in both, so this problem is intrinsic to process IDs.

whence [**-vcwfamsS**] [**-x num**] *name* ...

For each *name*, indicate how it would be interpreted if used as a command name.

If *name* is not an alias, built-in command, external command, shell function, hashed command, or a reserved word, the exit status shall be non-zero, and -- if **-v**, **-c**, or **-w** was passed -- a message will be written to standard output. (This is different from other shells that write that message to standard error.)

whence is most useful when *name* is only the last path component of a command, i.e. does not include a ‘/’; in particular, pattern matching only succeeds if just the non-directory component of the command is passed.

-v Produce a more verbose report.

-c Print the results in a **csh**-like format. This takes precedence over **-v**.

-w For each *name*, print ‘*name*: *word*’ where *word* is one of **alias**, **builtin**, **command**, **function**, **hashed**, **reserved** or **none**, according as *name* corresponds to an alias, a built-in command, an external command, a shell function, a command defined with the **hash**

builtin, a reserved word, or is not recognised. This takes precedence over **-v** and **-c**.

- f** Causes the contents of a shell function to be displayed, which would otherwise not happen unless the **-c** flag were used.
- p** Do a path search for *name* even if it is an alias, reserved word, shell function or builtin.
- a** Do a search for all occurrences of *name* throughout the command path. Normally only the first occurrence is printed.
- m** The arguments are taken as patterns (pattern characters should be quoted), and the information is displayed for each command matching one of these patterns.
- s** If a pathname contains symlinks, print the symlink-free pathname as well.
- S** As **-s**, but if the pathname had to be resolved by following multiple symlinks, the intermediate steps are printed, too. The symlink resolved at each step might be anywhere in the path.
- x num** Expand tabs when outputting shell functions using the **-c** option. This has the same effect as the **-x** option to the **functions** builtin.

where [**-wpmsS**] [**-x num**] *name* ...

Equivalent to **whence -ca**.

which [**-wpamsS**] [**-x num**] *name* ...

Equivalent to **whence -c**.

zcompile [**-U**] [**-z** | **-k**] [**-R** | **-M**]*file* [*name* ...]

zcompile -ca [**-m**] [**-R** | **-M**]*file* [*name* ...]

zcompile -t*file* [*name* ...]

This builtin command can be used to compile functions or scripts, storing the compiled form in a file, and to examine files containing the compiled form. This allows faster autoloading of functions and sourcing of scripts by avoiding parsing of the text when the files are read.

The first form (without the **-c**, **-a** or **-t** options) creates a compiled file. If only the *file* argument is given, the output file has the name '*file.zwc*' and will be placed in the same directory as the *file*. The shell will load the compiled file instead of the normal function file when the function is autoloaded; see the section ‘Autoloading Functions’ in *zshmisc(1)* for a description of how autoloaded functions are searched. The extension **.zwc** stands for ‘zsh word code’.

If there is at least one *name* argument, all the named files are compiled into the output *file* given as the first argument. If *file* does not end in **.zwc**, this extension is automatically appended. Files containing multiple compiled functions are called ‘digest’ files, and are intended to be used as elements of the **FPATH/fpath** special array.

The second form, with the **-c** or **-a** options, writes the compiled definitions for all the named functions into *file*. For **-c**, the names must be functions currently defined in the shell, not those marked for autoloading. Undefined functions that are marked for autoloading may be written by using the **-a** option, in which case the **fpath** is searched and the contents of the definition files for those functions, if found, are compiled into *file*. If both **-c** and **-a** are given, names of both defined functions and functions marked for autoloading may be given. In either case, the functions in files written with the **-c** or **-a** option will be autoloaded as if the **KSH_AUTOLOAD** option were unset.

The reason for handling loaded and not-yet-loaded functions with different options is that some definition files for autoloading define multiple functions, including the function with the same name as the file, and, at the end, call that function. In such cases the output of ‘**zcompile -c**’ does not include the additional functions defined in the file, and any other initialization code in the file is lost. Using ‘**zcompile -a**’ captures all this extra information.

If the **-m** option is combined with **-c** or **-a**, the *names* are used as patterns and all functions whose names match one of these patterns will be written. If no *name* is given, the definitions of all

functions currently defined or marked as autoloaded will be written.

Note the second form cannot be used for compiling functions that include redirections as part of the definition rather than within the body of the function; for example

```
fn1() { { ... } >~/logfile }
```

can be compiled but

```
fn1() { ... } >~/logfile
```

cannot. It is possible to use the first form of **zcompile** to compile autoloadable functions that include the full function definition instead of just the body of the function.

The third form, with the **-t** option, examines an existing compiled file. Without further arguments, the names of the original files compiled into it are listed. The first line of output shows the version of the shell which compiled the file and how the file will be used (i.e. by reading it directly or by mapping it into memory). With arguments, nothing is output and the return status is set to zero if definitions for *all names* were found in the compiled file, and non-zero if the definition for at least one *name* was not found.

