congctl NAME (Linux 3.20+ only)**congctl lock NAME (Linux 3.20+ only)**

Sets a specific TCP congestion control algorithm only for a given destination. If not specified, Linux keeps the current global default TCP congestion control algorithm, or the one set from the application. If the modifier **lock** is not used, an application may nevertheless overwrite the suggested congestion control algorithm for that destination. If the modifier **lock** is used, then an application is not allowed to overwrite the specified congestion control algorithm for that destination, thus it will be enforced/guaranteed to use the proposed algorithm.

advmss NUMBER (Linux 2.3.15+ only)

the MSS ('Maximal Segment Size') to advertise to these destinations when establishing TCP connections. If it is not given, Linux uses a default value calculated from the first hop device MTU. (If the path to these destination is asymmetric, this guess may be wrong.)

reordering NUMBER (Linux 2.3.15+ only)

Maximal reordering on the path to this destination. If it is not given, Linux uses the value selected with sysctl variable **net/ipv4/tcp_reordering**.

nexthop *NEXTHOP*

the nexthop of a multipath route. *NEXTHOP* is a complex value with its own syntax similar to the top level argument lists:

via [*FAMILY*] *ADDRESS* - is the nexthop router.

dev *NAME* - is the output device.

weight *NUMBER* - is a weight for this element of a multipath route reflecting its relative bandwidth or quality.

The internal buffer used in iproute2 limits the maximum number of nexthops that may be specified in one go. If only *ADDRESS* is given, the current buffer size allows for 144 IPv6 nexthops and 253 IPv4 ones. For IPv4, this effectively limits the number of nexthops possible per route. With IPv6, further nexthops may be appended to the same route via **ip route append** command.

scope *SCOPE_VAL*

the scope of the destinations covered by the route prefix. *SCOPE_VAL* may be a number or a string from the file */etc/iproute2/rt_scopes*. If this parameter is omitted, ip assumes scope **global** for all gatewayed unicast routes, scope **link** for direct unicast and broadcast routes and scope **host** for local routes.

protocol *RTPROTO*

the routing protocol identifier of this route. *RTPROTO* may be a number or a string from the file */etc/iproute2/rt_protos*. If the routing protocol ID is not given, ip assumes protocol **boot** (i.e. it assumes the route was added by someone who doesn't understand what they are doing). Several protocol values have a fixed interpretation. Namely:

redirect - the route was installed due to an ICMP redirect.

kernel - the route was installed by the kernel during autoconfiguration.

boot - the route was installed during the bootup sequence. If a routing daemon starts, it will purge all of them.

static - the route was installed by the administrator to override dynamic routing. Routing daemon will respect them and, probably, even advertise them to its peers.

ra - the route was installed by Router Discovery protocol.

The rest of the values are not reserved and the administrator is free to assign (or not to assign) protocol tags.

onlink pretend that the nexthop is directly attached to this link, even if it does not match any interface prefix.

pref *PREF*

the IPv6 route preference. *PREF* is a string specifying the route preference as defined in RFC4191 for Router Discovery messages. Namely:

low - the route has a lowest priority

medium - the route has a default priority

high - the route has a highest priority

nhid *ID*

use nexthop object with given id as nexthop specification.

encap *ENCAPTYPE ENCAPHDR*

attach tunnel encapsulation attributes to this route.

ENCAPTYPE is a string specifying the supported encapsulation type. Namely:

mpls - encapsulation type MPLS

ip - IP encapsulation (Geneve, GRE, VXLAN, ...)

bpf - Execution of BPF program

seg6 - encapsulation type IPv6 Segment Routing

seg6local - local SRv6 segment processing

ioam6 - encapsulation type IPv6 IOAM

ENCAPHDR is a set of encapsulation attributes specific to the *ENCAPTYPE*.

mpls

MPLSLABEL - mpls label stack with labels separated by /

ttl *TTL* - TTL to use for MPLS header or 0 to inherit from IP header

ip

id *TUNNEL_ID* **dst** *REMOTE_IP* [**src** *SRC*] [**tos** *TOS*] [**ttl** *TTL*] [**key**] [**csum**] [**seq**]

bpf

in *PROG* - BPF program to execute for incoming packets

out PROG - BPF program to execute for outgoing packets

xmit PROG - BPF program to execute for transmitted packets

headroom SIZE - Size of header BPF program will attach
(xmit)

seg6

mode inline - Directly insert Segment Routing Header after
IPv6 header

mode encaps - Encapsulate packet in an outer IPv6 header with
SRH

mode l2encap - Encapsulate ingress L2 frame within an outer
IPv6 header and SRH

SEGMENTS - List of comma-separated IPv6 addresses

KEYID - Numerical value in decimal representation. See **ip-
sr(8)**.

seg6local

SEG6_ACTION [SEG6_ACTION_PARAM] [count] - Operation to perform on matching packets. The optional **count** attribute is used to collect statistics on the processing of actions. Three counters are implemented: 1) packets correctly processed; 2) bytes correctly processed; 3) packets that cause a processing error (i.e., missing SID List, wrong SID List, etc). To retrieve the counters related to an action use the **-s** flag in the **show** command. The following actions are currently supported (**Linux 4.14+ only**).

End - Regular SRv6 processing as intermediate segment endpoint. This action only accepts packets with a non-zero Segments Left value. Other matching packets are dropped.

End.X nh6 NEXTHOP - Regular SRv6 processing as intermediate segment endpoint. Additionally, forward processed packets to given next-hop. This action only accepts packets with a non-zero Segments Left value. Other matching packets are dropped.

End.DX6 nh6 NEXTHOP - Decapsulate inner IPv6 packet and forward it to the specified next-hop. If the argument is set to ::, then the next-hop is selected according to the local

selection rules. This action only accepts packets with either a zero Segments Left value or no SRH at all, and an inner IPv6 packet. Other matching packets are dropped.

End.DT6 { table | vrftable } TABLEID - Decapsulate the inner IPv6 packet and forward it according to the specified lookup table. *TABLEID* is either a number or a string from the file */etc/iproute2/rt_tables*. If *vrftable* is used, the argument must be a VRF device associated with the table id. Moreover, the VRF table associated with the table id must be configured with the VRF strict mode turned on (net.vrf.strict_mode=1). This action only accepts packets with either a zero Segments Left value or no SRH at all, and an inner IPv6 packet. Other matching packets are dropped.

End.DT4 vrftable TABLEID - Decapsulate the inner IPv4 packet and forward it according to the specified lookup table. *TABLEID* is either a number or a string from the file */etc/iproute2/rt_tables*. The argument must be a VRF device associated with the table id. Moreover, the VRF table associated with the table id must be configured with the VRF strict mode turned on (net.vrf.strict_mode=1). This action only accepts packets with either a zero Segments Left value or no SRH at all, and an inner IPv4 packet. Other matching packets are dropped.

End.DT46 vrftable TABLEID - Decapsulate the inner IPv4 or IPv6 packet and forward it according to the specified lookup table. *TABLEID* is either a number or a string from the file */etc/iproute2/rt_tables*. The argument must be a VRF device associated with the table id. Moreover, the VRF table associated with the table id must be configured with the VRF strict mode turned on (net.vrf.strict_mode=1). This action only accepts packets with either a zero Segments Left value or no SRH at all, and an inner IPv4 or IPv6 packet. Other matching packets are dropped.

End.B6 srh segs SEGMENTS [hmac KEYID] - Insert the specified SRH immediately after the IPv6 header, update the DA with the first segment of the newly inserted SRH, then forward the resulting packet. The original SRH is not modified. This action only accepts packets with a non-zero Segments Left value. Other matching packets are dropped.

End.B6.Encaps srh segs SEGMENTS [hmac KEYID] - Regular SRv6 processing as intermediate segment endpoint. Additionally, encapsulate the matching packet within an outer IPv6 header followed by the specified SRH. The destination address of the outer IPv6 header is set to the first segment of the new SRH. The source address is set as described in **ip-sr(8)**.

ioam6

IOAM6_TRACE_TYPE - List of IOAM data required in the trace, represented by a bitfield (24 bits).

IOAM6_NAMESPACE - Numerical value to represent an IOAM namespace. See **ip-ioam(8)**.

IOAM6_TRACE_SIZE - Size, in octets, of the pre-allocated trace data block.

expires TIME (Linux 4.4+ only)

the route will be deleted after the expires time. **Only** support IPv6 at present.

ttl-propagate { enabled | disabled }

Control whether TTL should be propagated from any encap into the un-encapsulated packet, overriding any global configuration. Only supported for MPLS at present.

ip route delete

delete route

ip route del has the same arguments as **ip route add**, but their semantics are a bit different.

Key values (**to**, **tos**, **preference** and **table**) select the route to delete. If optional attributes are present, **ip** verifies that they coincide with the attributes of the route to delete. If no route with the given key and attributes was found, **ip route del** fails.

ip route show

list routes

the command displays the contents of the routing tables or the route(s) selected by some criteria.

to SELECTOR (default)

only select routes from the given range of destinations. *SELECTOR* consists of an optional modifier (**root**, **match** or **exact**) and a prefix. **root** *PREFIX* selects routes with prefixes not shorter than *PREFIX*. F.e. **root** *0/0* selects the entire routing table. **match** *PREFIX* selects routes with prefixes not longer than *PREFIX*. F.e. **match** *10.0/16* selects *10.0/16*, *10/8* and *0/0*, but it does not select *10.1/16* and *10.0.0/24*. And **exact** *PREFIX* (or just *PREFIX*) selects routes with this exact prefix. If neither of these options are present, **ip** assumes **root** *0/0* i.e. it lists the entire table.

tos TOS**dsfield TOS**

only select routes with the given TOS.

table TABLEID

show the routes from this table(s). The default setting is to show table **main**. *TABLEID* may either be the ID of a real table or one of the special values:

all - list all of the tables.

cache - dump the routing cache.

vrf *NAME*

show the routes for the table associated with the vrf name

cloned

cached list cloned routes i.e. routes which were dynamically forked from other routes because some route attribute (f.e. MTU) was updated. Actually, it is equivalent to **table cache**.

from *SELECTOR*

the same syntax as for **to**, but it binds the source address range rather than destinations.
Note that the **from** option only works with cloned routes.

protocol *RTPROTO*

only list routes of this protocol.

scope *SCOPE_VAL*

only list routes with this scope.

type *TYPE*

only list routes of this type.

dev *NAME*

only list routes going via this device.

via [*FAMILY*] *PREFIX*

only list routes going via the nexthop routers selected by *PREFIX*.

src *PREFIX*

only list routes with preferred source addresses selected by *PREFIX*.

realm *REALMID*

realms *FROMREALM/TOREALM*

only list routes with these realms.

ip route flush

flush routing tables

this command flushes routes selected by some criteria.