Other options:

- U** Aliases are not expanded when compiling the *named* files.
- R** When the compiled file is read, its contents are copied into the shell's memory, rather than memory-mapped (see **-M**). This happens automatically on systems that do not support memory mapping.
- When compiling scripts instead of autoloadable functions, it is often desirable to use this option; otherwise the whole file, including the code to define functions which have already been defined, will remain mapped, consequently wasting memory.
- M** The compiled file is mapped into the shell's memory when read. This is done in such a way that multiple instances of the shell running on the same host will share this mapped file. If neither **-R** nor **-M** is given, the **zcompile** builtin decides what to do based on the size of the compiled file.
- k**
- z** These options are used when the compiled file contains functions which are to be autoloaded. If **-z** is given, the function will be autoloaded as if the **KSH_AUTOLOAD** option is *not* set, even if it is set at the time the compiled file is read, while if the **-k** is given, the function will be loaded as if **KSH_AUTOLOAD** is set. These options also take precedence over any **-k** or **-z** options specified to the **autoload** builtin. If neither of these options is given, the function will be loaded as determined by the setting of the **KSH_AUTOLOAD** option at the time the compiled file is read.

These options may also appear as many times as necessary between the listed *names* to specify the loading style of all following functions, up to the next **-k** or **-z**.

The created file always contains two versions of the compiled format, one for big-endian machines and one for small-endian machines. The upshot of this is that the compiled file is machine independent and if it is read or mapped, only one half of the file is actually used (and mapped).

zformat

See the section 'The zsh/zutil Module' in *zshmodules*(1).

zftp See the section 'The zsh/zftp Module' in *zshmodules*(1).

zle See the section 'Zle Builtins' in *zshzle*(1).

```
zmodload [ -dL ] [ -s ] [ ... ]
zmodload -F [ -alLme -P param ] module [ [+−]feature ... ]
zmodload -e [ -A ] [ ... ]
zmodload [ -a [ -bcpf [ -I ] ] [ -iL ] ... ]
zmodload -u [ -abcdpf [ -I ] ] [ -iL ] ...
zmodload -A [ -L ] [ modalias[=module] ... ]
zmodload -R modalias ...
```

Performs operations relating to zsh's loadable modules. Loading of modules while the shell is running ('dynamical loading') is not available on all operating systems, or on all installations on a particular operating system, although the **zmodload** command itself is always available and can be used to manipulate modules built into versions of the shell executable without dynamical loading.

Without arguments the names of all currently loaded binary modules are printed. The **-L** option causes this list to be in the form of a series of **zmodload** commands. Forms with arguments are:

```
zmodload [ -is ] name ...
zmodload -u [ -i ] name ...
```

In the simplest case, **zmodload** loads a binary module. The module must be in a file with a name consisting of the specified *name* followed by a standard suffix, usually '.so' ('.sl' on HPUX). If the module to be loaded is already loaded the duplicate module is ignored. If **zmodload** detects an inconsistency, such as an invalid module name or circular dependency list, the current code block is aborted. If it is available, the module is loaded if necessary, while if it is not available, non-zero status is silently returned. The option **-i** is accepted for compatibility but has no effect.

The *named* module is searched for in the same way a command is, using **\$module_path** instead of **\$path**. However, the path search is performed even when the module name contains a '/', which it usually does. There is no way to prevent the path search.

If the module supports features (see below), **zmodload** tries to enable all features when loading a module. If the module was successfully loaded but not all features could be enabled, **zmodload** returns status 2.

If the option **-s** is given, no error is printed if the module was not available (though other errors indicating a problem with the module are printed). The return status indicates if the module was loaded. This is appropriate if the caller considers the module optional.

With **-u**, **zmodload** unloads modules. The same *name* must be given that was given when the module was loaded, but it is not necessary for the module to exist in the file system. The **-i** option suppresses the error if the module is already unloaded (or w as never loaded).

Each module has a boot and a cleanup function. The module will not be loaded if its boot function fails. Similarly a module can only be unloaded if its cleanup function runs successfully.

```
zmodload -F [ -almLe -P param ] module [ [+−]feature ... ]
```

zmodload **-F** allows more selective control over the features provided by modules. With no options apart from **-F**, the module named *module* is loaded, if it was not already loaded, and the list of *features* is set to the required state. If no *features* are specified, the module is loaded, if it was not already loaded, but the state of features is unchanged. Each feature may be preceded by a + to turn the feature on, or - to turn it off; the + is assumed if neither character is present. Any feature not explicitly mentioned is left in its current state; if the module was not previously loaded this means any such features will remain disabled. The return status is zero if all features were set, 1 if the module failed to load, and 2 if some features could not be set (for example, a parameter couldn't be added because there was a different parameter of the same name) but the module was loaded.