The arguments have the same syntax and semantics as the arguments of **ip route show**, but routing tables are not listed but purged. The only difference is the default action: **show** dumps all the IP main routing table but **flush** prints the helper page.

With the **-statistics** option, the command becomes verbose. It prints out the number of deleted routes and the number of rounds made to flush the routing table. If the option is given twice, **ip route flush** also dumps all the deleted routes in the format described in the previous subsection.

ip route get

get a single route

this command gets a single route to a destination and prints its contents exactly as the kernel sees it.

fibmatch

Return full fib lookup matched route. Default is to return the resolved dst entry

to ADDRESS (default)

the destination address.

from ADDRESS

the source address.

tos TOS

dsfield TOS

the Type Of Service.

iif NAME

the device from which this packet is expected to arrive.

oif NAME

force the output device on which this packet will be routed.

mark MARK

the firewall mark (**fwmark**)

vrf NAME

force the vrf device on which this packet will be routed.

ipproto PROTOCOL

ip protocol as seen by the route lookup

sport NUMBER

source port as seen by the route lookup

dport NUMBER

destination port as seen by the route lookup

connected

if no source address (option **from**) was given, relookup the route with the source set to the preferred address received from the first lookup. If policy routing is used, it may be a different route.

Note that this operation is not equivalent to **ip route show**. **show** shows existing routes. **get** resolves them and creates new clones if necessary. Essentially, **get** is equivalent to sending a packet along this path. If the **iif** argument is not given, the kernel creates a route to output packets towards the requested destination. This is equivalent to pinging the destination with a subsequent **ip route ls cache**, however, no packets are actually sent. With the **iif** argument, the kernel pretends

that a packet arrived from this interface and searches for a path to forward the packet.

ip route save

save routing table information to stdout

This command behaves like **ip route show** except that the output is raw data suitable for passing to **ip route restore**.

ip route restore

restore routing table information from stdin

This command expects to read a data stream as returned from **ip route save**. It will attempt to restore the routing table information exactly as it was at the time of the save, so any translation of information in the stream (such as device indexes) must be done first. Any existing routes are left unchanged. Any routes specified in the data stream that already exist in the table will be ignored.

NOTES

Starting with Linux kernel version 3.6, there is no routing cache for IPv4 anymore. Hence **ip route show cached** will never print any entries on systems with this or newer kernel versions.

EXAMPLES**ip ro**

Show all route entries in the kernel.

ip route add default via 192.168.1.1 dev eth0

Adds a default route (for all addresses) via the local gateway 192.168.1.1 that can be reached on device eth0.

ip route add 10.1.1.0/30 encaps mpls 200/300 via 10.1.1.1 dev eth0

Adds an ipv4 route with mpls encapsulation attributes attached to it.

ip -6 route add 2001:db8:1::/64 encaps seg6 mode encaps segs 2001:db8:42::1,2001:db8:ffff::2 dev eth0

Adds an IPv6 route with SRv6 encapsulation and two segments attached.

ip -6 route add 2001:db8:1::/64 encaps seg6local action End.DT46 vrftable 100 dev vrf100

Adds an IPv6 route with SRv6 decapsulation and forward with lookup in VRF table.

ip -6 route add 2001:db8:1::/64 encaps ioam6 trace prealloc type 0x800000 ns 1 size 12 dev eth0

Adds an IPv6 route with an IOAM Pre-allocated Trace encapsulation that only includes the hop limit and the node id, configured for the IOAM namespace 1 and a pre-allocated data block of 12 octets.

ip route add 10.1.1.0/30 nhid 10

Adds an ipv4 route using nexthop object with id 10.

NAME

ip – Linux IPv4 protocol implementation

SYNOPSIS

```
#include <sys/socket.h>
#include <netinet/in.h>
#include <netinet/ip.h> /* superset of previous */

tcp_socket = socket(AF_INET, SOCK_STREAM, 0);
udp_socket = socket(AF_INET, SOCK_DGRAM, 0);
raw_socket = socket(AF_INET, SOCK_RAW, protocol);
```

DESCRIPTION

Linux implements the Internet Protocol, version 4, described in RFC 791 and RFC 1122. **ip** contains a level 2 multicasting implementation conforming to RFC 1112. It also contains an IP router including a packet filter.

The programming interface is BSD-sockets compatible. For more information on sockets, see **socket(7)**.

An IP socket is created using **socket(2)**:

```
socket(AF_INET, socket_type, protocol);
```

Valid socket types include **SOCK_STREAM** to open a stream socket, **SOCK_DGRAM** to open a datagram socket, and **SOCK_RAW** to open a **raw(7)** socket to access the IP protocol directly.

protocol is the IP protocol in the IP header to be received or sent. Valid values for *protocol* include:

- 0 and **IPPROTO_TCP** for **tcp(7)** stream sockets;
- 0 and **IPPROTO_UDP** for **udp(7)** datagram sockets;
- **IPPROTO_SCTP** for **sctp(7)** stream sockets; and
- **IPPROTO_UDPLITE** for **udplite(7)** datagram sockets.

For **SOCK_RAW** you may specify a valid IANA IP protocol defined in RFC 1700 assigned numbers.

When a process wants to receive new incoming packets or connections, it should bind a socket to a local interface address using **bind(2)**. In this case, only one IP socket may be bound to any given local (address, port) pair. When **IN_ADDR_ANY** is specified in the bind call, the socket will be bound to *all* local interfaces. When **listen(2)** is called on an unbound socket, the socket is automatically bound to a random free port with the local address set to **INADDR_ANY**. When **connect(2)** is called on an unbound socket, the socket is automatically bound to a random free port or to a usable shared port with the local address set to **INADDR_ANY**.

A TCP local socket address that has been bound is unavailable for some time after closing, unless the **SO_REUSEADDR** flag has been set. Care should be taken when using this flag as it makes TCP less reliable.

Address format

An IP socket address is defined as a combination of an IP interface address and a 16-bit port number. The basic IP protocol does not supply port numbers, they are implemented by higher level protocols like **udp(7)** and **tcp(7)**. On raw sockets *sin_port* is set to the IP protocol.

```
struct sockaddr_in {
    sa_family_t    sin_family; /* address family: AF_INET */
    in_port_t      sin_port;   /* port in network byte order */
    struct in_addr sin_addr;  /* internet address */
};

/* Internet address */
struct in_addr {
    uint32_t        s_addr;    /* address in network byte order */
};
```

sin_family is always set to **AF_INET**. This is required; in Linux 2.2 most networking functions return **EINVAL** when this setting is missing. *sin_port* contains the port in network byte order. The port numbers below 1024 are called *privileged ports* (or sometimes: *reserved ports*). Only a privileged process (on Linux: a process that has the **CAP_NET_BIND_SERVICE** capability in the user namespace governing its network namespace) may **bind**(2) to these sockets. Note that the raw IPv4 protocol as such has no concept of a port, they are implemented only by higher protocols like **tcp**(7) and **udp**(7).

sin_addr is the IP host address. The *s_addr* member of *struct in_addr* contains the host interface address in network byte order. *in_addr* should be assigned one of the **INADDR_*** values (e.g., **INADDR_LOOPBACK**) using **htonl**(3) or set using the **inet_aton**(3), **inet_addr**(3), **inet_makeaddr**(3) library functions or directly with the name resolver (see **gethostbyname**(3)).

IPv4 addresses are divided into unicast, broadcast, and multicast addresses. Unicast addresses specify a single interface of a host, broadcast addresses specify all hosts on a network, and multicast addresses address all hosts in a multicast group. Datagrams to broadcast addresses can be sent or received only when the **SO_BROADCAST** socket flag is set. In the current implementation, connection-oriented sockets are allowed to use only unicast addresses.

Note that the address and the port are always stored in network byte order. In particular, this means that you need to call **htonl**(3) on the number that is assigned to a port. All address/port manipulation functions in the standard library work in network byte order.

There are several special addresses: **INADDR_LOOPBACK** (127.0.0.1) always refers to the local host via the loopback device; **INADDR_ANY** (0.0.0.0) means any address for binding; **INADDR_BROADCAST** (255.255.255.255) means any host and has the same effect on bind as **INADDR_ANY** for historical reasons.

Socket options

IP supports some protocol-specific socket options that can be set with **setsockopt**(2) and read with **getsockopt**(2). The socket option level for IP is **IPPROTO_IP**. A boolean integer flag is zero when it is false, otherwise true.

When an invalid socket option is specified, **getsockopt**(2) and **setsockopt**(2) fail with the error **ENOPROTOOPT**.

IP_ADD_MEMBERSHIP (since Linux 1.2)

Join a multicast group. Argument is an *ip_mreqn* structure.

```
struct ip_mreqn {
    struct in_addr imr_multiaddr; /* IP multicast group
                                   address */
    struct in_addr imr_address;   /* IP address of local
                                   interface */
    int           imr_ifindex;    /* interface index */
};
```

imr_multiaddr contains the address of the multicast group the application wants to join or leave. It must be a valid multicast address (or **setsockopt**(2) fails with the error **EINVAL**). *imr_address* is the address of the local interface with which the system should join the multicast group; if it is equal to **INADDR_ANY**, an appropriate interface is chosen by the system. *imr_ifindex* is the interface index of the interface that should join/leave the *imr_multiaddr* group, or 0 to indicate any interface.

The *ip_mreqn* structure is available only since Linux 2.2. For compatibility, the old *ip_mreq* structure (present since Linux 1.2) is still supported; it differs from *ip_mreqn* only by not including the *imr_ifindex* field. (The kernel determines which structure is being passed based on the size passed in *optlen*.)

IP_ADD_MEMBERSHIP is valid only for **setsockopt**(2).

IP_ADD_SOURCE_MEMBERSHIP (since Linux 2.4.22 / Linux 2.5.68)

Join a multicast group and allow receiving data only from a specified source. Argument is an *ip_mreq_source* structure.

```
struct ip_mreq_source {
    struct in_addr imr_multiaddr; /* IP multicast group
                                   address */
    struct in_addr imr_interface; /* IP address of local
                                   interface */
    struct in_addr imr_sourceaddr; /* IP address of
                                   multicast source */
};
```

The *ip_mreq_source* structure is similar to *ip_mreqn* described under **IP_ADD_MEMBERSHIP**. The *imr_multiaddr* field contains the address of the multicast group the application wants to join or leave. The *imr_interface* field is the address of the local interface with which the system should join the multicast group. Finally, the *imr_sourceaddr* field contains the address of the source the application wants to receive data from.

This option can be used multiple times to allow receiving data from more than one source.

IP_BIND_ADDRESS_NO_PORT (since Linux 4.2)

Inform the kernel to not reserve an ephemeral port when using **bind(2)** with a port number of 0. The port will later be automatically chosen at **connect(2)** time, in a way that allows sharing a source port as long as the 4-tuple is unique.

IP_BLOCK_SOURCE (since Linux 2.4.22 / 2.5.68)

Stop receiving multicast data from a specific source in a given group. This is valid only after the application has subscribed to the multicast group using either **IP_ADD_MEMBERSHIP** or **IP_ADD_SOURCE_MEMBERSHIP**.

Argument is an *ip_mreq_source* structure as described under **IP_ADD_SOURCE_MEMBERSHIP**.

IP_DROP_MEMBERSHIP (since Linux 1.2)

Leave a multicast group. Argument is an *ip_mreqn* or *ip_mreq* structure similar to **IP_ADD_MEMBERSHIP**.

IP_DROP_SOURCE_MEMBERSHIP (since Linux 2.4.22 / 2.5.68)

Leave a source-specific group—that is, stop receiving data from a given multicast group that come from a given source. If the application has subscribed to multiple sources within the same group, data from the remaining sources will still be delivered. To stop receiving data from all sources at once, use **IP_DROP_MEMBERSHIP**.

Argument is an *ip_mreq_source* structure as described under **IP_ADD_SOURCE_MEMBERSHIP**.

IP_FREEBIND (since Linux 2.4)

If enabled, this boolean option allows binding to an IP address that is nonlocal or does not (yet) exist. This permits listening on a socket, without requiring the underlying network interface or the specified dynamic IP address to be up at the time that the application is trying to bind to it. This option is the per-socket equivalent of the *ip_nonlocal_bind /proc* interface described below.

IP_HDRINCL (since Linux 2.0)

If enabled, the user supplies an IP header in front of the user data. Valid only for **SOCK_RAW** sockets; see **raw(7)** for more information. When this flag is enabled, the values set by **IP_OPTIONS**, **IP_TTL**, and **IP_TOS** are ignored.

IP_MSFILTER (since Linux 2.4.22 / 2.5.68)

This option provides access to the advanced full-state filtering API. Argument is an *ip_msfilter* structure.

```
struct ip_msfilter {
    struct in_addr imsf_multiaddr; /* IP multicast group
                                   address */
    struct in_addr imsf_interface; /* IP address of local
```

```

        interface */
    uint32_t      imsf_fmode;      /* Filter-mode */

    uint32_t      imsf_numsorc;   /* Number of sources in
                                  the following array */
    struct in_addr imsf_slist[1]; /* Array of source
                                  addresses */
};

}

```

There are two macros, **MCAST_INCLUDE** and **MCAST_EXCLUDE**, which can be used to specify the filtering mode. Additionally, the **IP_MSFILTER_SIZE(n)** macro exists to determine how much memory is needed to store *ip_msfilter* structure with *n* sources in the source list.

For the full description of multicast source filtering refer to RFC 3376.

IP_MTU (since Linux 2.2)

Retrieve the current known path MTU of the current socket. Returns an integer.

IP_MTU is valid only for **getsockopt(2)** and can be employed only when the socket has been connected.

IP_MTU_DISCOVER (since Linux 2.2)

Set or receive the Path MTU Discovery setting for a socket. When enabled, Linux will perform Path MTU Discovery as defined in RFC 1191 on **SOCK_STREAM** sockets. For non-**SOCK_STREAM** sockets, **IP_PMTUDISC_DO** forces the don't-fragment flag to be set on all outgoing packets. It is the user's responsibility to packetize the data in MTU-sized chunks and to do the retransmits if necessary. The kernel will reject (with **EMSGSIZE**) datagrams that are bigger than the known path MTU. **IP_PMTUDISC_WANT** will fragment a datagram if needed according to the path MTU, or will set the don't-fragment flag otherwise.

The system-wide default can be toggled between **IP_PMTUDISC_WANT** and **IP_PMTUDISC_DONT** by writing (respectively, zero and nonzero values) to the */proc/sys/net/ipv4/ip_no_pmtu_disc* file.

Path MTU discovery value	Meaning
IP_PMTUDISC_WANT	Use per-route settings.
IP_PMTUDISC_DONT	Never do Path MTU Discovery.
IP_PMTUDISC_DO	Always do Path MTU Discovery.
IP_PMTUDISC_PROBE	Set DF but ignore Path MTU.

When PMTU discovery is enabled, the kernel automatically keeps track of the path MTU per destination host. When it is connected to a specific peer with **connect(2)**, the currently known path MTU can be retrieved conveniently using the **IP_MTU** socket option (e.g., after an **EMSGSIZE** error occurred). The path MTU may change over time. For connectionless sockets with many destinations, the new MTU for a given destination can also be accessed using the error queue (see **IP_RECVERR**). A new error will be queued for every incoming MTU update.

While MTU discovery is in progress, initial packets from datagram sockets may be dropped. Applications using UDP should be aware of this and not take it into account for their packet retransmit strategy.

To bootstrap the path MTU discovery process on unconnected sockets, it is possible to start with a big datagram size (headers up to 64 kilobytes long) and let it shrink by updates of the path MTU.

To get an initial estimate of the path MTU, connect a datagram socket to the destination address using **connect(2)** and retrieve the MTU by calling **getsockopt(2)** with the **IP_MTU** option.

It is possible to implement RFC 4821 MTU probing with **SOCK_DGRAM** or **SOCK_RAW** sockets by setting a value of **IP_PMTUDISC_PROBE** (available since Linux 2.6.22). This is also particularly useful for diagnostic tools such as **tracepath(8)** that wish to deliberately send probe packets larger than the observed Path MTU.

IP_MULTICAST_ALL (since Linux 2.6.31)

This option can be used to modify the delivery policy of multicast messages to sockets bound to the wildcard **INADDR_ANY** address. The argument is a boolean integer (defaults to 1). If set to 1, the socket will receive messages from all the groups that have been joined globally on the whole system. Otherwise, it will deliver messages only from the groups that have been explicitly joined (for example via the **IP_ADD_MEMBERSHIP** option) on this particular socket.

IP_MULTICAST_IF (since Linux 1.2)

Set the local device for a multicast socket. The argument for **setsockopt(2)** is an *ip_mreqn* or (since Linux 3.5) *ip_mreq* structure similar to **IP_ADD_MEMBERSHIP**, or an *in_addr* structure. (The kernel determines which structure is being passed based on the size passed in *optlen*.) For **getsockopt(2)**, the argument is an *in_addr* structure.

IP_MULTICAST_LOOP (since Linux 1.2)

Set or read a boolean integer argument that determines whether sent multicast packets should be looped back to the local sockets.

IP_MULTICAST_TTL (since Linux 1.2)

Set or read the time-to-live value of outgoing multicast packets for this socket. It is very important for multicast packets to set the smallest TTL possible. The default is 1 which means that multicast packets don't leave the local network unless the user program explicitly requests it. Argument is an integer.

IP_NODEFRAG (since Linux 2.6.36)

If enabled (argument is nonzero), the reassembly of outgoing packets is disabled in the netfilter layer. The argument is an integer.

This option is valid only for **SOCK_RAW** sockets.

IP_OPTIONS (since Linux 2.0)

Set or get the IP options to be sent with every packet from this socket. The arguments are a pointer to a memory buffer containing the options and the option length. The **setsockopt(2)** call sets the IP options associated with a socket. The maximum option size for IPv4 is 40 bytes. See RFC 791 for the allowed options. When the initial connection request packet for a **SOCK_STREAM** socket contains IP options, the IP options will be set automatically to the options from the initial packet with routing headers reversed. Incoming packets are not allowed to change options after the connection is established. The processing of all incoming source routing options is disabled by default and can be enabled by using the *accept_source_route /proc* interface. Other options like timestamps are still handled. For datagram sockets, IP options can be set only by the local user. Calling **getsockopt(2)** with **IP_OPTIONS** puts the current IP options used for sending into the supplied buffer.

IP_PASSEC (since Linux 2.6.17)

If labeled IPSEC or NetLabel is configured on the sending and receiving hosts, this option enables receiving of the security context of the peer socket in an ancillary message of type **SCM_SECURITY** retrieved using **recvmsg(2)**. This option is supported only for UDP sockets; for TCP or SCTP sockets, see the description of the **SO_PEERSEC** option below.

The value given as an argument to **setsockopt(2)** and returned as the result of **getsockopt(2)** is an integer boolean flag.

The security context returned in the **SCM_SECURITY** ancillary message is of the same format as the one described under the **SO_PEERSEC** option below.

Note: the reuse of the **SCM_SECURITY** message type for the **IP_PASSEC** socket option was likely a mistake, since other IP control messages use their own numbering scheme in the IP namespace and often use the socket option value as the message type. There is no conflict currently since the IP option with the same value as **SCM_SECURITY** is **IP_HDRINCL** and this is never used for a control message type.

IP_PKTINFO (since Linux 2.2)

Pass an **IP_PKTINFO** ancillary message that contains a *pktinfo* structure that supplies some information about the incoming packet. This works only for datagram oriented sockets. The argument is a flag that tells the socket whether the **IP_PKTINFO** message should be passed or not. The message itself can be sent/retrieved only as a control message with a packet using **recvmsg(2)** or **sendmsg(2)**.

```
struct in_pktinfo {
    unsigned int    ipi_ifindex; /* Interface index */
    struct in_addr ipi_spec_dst; /* Local address */
    struct in_addr ipi_addr;    /* Header Destination
                                address */
};
```

ipi_ifindex is the unique index of the interface the packet was received on. *ipi_spec_dst* is the local address of the packet and *ipi_addr* is the destination address in the packet header. If **IP_PKTINFO** is passed to **sendmsg(2)** and *ipi_spec_dst* is not zero, then it is used as the local source address for the routing table lookup and for setting up IP source route options. When *ipi_ifindex* is not zero, the primary local address of the interface specified by the index overwrites *ipi_spec_dst* for the routing table lookup.

IP_RECVERR (since Linux 2.2)

Enable extended reliable error message passing. When enabled on a datagram socket, all generated errors will be queued in a per-socket error queue. When the user receives an error from a socket operation, the errors can be received by calling **recvmsg(2)** with the **MSG_ERRQUEUE** flag set. The *sock_extended_err* structure describing the error will be passed in an ancillary message with the type **IP_RECVERR** and the level **IPPROTO_IP**. This is useful for reliable error handling on unconnected sockets. The received data portion of the error queue contains the error packet.