The standard features are builtins, conditions, parameters and math functions; these are indicated by the prefix '**b:**', '**c:**' ('**C:**' for an infix condition), '**p:**' and '**f:**', respectively,

followed by the name that the corresponding feature would have in the shell. For example, ‘**b:strftime**’ indicates a builtin named **strftime** and **p:EPOCHSECONDS** indicates a parameter named **EPOCHSECONDS**. The module may provide other (‘abstract’) features of its own as indicated by its documentation; these have no prefix.

With **-I** or **-L**, features provided by the module are listed. With **-I** alone, a list of features together with their states is shown, one feature per line. With **-L** alone, a **zmodload -F** command that would cause enabled features of the module to be turned on is shown. With **-IL**, a **zmodload -F** command that would cause all the features to be set to their current state is shown. If one of these combinations is given with the option **-P param** then the parameter *param* is set to an array of features, either features together with their state or (if **-L** alone is given) enabled features.

With the option **-L** the module name may be omitted; then a list of all enabled features for all modules providing features is printed in the form of **zmodload -F** commands. If **-I** is also given, the state of both enabled and disabled features is output in that form.

A set of features may be provided together with **-I** or **-L** and a module name; in that case only the state of those features is considered. Each feature may be preceded by + or – but the character has no effect. If no set of features is provided, all features are considered.

With **-e**, the command first tests that the module is loaded; if it is not, status 1 is returned. If the module is loaded, the list of features given as an argument is examined. Any feature given with no prefix is simply tested to see if the module provides it; any feature given with a prefix + or – is tested to see if it is provided and in the given state. If the tests on all features in the list succeed, status 0 is returned, else status 1.

With **-m**, each entry in the given list of features is taken as a pattern to be matched against the list of features provided by the module. An initial + or – must be given explicitly. This may not be combined with the **-a** option as autoloads must be specified explicitly.

With **-a**, the given list of features is marked for autoload from the specified module, which may not yet be loaded. An optional + may appear before the feature name. If the feature is prefixed with –, any existing autoload is removed. The options **-I** and **-L** may be used to list autoloads. Autoloading is specific to individual features; when the module is loaded only the requested feature is enabled. Autoload requests are preserved if the module is subsequently unloaded until an explicit ‘**zmodload -Fa module -feature**’ is issued. It is not an error to request an autoload for a feature of a module that is already loaded.

When the module is loaded each autoload is checked against the features actually provided by the module; if the feature is not provided the autoload request is deleted. A warning message is output; if the module is being loaded to provide a different feature, and that autoload is successful, there is no effect on the status of the current command. If the module is already loaded at the time when **zmodload -Fa** is run, an error message is printed and status 1 returned.

zmodload -Fa can be used with the **-I**, **-L**, **-e** and **-P** options for listing and testing the existence of autoloadable features. In this case **-I** is ignored if **-L** is specified. **zmodload -FaL** with no module name lists autoloads for all modules.

Note that only standard features as described above can be autoloaded; other features require the module to be loaded before enabling.

```
zmodload -d [ -L ] [ name ]
zmodload -d name dep ...
zmodload -ud name [ dep ... ]
```

The **-d** option can be used to specify module dependencies. The modules named in the second and subsequent arguments will be loaded before the module named in the first

argument.

With **-d** and one argument, all dependencies for that module are listed. With **-d** and no arguments, all module dependencies are listed. This listing is by default in a Makefile-like format. The **-L** option changes this format to a list of **zmodload -d** commands.

If **-d** and **-u** are both used, dependencies are removed. If only one argument is given, all dependencies for that module are removed.

```
zmodload -ab [ -L ]
zmodload -ab [ -i ] name [ builtin ... ]
zmodload -ub [ -i ] builtin ...
```

The **-ab** option defines autoloaded builtins. It defines the specified *builtins*. When any of those builtins is called, the module specified in the first argument is loaded and all its features are enabled (for selective control of features use '**zmodload -F -a**' as described above). If only the *name* is given, one builtin is defined, with the same name as the module. **-i** suppresses the error if the builtin is already defined or autoloaded, but not if another builtin of the same name is already defined.

With **-ab** and no arguments, all autoloaded builtins are listed, with the module name (if different) shown in parentheses after the builtin name. The **-L** option changes this format to a list of **zmodload -a** commands.

If **-b** is used together with the **-u** option, it removes builtins previously defined with **-ab**. This is only possible if the builtin is not yet loaded. **-i** suppresses the error if the builtin is already removed (or never existed).