The **IP_RECVERR** control message contains a *sock_extended_err* structure:

```
#define SO_EE_ORIGIN_NONE      0
#define SO_EE_ORIGIN_LOCAL      1
#define SO_EE_ORIGIN_ICMP       2
#define SO_EE_ORIGIN_ICMP6      3

struct sock_extended_err {
    uint32_t ee_errno;        /* error number */
    uint8_t  ee_origin;       /* where the error originated */
    uint8_t  ee_type;         /* type */
    uint8_t  ee_code;         /* code */
    uint8_t  ee_pad;
    uint32_t ee_info;         /* additional information */
    uint32_t ee_data;         /* other data */
    /* More data may follow */
};

struct sockaddr *SO_EE_OFFENDER(struct sock_extended_err *);
```

ee_errno contains the *errno* number of the queued error. *ee_origin* is the origin code of where the error originated. The other fields are protocol-specific. The macro **SO_EE_OFFENDER** returns a pointer to the address of the network object where the error originated from given a pointer to the ancillary message. If this address is not known, the *sa_family* member of the *sockaddr* contains **AF_UNSPEC** and the other fields of the *sockaddr* are undefined.

IP uses the *sock_extended_err* structure as follows: *ee_origin* is set to **SO_EE_ORIGIN_ICMP** for errors received as an ICMP packet, or **SO_EE_ORIGIN_LOCAL** for locally generated errors. Unknown values should be ignored. *ee_type* and *ee_code* are set from the type and code

fields of the ICMP header. *ee_info* contains the discovered MTU for **EMSGSIZE** errors. The message also contains the *sockaddr_in* of the node caused the error, which can be accessed with the **SO_EE_OFFENDER** macro. The *sin_family* field of the **SO_EE_OFFENDER** address is **AF_UNSPEC** when the source was unknown. When the error originated from the network, all IP options (**IP_OPTIONS**, **IP_TTL**, etc.) enabled on the socket and contained in the error packet are passed as control messages. The payload of the packet causing the error is returned as normal payload. Note that TCP has no error queue; **MSG_ERRQ UEUE** is not permitted on **SOCK_STREAM** sockets. **IP_RECVERR** is valid for TCP, but all errors are returned by socket function return or **SO_ERROR** only.

For raw sockets, **IP_RECVERR** enables passing of all received ICMP errors to the application, otherwise errors are reported only on connected sockets

It sets or retrieves an integer boolean flag. **IP_RECVERR** defaults to off.

IP_RECVOPTS (since Linux 2.2)

Pass all incoming IP options to the user in a **IP_OPTIONS** control message. The routing header and other options are already filled in for the local host. Not supported for **SOCK_STREAM** sockets.

IP_RECVORIGSTADDR (since Linux 2.6.29)

This boolean option enables the **IP_ORIGSTADDR** ancillary message in **recvmsg(2)**, in which the kernel returns the original destination address of the datagram being received. The ancillary message contains a *struct sockaddr_in*.

IP_RECVTOS (since Linux 2.2)

If enabled, the **IP_TOS** ancillary message is passed with incoming packets. It contains a byte which specifies the Type of Service/Precedence field of the packet header. Expects a boolean integer flag.

IP_RECVTTL (since Linux 2.2)

When this flag is set, pass a **IP_TTL** control message with the time-to-live field of the received packet as a 32 bit integer. Not supported for **SOCK_STREAM** sockets.

IP_RECVTOPTS (since Linux 2.2)

Identical to **IP_RECVOPTS**, but returns raw unprocessed options with timestamp and route record options not filled in for this hop.

IP_ROUTER_ALERT (since Linux 2.2)

Pass all to-be forwarded packets with the IP Router Alert option set to this socket. Valid only for raw sockets. This is useful, for instance, for user-space RSVP daemons. The tapped packets are not forwarded by the kernel; it is the user's responsibility to send them out again. Socket binding is ignored, such packets are filtered only by protocol. Expects an integer flag.

IP_TOS (since Linux 1.0)

Set or receive the Type-Of-Service (TOS) field that is sent with every IP packet originating from this socket. It is used to prioritize packets on the network. TOS is a byte. There are some standard TOS flags defined: **IPTOS_LOWDELAY** to minimize delays for interactive traffic, **IP-TOS_THROUGHPUT** to optimize throughput, **IPTOS_RELIABILITY** to optimize for reliability, **IPTOS_MINCOST** should be used for "filler data" where slow transmission doesn't matter. At most one of these TOS values can be specified. Other bits are invalid and shall be cleared. Linux sends **IPTOS_LOWDELAY** datagrams first by default, but the exact behavior depends on the configured queueing discipline. Some high-priority levels may require superuser privileges (the **CAP_NET_ADMIN** capability).

IP_TRANSPARENT (since Linux 2.6.24)

Setting this boolean option enables transparent proxying on this socket. This socket option allows the calling application to bind to a nonlocal IP address and operate both as a client and a server with the foreign address as the local endpoint. NOTE: this requires that routing be set up in a way that packets going to the foreign address are routed through the TProxy box (i.e., the system

hosting the application that employs the **IP_TRANSPARENT** socket option). Enabling this socket option requires superuser privileges (the **CAP_NET_ADMIN** capability).

TProxy redirection with the iptables TPROXY target also requires that this option be set on the redirected socket.

IP_TTL (since Linux 1.0)

Set or retrieve the current time-to-live field that is used in every packet sent from this socket.

IP_UNBLOCK_SOURCE (since Linux 2.4.22 / 2.5.68)

Unblock previously blocked multicast source. Returns **EADDRNOTAVAIL** when given source is not being blocked.

Argument is an *ip_mreq_source* structure as described under **IP_ADD_SOURCE_MEMBERSHIP**.

SO_PEERSEC (since Linux 2.6.17)

If labeled IPSEC or NetLabel is configured on both the sending and receiving hosts, this read-only socket option returns the security context of the peer socket connected to this socket. By default, this will be the same as the security context of the process that created the peer socket unless overridden by the policy or by a process with the required permissions.

The argument to **getsockopt(2)** is a pointer to a buffer of the specified length in bytes into which the security context string will be copied. If the buffer length is less than the length of the security context string, then **getsockopt(2)** returns -1, sets *errno* to **ERANGE**, and returns the required length via *optlen*. The caller should allocate at least **NAME_MAX** bytes for the buffer initially, although this is not guaranteed to be sufficient. Resizing the buffer to the returned length and retrying may be necessary.

The security context string may include a terminating null character in the returned length, but is not guaranteed to do so: a security context "foo" might be represented as either {'f','o','o'} of length 3 or {'f','o','o','\0'} of length 4, which are considered to be interchangeable. The string is printable, does not contain non-terminating null characters, and is in an unspecified encoding (in particular, it is not guaranteed to be ASCII or UTF-8).

The use of this option for sockets in the **AF_INET** address family is supported since Linux 2.6.17 for TCP sockets, and since Linux 4.17 for SCTP sockets.

For SELinux, NetLabel conveys only the MLS portion of the security context of the peer across the wire, defaulting the rest of the security context to the values defined in the policy for the netmsg initial security identifier (SID). However, NetLabel can be configured to pass full security contexts over loopback. Labeled IPSEC always passes full security contexts as part of establishing the security association (SA) and looks them up based on the association for each packet.

/proc interfaces

The IP protocol supports a set of */proc* interfaces to configure some global parameters. The parameters can be accessed by reading or writing files in the directory */proc/sys/net/ipv4/*. Interfaces described as *Boolean* take an integer value, with a nonzero value ("true") meaning that the corresponding option is enabled, and a zero value ("false") meaning that the option is disabled.

ip_always_defrag (Boolean; since Linux 2.2.13)

[New with Linux 2.2.13; in earlier kernel versions this feature was controlled at compile time by the **CONFIG_IP_ALWAYS_DEFRAG** option; this option is not present in Linux 2.4.x and later]

When this boolean flag is enabled (not equal 0), incoming fragments (parts of IP packets that arose when some host between origin and destination decided that the packets were too large and cut them into pieces) will be reassembled (defragmented) before being processed, even if they are about to be forwarded.

Enable only if running either a firewall that is the sole link to your network or a transparent proxy; never ever use it for a normal router or host. Otherwise, fragmented communication can be disturbed if the fragments travel over different links. Defragmentation also has a large memory and

CPU time cost.

This is automatically turned on when masquerading or transparent proxying are configured.

ip_autoconfig (since Linux 2.2 to Linux 2.6.17)

Not documented.

ip_default_ttl (integer; default: 64; since Linux 2.2)

Set the default time-to-live value of outgoing packets. This can be changed per socket with the **IP_TTL** option.

ip_dynaddr (Boolean; default: disabled; since Linux 2.0.31)

Enable dynamic socket address and masquerading entry rewriting on interface address change. This is useful for dialup interface with changing IP addresses. 0 means no rewriting, 1 turns it on and 2 enables verbose mode.

ip_forward (Boolean; default: disabled; since Linux 1.2)

Enable IP forwarding with a boolean flag. IP forwarding can be also set on a per-interface basis.

ip_local_port_range (since Linux 2.2)

This file contains two integers that define the default local port range allocated to sockets that are not explicitly bound to a port number—that is, the range used for *ephemeral ports*. An ephemeral port is allocated to a socket in the following circumstances:

- the port number in a socket address is specified as 0 when calling **bind**(2);
- **listen**(2) is called on a stream socket that was not previously bound;
- **connect**(2) was called on a socket that was not previously bound;
- **sendto**(2) is called on a datagram socket that was not previously bound.

Allocation of ephemeral ports starts with the first number in *ip_local_port_range* and ends with the second number. If the range of ephemeral ports is exhausted, then the relevant system call returns an error (but see BUGS).