Autoload requests are retained if the module is subsequently unloaded until an explicit '**zmodload -ub builtin**' is issued.

```
zmodload -ac [ -IL ]
zmodload -ac [ -iI ] name [ cond ... ]
zmodload -uc [ -iI ] cond ...
```

The **-ac** option is used to define autoloaded condition codes. The *cond* strings give the names of the conditions defined by the module. The optional **-I** option is used to define infix condition names. Without this option prefix condition names are defined.

If given no condition names, all defined names are listed (as a series of **zmodload** commands if the **-L** option is given).

The **-uc** option removes definitions for autoloaded conditions.

```
zmodload -ap [ -L ]
zmodload -ap [ -i ] name [ parameter ... ]
zmodload -up [ -i ] parameter ...
```

The **-p** option is like the **-b** and **-c** options, but makes **zmodload** work on autoloaded parameters instead.

```
zmodload -af [ -L ]
zmodload -af [ -i ] name [ function ... ]
zmodload -uf [ -i ] function ...
```

The **-f** option is like the **-b**, **-p**, and **-c** options, but makes **zmodload** work on autoloaded math functions instead.

```
zmodload -a [ -L ]
zmodload -a [ -i ] name [ builtin ... ]
zmodload -ua [ -i ] builtin ...
```

Equivalent to **-ab** and **-ub**.

```
zmodload -e [ -A ] [ string ... ]
```

The **-e** option without arguments lists all loaded modules; if the **-A** option is also given, module aliases corresponding to loaded modules are also shown. If arguments are

provided, nothing is printed; the return status is set to zero if all *strings* given as arguments are names of loaded modules and to one if at least one *string* is not the name of a loaded module. This can be used to test for the availability of things implemented by modules. In this case, any aliases are automatically resolved and the **-A** flag is not used.

zmodload -A [-L] [*modalias[=module]* ...]

For each argument, if both *modalias* and *module* are given, define *modalias* to be an alias for the module *module*. If the module *modalias* is ever subsequently requested, either via a call to **zmodload** or implicitly, the shell will attempt to load *module* instead. If *module* is not given, show the definition of *modalias*. If no arguments are given, list all defined module aliases. When listing, if the **-L** flag was also given, list the definition as a **zmodload** command to recreate the alias.

The existence of aliases for modules is completely independent of whether the name resolved is actually loaded as a module: while the alias exists, loading and unloading the module under any alias has exactly the same effect as using the resolved name, and does not affect the connection between the alias and the resolved name which can be removed either by **zmodload -R** or by redefining the alias. Chains of aliases (i.e. where the first resolved name is itself an alias) are valid so long as these are not circular. As the aliases take the same format as module names, they may include path separators: in this case, there is no requirement for any part of the path named to exist as the alias will be resolved first. For example, ‘**any/old/alias**’ is always a valid alias.

Dependencies added to aliased modules are actually added to the resolved module; these remain if the alias is removed. It is valid to create an alias whose name is one of the standard shell modules and which resolves to a different module. However, if a module has dependencies, it will not be possible to use the module name as an alias as the module will already be marked as a loadable module in its own right.

Apart from the above, aliases can be used in the **zmodload** command anywhere module names are required. However, aliases will not be shown in lists of loaded modules with a bare ‘**zmodload**’.

zmodload -R *modalias* ...

For each *modalias* argument that was previously defined as a module alias via **zmodload -A**, delete the alias. If any was not defined, an error is caused and the remainder of the line is ignored.

Note that **zsh** makes no distinction between modules that were linked into the shell and modules that are loaded dynamically. In both cases this builtin command has to be used to make available the builtins and other things defined by modules (unless the module is autoloaded on these definitions). This is true even for systems that don’t support dynamic loading of modules.

B.1. Characteristics of Linux RAID levels

All RAID levels are used to combine multiple devices into a single MD array. The MD plug-in is a region-manager, so EVMS refers to MD arrays as "regions." MD can create these regions using disks, segments or other regions. This means that it's possible to create RAID regions using other RAID regions, and thus combine multiple RAID levels within a single volume stack.

The following subsections describe the characteristics of each Linux RAID level. Within EVMS, these levels can be thought of as sub-modules of the MD plug-in.

B.1.1. Linear mode

Linear-RAID regions combine objects by appending them to each other. Writing (or reading) linearly to the MD region starts by writing to the first child object. When that object is full, writes continue on the second child object, and so on until the final child object is full. Child objects of a Linear-RAID region do not have to be the same size.

Advantage:

- Linear-RAID provides a simple method for building very large regions using several small objects.

Disadvantages:

- Linear-RAID is not "true" RAID, in the sense that there is no data redundancy. If one disk crashes, the RAID region will be unavailable, and will result in a loss of some or all data on that region.
- Linear-RAID provides little or no performance benefit. The objects are combined in a simple, linear fashion that doesn't allow for much (if any) I/O in parallel to multiple child objects. The performance of a Linear-RAID will generally be equivalent to the performance of a single disk.

B.1.2. RAID-0

RAID-0 is usually referred to as "striping." This means that data in a RAID-0 region is evenly distributed and interleaved on all the child objects. For example, when writing 16 KB of data to a RAID-0 region with three child objects and a chunk-size of 4 KB, the data would be written as follows:

- 4 KB to object 0
- 4 KB to object 1
- 4 KB to object 2
- 4 KB to object 0

Advantages:

- Like Linear-RAID, RAID-0 provides a simple method for building very large regions using several small objects.

- In general, RAID-0 provides I/O performance improvements, because it can break large I/O requests up and submit them in parallel across several disks.

Disadvantage:

- Also like Linear-RAID, RAID-0 is not "true" RAID, in the sense that there is no data redundancy (hence the name RAID "zero"). If one disk crashes, the RAID region will be unavailable, and will likely result in a loss of all data on that region.

B.1.3. RAID-1

RAID-1 is usually referred to as "mirroring." Each child object in a RAID-1 region contains an identical copy of the data in the region. A write to a RAID-1 region results in that data being written simultaneously to all child objects. A read from a RAID-1 region can result in reading the data from any one of the child objects. Child objects of a RAID-1 region do not have to be the same size, but the size of the region will be equal to the size of the smallest child object.

Advantages:

- RAID-1 provides complete data redundancy. In a RAID-1 region made from N child objects, up to N-1 of those objects can crash and the region will still be operational, and can retrieve data from the remaining objects.
- RAID-1 can provide improved performance on I/O-reads. Because all child objects contain a full copy of the data, multiple read requests can be load-balanced among all the objects.

Disadvantages:

- RAID-1 can cause a decrease in performance on I/O-writes. Because each child object must have a full copy of the data, each write to the region must be duplicated and sent to each object. A write request cannot be completed until all duplicated writes to the child objects are complete.
- A RAID-1 region with N disks costs N times as much as a single disk, but only provides the storage space of a single disk.

B.1.4. RAID-4/5

RAID-4/5 is often referred to as "striping with parity." Like RAID-0, the data in a RAID-4/5 region is striped, or interleaved, across all the child objects. However, in RAID-4/5, parity information is also calculated and recorded for each stripe of data in order to provide redundancy in case one of the objects is lost. In the event of a disk crash, the data from that disk can be recovered based on the data on the remaining disks and the parity information.

In RAID-4 regions, a single child object is used to store the parity information for each data stripe. However, this can cause an I/O bottleneck on this one object, because the parity information must be updated for each I/O-write to the region.

In RAID-5 regions, the parity is spread evenly across all the child objects in the region, thus eliminating the parity bottleneck in RAID-4. RAID-5 provides four different algorithms for how the parity is distributed. In fact, RAID-4 is often thought of as a special case of RAID-5 with a parity algorithm that simply uses one object instead of all objects. This is the viewpoint that Linux and EVMS use. Therefore, the RAID-4/5 level is often just referred to as RAID-5, with RAID-4 simply being one of the five available parity algorithms.

Advantages and disadvantages

- Like RAID-1, RAID-4/5 provides redundancy in the event of a hardware failure. However, unlike RAID-1, RAID-4/5 can only survive the loss of a single object. This is because only one object's worth of parity is recorded. If more than one object is lost, there isn't enough parity information to recover the lost data.
- RAID-4/5 provides redundancy more cost effectively than RAID-1. A RAID-4/5 region with N disks provides N-1 times the storage space of a single disk. The redundancy comes at the cost of only a single disk in the region.
- Like RAID-0, RAID-4/5 can generally provide an I/O performance improvement, because large I/O requests can be broken up and submitted in parallel to the multiple child objects. However, on I/O-writes the performance improvement will be less than that of RAID-0, because the parity information must be calculated and rewritten each time a write request is serviced. In addition, in order to provide any performance improvement on I/O-writes, an in-memory cache must be maintained for recently accessed stripes so the parity information can be quickly recalculated. If a write request is received for a stripe of data that isn't in the cache, the data chunks for the stripe must first be read from disk in order to calculate the parity. If such cache-misses occur too often, the I/O-write performance could potentially be worse than even a Linear-RAID region.

B.1.5. Multipath

A multipath region consists of one or more objects, just like the other RAID levels. However, in multipath, the child objects actually represent multiple physical paths to the same physical disk. Such setups are often found on systems with fiber-attached storage devices or SANs.

Multipath is not actually part of the RAID standard, but was added to the Linux MD driver because it provides a convenient place to create "virtual" devices that consist of multiple underlying devices.

The previous RAID levels can all be created using a wide variety of storage devices, including generic, locally attached disks (for example, IDE and SCSI). However, Multipath can only be used if the hardware actually contains multiple physical paths to the storage device, and such hardware is usually available on high-end systems with fiber- or network-attached storage. Therefore, if you don't know whether you should be using the Multipath module, chances are you don't need to use it.