Note that the port range in *ip_local_port_range* should not conflict with the ports used by masquerading (although the case is handled). Also, arbitrary choices may cause problems with some firewall packet filters that make assumptions about the local ports in use. The first number should be at least greater than 1024, or better, greater than 4096, to avoid clashes with well known ports and to minimize firewall problems.

ip_no_pmtu_disc (Boolean; default: disabled; since Linux 2.2)

If enabled, don't do Path MTU Discovery for TCP sockets by default. Path MTU discovery may fail if misconfigured firewalls (that drop all ICMP packets) or misconfigured interfaces (e.g., a point-to-point link where the both ends don't agree on the MTU) are on the path. It is better to fix the broken routers on the path than to turn off Path MTU Discovery globally, because not doing it incurs a high cost to the network.

ip_nonlocal_bind (Boolean; default: disabled; since Linux 2.4)

If set, allows processes to **bind**(2) to nonlocal IP addresses, which can be quite useful, but may break some applications.

ip6frag_time (integer; default: 30)

Time in seconds to keep an IPv6 fragment in memory.

ip6frag_secret_interval (integer; default: 600)

Regeneration interval (in seconds) of the hash secret (or lifetime for the hash secret) for IPv6 fragments.

ipfrag_high_thresh (integer), *ipfrag_low_thresh* (integer)

If the amount of queued IP fragments reaches *ipfrag_high_thresh*, the queue is pruned down to *ipfrag_low_thresh*. Contains an integer with the number of bytes.

*neigh/** See **arp(7)**.

Ioctl

All ioctls described in **socket(7)** apply to **ip**.

Ioctl to configure generic device parameters are described in **netdevice(7)**.

ERRORS

EACCES

The user tried to execute an operation without the necessary permissions. These include: sending a packet to a broadcast address without having the **SO_BROADCAST** flag set; sending a packet via a *prohibit* route; modifying firewall settings without superuser privileges (the **CAP_NET_ADMIN** capability); binding to a privileged port without superuser privileges (the **CAP_NET_BIND_SERVICE** capability).

EADDRINUSE

Tried to bind to an address already in use.

EADDRNOTAVAIL

A nonexistent interface was requested or the requested source address was not local.

EAGAIN

Operation on a nonblocking socket would block.

EALREADY

A connection operation on a nonblocking socket is already in progress.

ECONNABORTED

A connection was closed during an **accept(2)**.

EHOSTUNREACH

No valid routing table entry matches the destination address. This error can be caused by an ICMP message from a remote router or for the local routing table.

EINVAL

Invalid argument passed. For send operations this can be caused by sending to a *blackhole* route.

EISCONN

connect(2) was called on an already connected socket.

EMSGSIZE

Datagram is bigger than an MTU on the path and it cannot be fragmented.

ENOBUFS, ENOMEM

Not enough free memory. This often means that the memory allocation is limited by the socket buffer limits, not by the system memory, but this is not 100% consistent.

ENOENT

SIOCGSTAMP was called on a socket where no packet arrived.

ENOPKG

A kernel subsystem was not configured.

ENOPROTOOPT and EOPNOTSUPP

Invalid socket option passed.

ENOTCONN

The operation is defined only on a connected socket, but the socket wasn't connected.

EPERM

User doesn't have permission to set high priority, change configuration, or send signals to the requested process or group.

EPIPE The connection was unexpectedly closed or shut down by the other end.

ESOCKTNOSUPPORT

The socket is not configured or an unknown socket type was requested.

Other errors may be generated by the overlaying protocols; see **tcp(7)**, **raw(7)**, **udp(7)**, and **socket(7)**.

NOTES

IP_FREEBIND, **IP_MSFILTER**, **IP_MTU**, **IP_MTU_DISCOVER**, **IP_RECVORIGDSTADDR**, **IP_PASSEC**, **IP_PKTINFO**, **IP_RECVERR**, **IP_ROUTER_ALERT**, and **IP_TRANSPARENT** are Linux-specific.

Be very careful with the **SO_BROADCAST** option – it is not privileged in Linux. It is easy to overload the network with careless broadcasts. For new application protocols it is better to use a multicast group instead of broadcasting. Broadcasting is discouraged.

Some other BSD sockets implementations provide **IP_RCVDSTADDR** and **IP_RECVIF** socket options to get the destination address and the interface of received datagrams. Linux has the more general **IP_PKTINFO** for the same task.

Some BSD sockets implementations also provide an **IP_RECVTTL** option, but an ancillary message with type **IP_RECVTTL** is passed with the incoming packet. This is different from the **IP_TTL** option used in Linux.

Using the **SOL_IP** socket options level isn't portable; BSD-based stacks use the **IPPROTO_IP** level.

INADDR_ANY (0.0.0.0) and **INADDR_BROADCAST** (255.255.255.255) are byte-order-neutral. This means **htonl(3)** has no effect on them.

Compatibility

For compatibility with Linux 2.0, the obsolete **socket(AF_INET, SOCK_PACKET, protocol)** syntax is still supported to open a **packet(7)** socket. This is deprecated and should be replaced by **socket(AF_PACKET, SOCK_RAW, protocol)** instead. The main difference is the new **sockaddr_ll** address structure for generic link layer information instead of the old **sockaddr_pkt**.

BUGS

There are too many inconsistent error values.

The error used to diagnose exhaustion of the ephemeral port range differs across the various system calls (**connect(2)**, **bind(2)**, **listen(2)**, **sendto(2)**) that can assign ephemeral ports.

The ioctls to configure IP-specific interface options and ARP tables are not described.

Receiving the original destination address with **MSG_ERRQUEUE** in *msg_name* by **recvmsg(2)** does not work in some Linux 2.2 kernels.

NAME

ip – show / manipulate routing, network devices, interfaces and tunnels

SYNOPSIS

ip [*OPTIONS*] *OBJECT* { *COMMAND* | **help** }

ip [**-force**] **-batch** *filename*

OBJECT := { **link** | **address** | **addrlabel** | **route** | **rule** | **neigh** | **ntable** | **tunnel** | **tuntap** | **maddress** |
mroute | **mrule** | **monitor** | **xfrm** | **netns** | **l2tp** | **tcp_metrics** | **token** | **macsec** | **vrf** |
mptcp | **ioam** }

OPTIONS := { **-V[ersion]** | **-h[uman-readable]** | **-s[tatistics]** | **-d[etails]** | **-r[esolve]** | **-iec** | **-f[amily]** | {
inet | **inet6** | **link** } | **-4** | **-6** | **-B** | **-0** | **-l[oops]** { **maximum-addr-flush-attempts** } |
-o[neline] | **-rc[vbuf]** [**size**] | **-t[imestamp]** | **-ts[hort]** | **-n[etns]** *name* | **-N[umeric]** |
-a[ll] | **-c[olor]** | **-br[ief]** | **-j[son]** | **-p[retty]** }

OPTIONS**-V, -Version**

Print the version of the **ip** utility and exit.

-h, -human, -human-readable

output statistics with human readable values followed by suffix.

-b, -batch <FILENAME>

Read commands from provided file or standard input and invoke them. First failure will cause termination of ip.

-force Don't terminate ip on errors in batch mode. If there were any errors during execution of the commands, the application return code will be non zero.

-s, -stats, -statistics

Output more information. If the option appears twice or more, the amount of information increases. As a rule, the information is statistics or some time values.

-d, -details

Output more detailed information.

-l, -loops <COUNT>

Specify maximum number of loops the 'ip address flush' logic will attempt before giving up. The default is 10. Zero (0) means loop until all addresses are removed.

-f, -family <FAMILY>

Specifies the protocol family to use. The protocol family identifier can be one of **inet**, **inet6**, **bridge**, **mpls** or **link**. If this option is not present, the protocol family is guessed from other arguments. If the rest of the command line does not give enough information to guess the family, **ip** falls back to the default one, usually **inet** or **any**. **link** is a special family identifier meaning that no networking protocol is involved.

-4 shortcut for **-family inet**.

-6 shortcut for **-family inet6**.

-B shortcut for **-family bridge**.

-M shortcut for **-family mpls**.

-0 shortcut for **-family link**.

-o, -oneline

output each record on a single line, replacing line feeds with the '\` character. This is convenient when you want to count records with **wc(1)** or to **grep(1)** the output.

-r, -resolve

use the system's name resolver to print DNS names instead of host addresses.

-n, -netns <NETNS>

switches **ip** to the specified network namespace *NETNS*. Actually it just simplifies executing of:

```
ip netns exec NETNS ip [ OPTIONS ] OBJECT { COMMAND | help }
```

to

```
ip -n[etns] NETNS [ OPTIONS ] OBJECT { COMMAND | help }
```

-N, -Numeric

Print the number of protocol, scope, dsfield, etc directly instead of converting it to human readable name.

-a, -all

executes specified command over all objects, it depends if command supports this option.

-c[color][={always|auto|never}]

Configure color output. If parameter is omitted or **always**, color output is enabled regardless of stdout state. If parameter is **auto**, stdout is checked to be a terminal before enabling color output. If parameter is **never**, color output is disabled. If specified multiple times, the last one takes precedence. This flag is ignored if **-json** is also given.

Used color palette can be influenced by **COLORFGBG** environment variable (see **ENVIRONMENT**).

-t, -timestamp

display current time when using monitor option.

-ts, -tshort

Like **-timestamp**, but use shorter format.

-rc, -recvbuf<SIZE>

Set the netlink socket receive buffer size, defaults to 1MB.

-iec print human readable rates in IEC units (e.g. 1Ki = 1024).**-br, -brief**

Print only basic information in a tabular format for better readability. This option is currently only supported by **ip addr show**, **ip link show** & **ip neigh show** commands.

-j, -json

Output results in JavaScript Object Notation (JSON).

-p, -pretty

The default JSON format is compact and more efficient to parse but hard for most users to read.
This flag adds indentation for readability.

IP - COMMAND SYNTAX*OBJECT***address**

- protocol (IP or IPv6) address on a device.

addrlabel

- label configuration for protocol address selection.

ioam - manage IOAM namespaces and IOAM schemas.**l2tp** - tunnel ethernet over IP (L2TPv3).**link** - network device.**maddress**

- multicast address.

monitor

- watch for netlink messages.

mptcp - manage MPTCP path manager.**mroute** - multicast routing cache entry.**mrule** - rule in multicast routing policy database.**neighbour**

- manage ARP or NDISC cache entries.

netns - manage network namespaces.

ntable - manage the neighbor cache's operation.

route - routing table entry.

rule - rule in routing policy database.

tcp_metrics/tcpmetrics

- manage TCP Metrics

token - manage tokenized interface identifiers.

tunnel - tunnel over IP.

tuntap - manage TUN/TAP devices.

vrf - manage virtual routing and forwarding devices.

xfrm - manage IPSec policies.

The names of all objects may be written in full or abbreviated form, for example **address** can be abbreviated as **addr** or just **a**.

COMMAND

Specifies the action to perform on the object. The set of possible actions depends on the object type. As a rule, it is possible to **add**, **delete** and **show** (or **list**) objects, but some objects do not allow all of these operations or have some additional commands. The **help** command is available for all objects. It prints out a list of available commands and argument syntax conventions.