Like RAID-1 and RAID-4/5, Multipath provides redundancy against hardware failures. However, unlike these other RAID levels, Multipath protects against failures in the paths to the device, and not failures in the device itself. If one of the paths is lost (for example, a network adapter breaks or a fiber-optic cable is removed), I/O will be redirected to the remaining paths.

Like RAID-0 and RAID-4/5, Multipath can provide I/O performance improvements by load balancing I/O requests across the various paths.

What does " 2>&1 " mean?

Asked 13 years, 10 months ago Modified 6 months ago Viewed 1.6m times

To combine stderr and stdout into the stdout stream, we append this to a command:

3037

2>&1

e.g. to see the first few errors from compiling g++ main.cpp :

g++ main.cpp 2>&1 | head

What does 2>&1 mean, in detail?

bash shell unix redirect

Highest score (default)

File descriptor 1 is the standard output (stdout).

File descriptor 2 is the standard error (stderr).

3383

At first, 2>1 may look like a good way to redirect stderr to stdout . However, it will actually be interpreted as "redirect stderr to a file named 1 ".

What is the difference between /etc/fstab and /etc/mtab?

Asked 7 years, 10 months ago Modified 5 years, 4 months ago Viewed 98k times

Both `/etc/mtab` and `/etc/fstab` contain data about mounted volumes, for example:

45

`/etc/mtab`

```
/dev/xvda1 / ext4 rw,discard 0 0
proc /proc proc rw,noexec,nosuid,nodev 0 0
...
```

`/etc/fstab`

```
LABEL=cloudimg-rootfs / ext4 defaults,discard 0 0
/dev/xvdf /home/ubuntu/logs ext4 rw 0 0
```

What is the difference between the files?

`mount` `fstab`

`/etc/fstab` is a list of filesystems to be mounted at boot time. If you want your Windows or file-storage partitions mounted once your computer boots, you'll need to put appropriate entries into `/etc/fstab`.

47

`/etc/mtab` is a list of *currently* mounted filesystems. If you have a disk connected but not mounted, it won't show up in the `/etc/mtab` file. Once you mount it, it will show up there.

Note also, that with systemd (to which Ubuntu switched beginning from 15.04 release) it is possible to declare filesystems that need to be mounted at boot via `*.mount` files. See [James O'Guya's tutorial](#) on the topic.

For more info, read [mount manual](#).

 slm 2,975 ● 1 □ 26 ● 33

 Sergiy Kolodyazhny 105k ● 20 □ 278 ● 496

Also note that on modern systems `/etc/mtab` is normally not written to disk anymore. Instead, it is a symbolic link pointing to `/proc/self/mounts`, which is a virtual file whose contents are generated by the kernel. – [Bachsau](#) Jul 7, 2021 at 10:12

TL;DR

30

- `/etc/fstab` is created by the user. It contains list of volumes to be mounted by `mount`.
- `/etc/mtab` is created by the system. It contains a list of currently mounted devices.
- The format of the files is similar. After mounting a new device, copy the relevant line from `/etc/mtab` to `/etc/fstab` so that it will be auto-mounted after boot or when calling `mount -a`.

Quotes from the `mount` manual

The `/etc/fstab`, `/etc/mtab` and `/proc/mounts` files

The file `/etc/fstab` may contain lines describing what devices are usually mounted where, using which options.

The programs `mount` and `umount` maintain a list of currently mounted filesystems in the file `/etc/mtab`.

When the proc filesystem is mounted (say at `/proc`), the files `/etc/mtab` and `/proc/mounts` have very similar contents. The former has somewhat more information, such as the mount options used, but is not necessarily up-to-date.

`mount -a`

`mount -a [-t type] [-O optlist]`

(usually given in a bootscript) causes all filesystems mentioned in fstab (of the proper type and/or having or not having the proper options) to be mounted as indicated, except for those whose line contains the `noauto` keyword. Adding the `-F` option will make `mount` fork, so that the filesystems are mounted simultaneously.