If no command is given, some default command is assumed. Usually it is **list** or, if the objects of this class cannot be listed, **help**.

ENVIRONMENT

COLORFGBG

If set, its value is used for detection whether background is dark or light and use contrast colors for it.

COLORFGBG environment variable usually contains either two or three values separated by semicolons; we want the last value in either case. If this value is 0-6 or 8, chose colors suitable for dark background:

```
COLORFGBG=";0" ip -c a
```

EXIT STATUS

Exit status is 0 if command was successful, and 1 if there is a syntax error. If an error was reported by the kernel exit status is 2.

EXAMPLES

`ip addr`

Shows addresses assigned to all network interfaces.

ip neigh
Shows the current neighbour table in kernel.

ip link set x up
Bring up interface x.

ip link set x down
Bring down interface x.

ip route
Show table routes.

HISTORY

ip was written by Alexey N. Kuznetsov and added in Linux 2.2.

NAME

xtables-nft — iptables using nftables kernel api

DESCRIPTION

xtables-nft are versions of iptables that use the nftables API. This is a set of tools to help the system administrator migrate the ruleset from **iptables(8)**, **ip6tables(8)**, **arptables(8)**, and **ebtables(8)** to **nftables(8)**.

The **xtables-nft** set is composed of several commands:

- **iptables-nft**
- **iptables-nft-save**
- **iptables-nft-restore**
- **ip6tables-nft**
- **ip6tables-nft-save**
- **ip6tables-nft-restore**
- **arptables-nft**
- **ebtables-nft**

These tools use the libxtables framework extensions and hook to the nf_tables kernel subsystem using the **nft_compat** module.

USAGE

The xtables-nft tools allow you to manage the nf_tables backend using the native syntax of **iptables(8)**, **ip6tables(8)**, **arptables(8)**, and **ebtables(8)**.

You should use the xtables-nft tools exactly the same way as you would use the corresponding original tools.

Adding a rule will result in that rule being added to the nf_tables kernel subsystem instead. Listing the ruleset will use the nf_tables backend as well.

When these tools were designed, the main idea was to replace each legacy binary with a symlink to the xtables-nft program, for example:

```
/sbin/iptables -> /usr/sbin/iptables-nft-multi
/sbin/ip6tables -> /usr/sbin/ip6tables-nft-multi
/sbin/arptables -> /usr/sbin/arptables-nft-multi
/sbin/ebtables -> /usr/sbin/ebtables-nft-multi
```

The iptables version string will indicate whether the legacy API (get/setsockopt) or the new nf_tables api is used:

```
iptables -V
iptables v1.7 (nf_tables)
```

DIFFERENCES TO LEGACY IPTABLES

Because the xtables-nft tools use the nf_tables kernel API, rule additions and deletions are always atomic. Unlike iptables-legacy, iptables-nft -A ... will NOT need to retrieve the current ruleset from the kernel, change it, and re-load the altered ruleset. Instead, iptables-nft will tell the kernel to add one rule. For this reason, the iptables-legacy --wait option is a no-op in iptables-nft.

Use of the xtables-nft tools allow monitoring ruleset changes using the **xtables-monitor(8)** command.

When using `-j TRACE` to debug packet traversal to the ruleset, note that you will need to use **xtables-monitor(8)** in `--trace` mode to obtain monitoring trace events.

EXAMPLES

One basic example is creating the skeleton ruleset in nf_tables from the xtables-nft tools, in a fresh machine:

```
root@machine:~# iptables-nft -L
[...]
root@machine:~# ip6tables-nft -L
[...]
root@machine:~# arptables-nft -L
[...]
root@machine:~# ebtables-nft -L
[...]
root@machine:~# nft list ruleset
table ip filter {
    chain INPUT {
        type filter hook input priority 0; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority 0; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority 0; policy accept;
    }
}
table ip6 filter {
    chain INPUT {
        type filter hook input priority 0; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority 0; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority 0; policy accept;
    }
}
table bridge filter {
    chain INPUT {
        type filter hook input priority -200; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority -200; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority -200; policy accept;
    }
}
```

```

}
table arp filter {
    chain INPUT {
        type filter hook input priority 0; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority 0; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority 0; policy accept;
    }
}

```

(please note that in fresh machines, listing the ruleset for the first time results in all tables an chain being created).

To migrate your complete filter ruleset, in the case of **iptables(8)**, you would use:

```

root@machine:~# iptables-legacy-save > myruleset # reads from x_tables
root@machine:~# iptables-nft-restore myruleset # writes to nf_tables
or
root@machine:~# iptables-legacy-save | iptables-translate-restore | less

```

to see how rules would look like in the nft **nft(8)** syntax.

LIMITATIONS

You should use **Linux kernel >= 4.17**.

The CLUSTERIP target is not supported.

To get up-to-date information about this, please head to <http://wiki.nftables.org/>.

NAME

iptables-save — dump iptables rules
ip6tables-save — dump ip6tables rules

SYNOPSIS

```
iptables-save [-M modprobe] [-c] [-t table] [-f filename]  
ip6tables-save [-M modprobe] [-c] [-t table] [-f filename]
```

DESCRIPTION

iptables-save and **ip6tables-save** are used to dump the contents of IP or IPv6 Table in easily parseable format either to STDOUT or to a specified file.

-M, --modprobe *modprobe_program*

Specify the path to the modprobe program. By default, **iptables-save** will inspect /proc/sys/kernel/modprobe to determine the executable's path.

-f, --file *filename*

Specify a filename to log the output to. If not specified, **iptables-save** will log to STDOUT.

-c, --counters

include the current values of all packet and byte counters in the output

-t, --table *tablename*

restrict output to only one table. If the kernel is configured with automatic module loading, an attempt will be made to load the appropriate module for that table if it is not already there.

If not specified, output includes all available tables.

BUGS

None known as of iptables-1.2.1 release

NAME

iptables/**ip6tables** — administration tool for IPv4/IPv6 packet filtering and NAT

SYNOPSIS

```
iptables [-t table] {-A|-C|-D} chain rule-specification
ip6tables [-t table] {-A|-C|-D} chain rule-specification
iptables [-t table] -I chain [rulenumber] rule-specification
iptables [-t table] -R chain rulenumber rule-specification
iptables [-t table] -D chain rulenumber
iptables [-t table] -S [chain [rulenumber]]
iptables [-t table] {-F|-L|-Z} [chain [rulenumber]] [options...]
iptables [-t table] -N chain
iptables [-t table] -X [chain]
iptables [-t table] -P chain target
iptables [-t table] -E old-chain-name new-chain-name
rule-specification = [matches...] [target]
match = -m matchname [per-match-options]
target = -j targetname [per-target-options]
```

DESCRIPTION

Iptables and **ip6tables** are used to set up, maintain, and inspect the tables of IPv4 and IPv6 packet filter rules in the Linux kernel. Several different tables may be defined. Each table contains a number of built-in chains and may also contain user-defined chains.

Each chain is a list of rules which can match a set of packets. Each rule specifies what to do with a packet that matches. This is called a ‘target’, which may be a jump to a user-defined chain in the same table.

TARGETS

A firewall rule specifies criteria for a packet and a target. If the packet does not match, the next rule in the chain is examined; if it does match, then the next rule is specified by the value of the target, which can be the name of a user-defined chain, one of the targets described in **iptables-extensions(8)**, or one of the special values **ACCEPT**, **DROP** or **RETURN**.

ACCEPT means to let the packet through. **DROP** means to drop the packet on the floor. **RETURN** means stop traversing this chain and resume at the next rule in the previous (calling) chain. If the end of a built-in chain is reached or a rule in a built-in chain with target **RETURN** is matched, the target specified by the chain policy determines the fate of the packet.

TABLES

There are currently five independent tables (which tables are present at any time depends on the kernel configuration options and which modules are present).

-t, --table table

This option specifies the packet matching table which the command should operate on. If the kernel is configured with automatic module loading, an attempt will be made to load the appropriate module for that table if it is not already there.

The tables are as follows:

filter: This is the default table (if no **-t** option is passed). It contains the built-in chains **INPUT** (for packets destined to local sockets), **FORWARD** (for packets being routed through the box), and **OUTPUT** (for locally-generated packets).

nat: This table is consulted when a packet that creates a new connection is encountered. It consists of four built-ins: **PREROUTING** (for altering packets as soon as they come in),

INPUT (for altering packets destined for local sockets), **OUTPUT** (for altering locally-generated packets before routing), and **POSTROUTING** (for altering packets as they are about to go out). IPv6 NAT support is available since kernel 3.7.

mangle:

This table is used for specialized packet alteration. Until kernel 2.4.17 it had two built-in chains: **PREROUTING** (for altering incoming packets before routing) and **OUTPUT** (for altering locally-generated packets before routing). Since kernel 2.4.18, three other built-in chains are also supported: **INPUT** (for packets coming into the box itself), **FORWARD** (for altering packets being routed through the box), and **POSTROUTING** (for altering packets as they are about to go out).

raw: This table is used mainly for configuring exemptions from connection tracking in combination with the NOTRACK target. It registers at the netfilter hooks with higher priority and is thus called before ip_conntrack, or any other IP tables. It provides the following built-in chains: **PREROUTING** (for packets arriving via any network interface) **OUTPUT** (for packets generated by local processes)

security:

This table is used for Mandatory Access Control (MAC) networking rules, such as those enabled by the **SECMARK** and **CONNSECMARK** targets. Mandatory Access Control is implemented by Linux Security Modules such as SELinux. The security table is called after the filter table, allowing any Discretionary Access Control (DAC) rules in the filter table to take effect before MAC rules. This table provides the following built-in chains: **INPUT** (for packets coming into the box itself), **OUTPUT** (for altering locally-generated packets before routing), and **FORWARD** (for altering packets being routed through the box).

OPTIONS

The options that are recognized by **iptables** and **ip6tables** can be divided into several different groups.

COMMANDS

These options specify the desired action to perform. Only one of them can be specified on the command line unless otherwise stated below. For long versions of the command and option names, you need to use only enough letters to ensure that **iptables** can differentiate it from all other options.

-A, --append *chain rule-specification*

Append one or more rules to the end of the selected chain. When the source and/or destination names resolve to more than one address, a rule will be added for each possible address combination.

-C, --check *chain rule-specification*

Check whether a rule matching the specification does exist in the selected chain. This command uses the same logic as **-D** to find a matching entry, but does not alter the existing iptables configuration and uses its exit code to indicate success or failure.

-D, --delete *chain rule-specification*

-D, --delete *chain rulenum*

Delete one or more rules from the selected chain. There are two versions of this command: the rule can be specified as a number in the chain (starting at 1 for the first rule) or a rule to match.