1 What if a device shows up as mounted in `/etc/fstab` but not under `/etc/mtab`? What is going on then? – [JohnyTex](#) Nov 25, 2020 at 15:02

2 @JohnyTex it means that the user intended to mount it, but it did not happen for some reason: it might be invalid, or that `mount` was not executed. – [Adam Matan](#) Nov 25, 2020 at 19:11

1 In my particular case I can access the partition even though it is not visible in `/etc/mtab` - any idea how that is possible? – [JohnyTex](#) Nov 26, 2020 at 9:04

Mdstat

From Linux Raid Wiki

Contents

- 1 /proc/mdstat
 - 1.1 querying the status
 - 1.2 Personalities line
 - 1.3 md device line
 - 1.4 md config/status line
 - 1.5 bitmap line
 - 1.6 recovery

/proc/mdstat

The **/proc/mdstat** file shows a snapshot of the kernel's RAID/md state.

querying the status

The kernel md state is easily viewed by running:

```
cat /proc/mdstat
```

It won't hurt. Let's learn how to read the file. Here are some examples:

example 1:

```
Personalities : [raid1] [raid6] [raid5] [raid4]
md_d0 : active raid5 sde1[0] sdf1[4] sdb1[5] sdd1[2] sdc1[1]
        1250241792 blocks super 1.2 level 5, 64k chunk, algorithm 2 [5/5] [UUUUU]
        bitmap: 0/10 pages [0KB], 16384KB chunk

unused devices: <none>
```

example 2:

```
Personalities : [raid6] [raid5] [raid4]
md0 : active raid5 sdal[0] sdd1[2] sdb1[1]
        1465151808 blocks level 5, 64k chunk, algorithm 2 [4/3] [UUU_]
        unused devices: <none>
```

example 3:

```
Personalities : [raid1] [raid6] [raid5] [raid4]
md1 : active raid1 sdb2[1] sda2[0]
        136448 blocks [2/2] [UU]

https://raid.wiki.kernel.org/index.php/Mdstat
```

```
md2 : active raid1 sdb3[1] sda3[0]
      129596288 blocks [2/2] [UU]

md3 : active raid5 sd1l[9] sd1k[8] sd1j[7] sd1l[6] sdh1[5] sdg1[4] sdf1[3] sde1[2] sdd1[1] sdc1[0]
      1318680576 blocks level 5, 1024k chunk, algorithm 2 [10/10] [UUUUUUUUUUUU]

md0 : active raid1 sdb1[1] sda1[0]
      16787776 blocks [2/2] [UU]

unused devices: <none>
```

example 4:

```
Personalities : [raid1] [raid6] [raid5] [raid4]
md127 : active raid5 sdh1[6] sdg1[4] sdf1[3] sde1[2] sdd1[1] sdc1[0]
      1464725760 blocks level 5, 64k chunk, algorithm 2 [6/5] [UUUUU_]
      [==>.....] recovery = 12.6% (37043392/292945152) finish=127.5min speed=33440K/sec

unused devices: <none>
```

example 5:

```
Personalities : [linear] [raid0] [raid1] [raid5] [raid4] [raid6]
md0 : active raid6 sdf1[0] sde1[1] sdd1[2] sdc1[3] sdb1[4] sda1[5] hdb1[6]
      1225557760 blocks level 6, 256k chunk, algorithm 2 [7/7] [UUUUUUU]
      bitmap: 0/234 pages [0KB], 512KB chunk

unused devices: <none>
```

example 6:

```
Personalities : [raid1]
md1 : active raid1 sde1[6](F) sdg1[1] sdb1[4] sdd1[3] sdc1[2]
      488383936 blocks [6/4] [_UUUU_]

unused devices: <none>
```

Personalities line

The "Personalities" line tells you what RAID level the kernel currently supports. This can be changed by either changing the raid modules or recompiling the kernel. Possible personalities include: [raid0] [raid1] [raid4] [raid5] [raid6] [linear] [multipath] [faulty]

Note: [faulty] is a diagnostic personality; it does not mean there is a problem with the array.

md device line

Each array is then described. from example 1:

```
md_d0 : active raid5 sde1[0] sdf1[4] sdb1[5] sdd1[2] sdc1[1]
```

This means we're looking at the device /dev/md_d0.

It is active or 'started'. An inactive array is usually faulty. Stopped arrays aren't visible here.

It is a raid5 array and the component devices are:

```
/dev/sde1 is device 0
/dev/sdf1 is device 4
/dev/sdb1 is device 5
/dev/sdd1 is device 2
/dev/sdc1 is device 1
```

The order in which the devices appear in this line means nothing.

The raid role numbers [#] following each device indicate its role, or function, within the raid set. Any device with "n" or higher are spare disks. 0,1,...,n-1 are for the working array. Notice that there is no device 3. At some point that device will have failed and been replaced by device 5. (check if this is true!)

To identify a spare devices, first look for the [#/#] value on a line. The first number is the number of a complete raid device as defined. Lets say it is "n".

Also, if you have a failure, the failed device will be marked with (F) after the [#] (see example 6 where sde1 has failed. The spare that replaces this device will be the device with the lowest role number n or higher that is not marked (F). Once the resync operation is complete, the device's role numbers are swapped.