-I, --insert *chain [rulenum] rule-specification*

Insert one or more rules in the selected chain as the given rule number. So, if the rule number is 1, the rule or rules are inserted at the head of the chain. This is also the default if no rule number is specified.

-R, --replace *chain rulenum rule-specification*

Replace a rule in the selected chain. If the source and/or destination names resolve to multiple addresses, the command will fail. Rules are numbered starting at 1.

-L, --list [chain]

List all rules in the selected chain. If no chain is selected, all chains are listed. Like every other iptables command, it applies to the specified table (filter is the default), so NAT rules get listed by `iptables -t nat -n -L`

Please note that it is often used with the **-n** option, in order to avoid long reverse DNS lookups. It is legal to specify the **-Z** (zero) option as well, in which case the chain(s) will be atomically listed and zeroed. The exact output is affected by the other arguments given. The exact rules are suppressed until you use

`iptables -L -v`
or `iptables-save(8)`.

-S, --list-rules [chain]

Print all rules in the selected chain. If no chain is selected, all chains are printed like `iptables-save`. Like every other iptables command, it applies to the specified table (filter is the default).

-F, --flush [chain]

Flush the selected chain (all the chains in the table if none is given). This is equivalent to deleting all the rules one by one.

-Z, --zero [chain [rulenum]]

Zero the packet and byte counters in all chains, or only the given chain, or only the given rule in a chain. It is legal to specify the **-L, --list** (list) option as well, to see the counters immediately before they are cleared. (See above.)

-N, --new-chain chain

Create a new user-defined chain by the given name. There must be no target of that name already.

-X, --delete-chain [chain]

Delete the optional user-defined chain specified. There must be no references to the chain. If there are, you must delete or replace the referring rules before the chain can be deleted. The chain must be empty, i.e. not contain any rules. If no argument is given, it will attempt to delete every non-built-in chain in the table.

-P, --policy chain target

Set the policy for the built-in (non-user-defined) chain to the given target. The policy target must be either **ACCEPT** or **DROP**.

-E, --rename-chain old-chain new-chain

Rename the user specified chain to the user supplied name. This is cosmetic, and has no effect on the structure of the table.

-h Help. Give a (currently very brief) description of the command syntax.**PARAMETERS**

The following parameters make up a rule specification (as used in the add, delete, insert, replace and append commands).

-4, --ipv4

This option has no effect in `iptables` and `iptables-restore`. If a rule using the **-4** option is inserted with (and only with) `ip6tables-restore`, it will be silently ignored. Any other uses will throw an error. This option allows IPv4 and IPv6 rules in a single rule file for use with both `iptables-restore` and `ip6tables-restore`.

-6, --ipv6

If a rule using the **-6** option is inserted with (and only with) `iptables-restore`, it will be silently ignored. Any other uses will throw an error. This option allows IPv4 and IPv6 rules in a single rule file for use with both `iptables-restore` and `ip6tables-restore`. This option has no effect in `ip6tables` and `ip6tables-restore`.

[!] -p, --protocol protocol

The protocol of the rule or of the packet to check. The specified protocol can be one of **tcp**, **udp**, **udplite**, **icmp**, **icmpv6**, **esp**, **ah**, **sctp**, **mh** or the special keyword "**all**", or it can be a numeric

value, representing one of these protocols or a different one. A protocol name from /etc/protocols is also allowed. A "!" argument before the protocol inverts the test. The number zero is equivalent to **all**. "all" will match with all protocols and is taken as default when this option is omitted. Note that, in ip6tables, IPv6 extension headers except **esp** are not allowed. **esp** and **ipv6-nonext** can be used with Kernel version 2.6.11 or later. The number zero is equivalent to **all**, which means that you cannot test the protocol field for the value 0 directly. To match on a HBH header, even if it were the last, you cannot use **-p 0**, but always need **-m hbh**.

[!] **-s, --source** *address[/mask][,...]*

Source specification. *Address* can be either a network name, a hostname, a network IP address (with */mask*), or a plain IP address. Hostnames will be resolved once only, before the rule is submitted to the kernel. Please note that specifying any name to be resolved with a remote query such as DNS is a really bad idea. The *mask* can be either an ipv4 network mask (for iptables) or a plain number, specifying the number of 1's at the left side of the network mask. Thus, an iptables mask of 24 is equivalent to 255.255.255.0. A "!" argument before the address specification inverts the sense of the address. The flag **--src** is an alias for this option. Multiple addresses can be specified, but this will **expand to multiple rules** (when adding with **-A**), or will cause multiple rules to be deleted (with **-D**).

[!] **-d, --destination** *address[/mask][,...]*

Destination specification. See the description of the **-s** (source) flag for a detailed description of the syntax. The flag **--dst** is an alias for this option.

-m, --match *match*

Specifies a match to use, that is, an extension module that tests for a specific property. The set of matches make up the condition under which a target is invoked. Matches are evaluated first to last as specified on the command line and work in short-circuit fashion, i.e. if one extension yields false, evaluation will stop.

-j, --jump *target*

This specifies the target of the rule; i.e., what to do if the packet matches it. The target can be a user-defined chain (other than the one this rule is in), one of the special builtin targets which decide the fate of the packet immediately, or an extension (see **EXTENSIONS** below). If this option is omitted in a rule (and **-g** is not used), then matching the rule will have no effect on the packet's fate, but the counters on the rule will be incremented.

-g, --goto *chain*

This specifies that the processing should continue in a user specified chain. Unlike the **--jump** option return will not continue processing in this chain but instead in the chain that called us via **--jump**.

[!] **-i, --in-interface** *name*

Name of an interface via which a packet was received (only for packets entering the **INPUT**, **FORWARD** and **PREROUTING** chains). When the "!" argument is used before the interface name, the sense is inverted. If the interface name ends in a "+", then any interface which begins with this name will match. If this option is omitted, any interface name will match.

[!] **-o, --out-interface** *name*

Name of an interface via which a packet is going to be sent (for packets entering the **FORWARD**, **OUTPUT** and **POSTROUTING** chains). When the "!" argument is used before the interface name, the sense is inverted. If the interface name ends in a "+", then any interface which begins with this name will match. If this option is omitted, any interface name will match.

[!] **-f, --fragment**

This means that the rule only refers to second and further IPv4 fragments of fragmented packets. Since there is no way to tell the source or destination ports of such a packet (or ICMP type), such a packet will not match any rules which specify them. When the "!" argument precedes the **-f** flag, the rule will only match head fragments, or unfragmented packets. This option is IPv4 specific, it is not available in ip6tables.

-c, --set-counters *packets bytes*

This enables the administrator to initialize the packet and byte counters of a rule (during **INSERT**, **APPEND**, **REPLACE** operations).

OTHER OPTIONS

The following additional options can be specified:

-v, --verbose

Verbose output. This option makes the list command show the interface name, the rule options (if any), and the TOS masks. The packet and byte counters are also listed, with the suffix 'K', 'M' or 'G' for 1000, 1,000,000 and 1,000,000,000 multipliers respectively (but see the **-x** flag to change this). For appending, insertion, deletion and replacement, this causes detailed information on the rule or rules to be printed. **-v** may be specified multiple times to possibly emit more detailed debug statements.

-w, --wait [*seconds*]

Wait for the xtables lock. To prevent multiple instances of the program from running concurrently, an attempt will be made to obtain an exclusive lock at launch. By default, the program will exit if the lock cannot be obtained. This option will make the program wait (indefinitely or for optional *seconds*) until the exclusive lock can be obtained.

-W, --wait-interval *microseconds*

Interval to wait per each iteration. When running latency sensitive applications, waiting for the xtables lock for extended durations may not be acceptable. This option will make each iteration take the amount of time specified. The default interval is 1 second. This option only works with **-w**.

-n, --numeric

Numeric output. IP addresses and port numbers will be printed in numeric format. By default, the program will try to display them as host names, network names, or services (whenever applicable).

-x, --exact

Expand numbers. Display the exact value of the packet and byte counters, instead of only the rounded number in K's (multiples of 1000) M's (multiples of 1000K) or G's (multiples of 1000M). This option is only relevant for the **-L** command.

--line-numbers

When listing rules, add line numbers to the beginning of each rule, corresponding to that rule's position in the chain.

--modprobe=*command*

When adding or inserting rules into a chain, use *command* to load any necessary modules (targets, match extensions, etc).

LOCK FILE

iptables uses the */run/xtables.lock* file to take an exclusive lock at launch.

The **XTABLES_LOCKFILE** environment variable can be used to override the default setting.

MATCH AND TARGET EXTENSIONS

iptables can use extended packet matching and target modules. A list of these is available in the **iptables-extensions(8)** manpage.

DIAGNOSTICS

Various error messages are printed to standard error. The exit code is 0 for correct functioning. Errors which appear to be caused by invalid or abused command line parameters cause an exit code of 2, and other errors cause an exit code of 1.

BUGS

Bugs? What's this? ;-) Well, you might want to have a look at <http://bugzilla.netfilter.org/>

COMPATIBILITY WITH IPCHAINS

This **iptables** is very similar to ipchains by Rusty Russell. The main difference is that the chains **INPUT** and **OUTPUT** are only traversed for packets coming into the local host and originating from the local host respectively. Hence every packet only passes through one of the three chains (except loopback traffic, which involves both INPUT and OUTPUT chains); previously a forwarded packet would pass through all three.

The other main difference is that **-i** refers to the input interface; **-o** refers to the output interface, and both are available for packets entering the **FORWARD** chain.

The various forms of NAT have been separated out; **iptables** is a pure packet filter when using the default 'filter' table, with optional extension modules. This should simplify much of the previous confusion over the combination of IP masquerading and packet filtering seen previously. So the following options are handled differently:

-j MASQ
-M -S
-M -L

There are several other changes in iptables.

AUTHORS

Rusty Russell originally wrote iptables, in early consultation with Michael Neuling.

Marc Boucher made Rusty abandon ipnatctl by lobbying for a generic packet selection framework in iptables, then wrote the mangle table, the owner match, the mark stuff, and ran around doing cool stuff everywhere.

James Morris wrote the TOS target, and tos match.

Jozsef Kadlecik wrote the REJECT target.

Harald Welte wrote the ULOG and NFQUEUE target, the new libiptc, as well as the TTL, DSCP, ECN matches and targets.