To identify the spare devices, first determine the number of device the array needs to be fully operational (see below for the [#/#] value). Lets say it is "m". The raid role numbers [#] following each device indicate its role, or function, within the raid set. Any device with "m" or higher are spare disks. 0,1,...,m-1 are for the working array.

md config/status line

The next line continues the decription of the array; in example 1 it is:

```
1250241792 blocks super 1.2 level 5, 64k chunk, algorithm 2 [5/5] [UUUUUU]
```

This line provides some basic data about the fixed size and layout: it indicates the useable size of the array in blocks is 1250241792; the array uses a 1.2 superblock and confirms a level 5 (this is redundant!) array with a chunk size of 64k using algorithm 2. (See RAID Creation for more details).

The final 2 entries on this line

```
[5/5]
[UUUUUU]
```

are more dynamic.

[n/m] means that ideally the array would have n devices however, currently, m devices are in use. Obviously when m >= n then things are good.

The

```
[UUUUUU]
```

represents the status of each device, either U for up or _ for down. So examples 2 and 6 show 'degraded' arrays with some devices 'down'.

bitmap line

If an array has a bitmap then this line describes the state. Example 1 shows

```
bitmap: 0/10 pages [0KB], 16384KB chunk
```

What would it mean when it's, eg: 23/234

This refers to the in-memory bitmap (basically a cache of what's in the on-disk bitmap – it allows bitmap operations to be more efficient).

If it's 23/234 that means there are 23 of 234 pages allocated in the in-memory bitmap. The pages are allocated on demand, and get freed when they're empty (all zeroes). The in-memory bitmap uses 16 bits for each bitmap chunk to count all ongoing writes to the chunk, so it's actually up to 16 times larger than the on-disk bitmap.

External bitmap references look like this:

```
bitmap: 5/113 pages [20KB], 8192KB chunk, file: /WIBS/<node>:md0/WIB_<node>:md0
```

recovery

example 4 is clearly showing some recovery activity:

```
[==>.....] recovery = 12.6% (37043392/292945152) finish=127.5min speed=33440K/sec
```

The first part is simply a graphical representation of the progress. The rest of the line is fairly self explanatory. The finish time is only an approximation since the resync speed will vary according to other I/O demands. See the resync page for more details.

Retrieved from "<https://raid.wiki.kernel.org/index.php?title=Mdstat&oldid=4731>"

- This page was last modified on 5 October 2013, at 09:39.

```
`-l'  
`--format=long'  
`--format=verbose'  
    In addition to the name of each file, print the file type, file  
    mode bits, number of hard links, owner name, group name, size, and  
    timestamp (*note Formatting file timestamps::), normally the  
    modification time. Print question marks for information that  
    cannot be determined.
```

Normally the size is printed as a byte count without punctuation,
but this can be overridden (*note Block size::). For example, ` -h'
prints an abbreviated, human-readable count, and
`--block-size='1'" prints a byte count with the thousands
separator of the current locale.

For each directory that is listed, preface the files with a line
`total BLOCKS', where BLOCKS is the total disk allocation for all
files in that directory. The block size currently defaults to 1024
bytes, but this can be overridden (*note Block size::). The
BLOCKS computed counts each hard link separately; this is arguably
a deficiency.

The file type is one of the following characters:

```
`-'  
    regular file  
  
'b'  
    block special file  
  
'c'  
    character special file  
  
'C'  
    high performance ("contiguous data") file  
  
'd'  
    directory  
  
'D'  
    door (Solaris 2.5 and up)  
  
'l'  
    symbolic link  
  
'M'  
    off-line ("migrated") file (Cray DMF)  
  
'n'  
    network special file (HP-UX)
```

```
`p'  
    FIFO (named pipe)  
  
'P'  
    port (Solaris 10 and up)  
  
's'  
    socket  
  
'?'  
    some other file type
```

The file mode bits listed are similar to symbolic mode specifications (*note Symbolic Modes::). But `ls' combines multiple bits into the third character of each set of permissions as follows:

```
's'  
    If the set-user-ID or set-group-ID bit and the corresponding executable bit are both set.  
  
'S'  
    If the set-user-ID or set-group-ID bit is set but the corresponding executable bit is not set.  
  
't'  
    If the restricted deletion flag or sticky bit, and the other-executable bit, are both set. The restricted deletion flag is another name for the sticky bit. *Note Mode Structure::.  
  
'T'  
    If the restricted deletion flag or sticky bit is set but the other-executable bit is not set.  
  
'x'  
    If the executable bit is set and none of the above apply.  
  
'-'  
    Otherwise.
```

Following the file mode bits is a single character that specifies whether an alternate access method such as an access control list applies to the file. When the character following the file mode bits is a space, there is no alternate access method. When it is a printing character, then there is such a method.

GNU `ls' uses a `.' character to indicate a file with an SELinux security context, but no other alternate access method.

A file with any other combination of alternate access methods is marked with a `+' character.

On a regular (MBR) system, there are a maximum of 4 reg. partitions.
On a GPT system, you can have up to 128 partitions.