The Netfilter Core Team is: Jozsef Kadlecik, Pablo Neira Ayuso, Eric Leblond, Florian Westphal and Arturo Borrero Gonzalez. Emeritus Core Team members are: Marc Boucher, Martin Josefsson, Yasuyuki Kozakai, James Morris, Harald Welte and Rusty Russell.

Man page originally written by Herve Eychenne <rv@wallfire.org>.

VERSION

This manual page applies to iptables/ip6tables 1.8.7.

ipsec(8) - Linux man page

Name

ipsec - invoke IPsec utilities

Synopsis

ipsec *command* [*argument...*] **ipsec** --help

ipsec --version
ipsec --versioncode
ipsec --copyright
ipsec --directory
ipsec --confdir

Description

Ipsec invokes any of several utilities involved in controlling the IPsec encryption/authentication system, running the specified *command* with the specified *arguments* as if it had been invoked directly. This largely eliminates possible name collisions with other software, and also permits some centralized services.

In particular, **ipsec** supplies the invoked *command* with a suitable PATH environment variable, and also provides IPSEC_DIR, IPSEC_CONFS, and IPSEC_VERSION environment variables, containing respectively the full pathname of the directory where the IPsec utilities are stored, the full pathname of the directory where the configuration files live, and the IPsec version number.

ipsec --help lists the available commands. Most have their own manual pages, e.g. **ipsec auto(8)** for *auto*.

ipsec --version outputs version information about Linux FreeS/WAN. A version code of the form "Uxxx/Kyyy" indicates that the user-level utilities are version xxx but the kernel portion appears to be version yyy (this form is used only if the two disagree).

ipsec --versioncode outputs *just* the version code, with none of **--version**'s supporting information, for use by scripts.

ipsec --copyright supplies boring copyright details.

ipsec --directory reports where **ipsec** thinks the IPsec utilities are stored.

ipsec --confdir reports where **ipsec** thinks the IPsec configuration files are stored.

Files

/usr/local/lib/ipsec usual utilities directory

Environment

The following environment variables control where FreeS/WAN finds its components. The **ipsec** command sets them if they are not already set.

IPSEC_EXECDIR

directory containing published commands

IPSEC_LIBDIR

directory containing internal executables

IPSEC_SBINDIR

directory containing **ipsec** command

IPSEC_CONFS

directory containing configuration files

See Also

ipsec.**conf**(5), ipsec.**secrets**(5), **ipsec_auto**(8), **ipsec_barf**(8), **ipsec_setup**(8),
ipsec_showdefaults(8), **ipsec_showhostkey**(8)

HTML documentation shipped with the release, starting with *doc/index.html*.

<<http://www.freeswan.org/doc.html>> may also be of use.

History

Written for Linux FreeS/WAN <<http://www.freeswan.org>> by Henry Spencer.

Bugs

The provision of centralized services, while convenient, does compromise the original concept of making the utilities invocable directly as well as via **ipsec**.

ipsec.conf(5) - Linux man page

Name

ipsec.conf - IPsec configuration and connections

Description

The optional *ipsec.conf* file specifies most configuration and control information for the Openswan IPsec subsystem. (The major exception is secrets for authentication; see [ipsec.secrets\(5\)](#).) Its contents are not security-sensitive *unless* manual keying is being done for more than just testing, in which case the encryption/authentication keys in the descriptions for the manually-keyed connections are very sensitive (and those connection descriptions are probably best kept in a separate file, via the include facility described below).

The file is a text file, consisting of one or more *sections*. White space followed by **#** followed by anything to the end of the line is a comment and is ignored, as are empty lines which are not within a section.

A line which contains **include** and a file name, separated by white space, is replaced by the contents of that file, preceded and followed by empty lines. If the file name is not a full pathname, it is considered to be relative to the directory containing the including file. Such inclusions can be nested. Only a single filename may be supplied, and it may not contain white space, but it may include shell wildcards (see [sh\(1\)](#)); for example:

include ipsec.*.conf

The intention of the include facility is mostly to permit keeping information on connections, or sets of connections, separate from the main configuration file. This permits such connection descriptions to be changed, copied to the other security gateways involved, etc., without having to constantly extract them from the configuration file and then insert them back into it. Note also the **also** and **alsoflip** parameters (described below) which permit splitting a single logical section (e.g. a connection description) into several actual sections.

The first significant line of the file must specify the version of this specification that it conforms to:

version 2

A section begins with a line of the form:

type name

where *type* indicates what type of section follows, and *name* is an arbitrary name which distinguishes the section from others of the same type. (Names must start with a letter and may contain only letters, digits, periods, underscores, and hyphens.) All subsequent non-empty lines which begin with white space are part of the section; comments within a section must begin with white space too. There may be only one section of a given type with a given name.

Lines within the section are generally of the form

parameter=value

(note the mandatory preceding white space). There can be white space on either side of the **=**. Parameter names follow the same syntax as section names, and are specific to a section type. Unless otherwise explicitly specified, no parameter name may appear more than once in a section.

An empty *value* stands for the system default value (if any) of the parameter, i.e. it is roughly equivalent to omitting the parameter line entirely. A *value* may contain white space only if the entire *value* is enclosed in double quotes (""); a *value* cannot itself contain a double quote, nor may it be continued across more than one line.

Numeric values are specified to be either an "integer" (a sequence of digits) or a "decimal number" (sequence of digits optionally followed by '.' and another sequence of digits).

There is currently one parameter which is available in any type of section:

also

the value is a section name; the parameters of that section are appended to this section, as if they had been written as part of it. The specified section must exist, must follow the current one, and must have the same section type. (Nesting is permitted, and there may be more than one **also** in a single section, although it is forbidden to append the same section more than once.) This allows, for example, keeping the encryption keys for a connection in a separate file from the rest of the description, by using both an **also** parameter and an **include** line. (Caution, see BUGS below for some restrictions.)

alsoflip

can be used in a **conn** section. It acts like an **also** that flips the referenced section's entries left-for-right.

Parameter names beginning with **x-** (or **X-**, or **x_**, or **X_**) are reserved for user extensions and will never be assigned meanings by IPsec. Parameters with such names must still observe the syntax rules (limits on characters used in the name; no white space in a non-quoted value; no newlines or double quotes within the value). All other as-yet-unused parameter names are reserved for future IPsec improvements.

A section with name **%default** specifies defaults for sections of the same type. For each parameter in it, any section of that type which does not have a parameter of the same name gets a copy of the one from the **%default** section. There may be multiple **%default** sections of a given type, but only one default may be supplied for any specific parameter name, and all **%default** sections of a given type must precede all non-**%default** sections of that type. **%default** sections may not contain **also** or **alsoflip** parameters.

Currently there are two types of section: a **config** section specifies general configuration information for IPsec, while a **conn** section specifies an IPsec connection.

Conn Sections

A **conn** section contains a *connection specification*, defining a network connection to be made using IPsec. The name given is arbitrary, and is used to identify the connection to **ipsec_auto**(8) and **ipsec_manual**(8). Here's a simple example:

```
conn snt
left=10.11.11.1
```

```
leftsubnet=10.0.1.0/24
leftnexthop=172.16.55.66
leftsourceip=10.0.1.1
right=192.168.22.1
rightsubnet=10.0.2.0/24
rightnexthop=172.16.88.99
rightsourceip=10.0.2.1
```

keyingtries=%forever

A note on terminology... In automatic keying, there are two kinds of communications going on: transmission of user IP packets, and gateway-to-gateway negotiations for keying, rekeying, and general control. The data path (a set of "IPsec SAs") used for user packets is herein referred to as the "connection"; the path used for negotiations (built with "ISAKMP SAs") is referred to as the "keying channel".

To avoid trivial editing of the configuration file to suit it to each system involved in a connection, connection specifications are written in terms of *left* and *right* participants, rather than in terms of local and remote. Which participant is considered *left* or *right* is arbitrary; IPsec figures out which one it is being run on based on internal information. This permits using identical connection specifications on both ends. There are cases where there is no symmetry; a good convention is to use *left* for the local side and *right* for the remote side (the first letters are a good mnemonic).

Many of the parameters relate to one participant or the other; only the ones for *left* are listed here, but every parameter whose name begins with **left** has a **right** counterpart, whose description is the same but with **left** and **right** reversed.

Parameters are optional unless marked "(required)"; a parameter required for manual keying need not be included for a connection which will use only automatic keying, and vice versa.

CONN PARAMETERS: GENERAL

The following parameters are relevant to both automatic and manual keying. Unless otherwise noted, for a connection to work, in general it is necessary for the two ends to agree exactly on the values of these parameters.

connaddrfamily

the connection address family of the connection; currently the accepted values are **ipv4** (the default); or **ipv6**,

The ipv6 family is currently only supported using the NETKEY stack.

type

the type of the connection; currently the accepted values are **tunnel** (the default) signifying a host-to-host, host-to-subnet, or subnet-to-subnet tunnel; **transport**, signifying host-to-host transport mode; **passthrough**, signifying that no IPsec processing should be done at all; **drop**,

signifying that packets should be discarded; and **reject**, signifying that packets should be discarded and a diagnostic ICMP returned.

left

(required) the IP address of the left participant's public-network interface, in any form accepted by **ipsec_ttoaddr**(3). Currently, IPv4 and IPv6 IP addresses are supported. There are several magic values. If it is **%defaultroute**, and the **config setup** section's, **interfaces** specification contains **%defaultroute**, **left** will be filled in automatically with the local address of the default-route interface (as determined at IPsec startup time); this also overrides any value supplied for **leftnexthop**. (Either **left** or **right** may be **%defaultroute**, but not both.) The value **%any** signifies an address to be filled in (by automatic keying) during negotiation. The value **%opportunistic** signifies that both **left** and **leftnexthop** are to be filled in (by automatic keying) from DNS data for **left**'s client. The value can also contain the interface name, which will then later be used to obtain the IP address from to fill in. For example **%ppp0** The values **%group** and **%opportunisticgroup** makes this a policy group conn: one that will be instantiated into a regular or opportunistic conn for each CIDR block listed in the policy group file with the same name as the conn.

If using IP addresses in combination with NAT, always use the actual local machine's (NAT'ed) IP address, and if the remote (eg **right=**) is NAT'ed as well, the remote's public (**not** NAT'ed) IP address. Note that this makes the configuration no longer symmetrical on both sides, so you cannot use an identical configuration file on both hosts.

leftsubnet

private subnet behind the left participant, expressed as *network/netmask* (actually, any form acceptable to **ipsec_ttosubnet**(3)); Currently, IPv4 and IPv6 ranges are supported. If omitted, essentially assumed to be */left/32*, signifying that the left end of the connection goes to the left participant only

leftsubnets

specify multiple private subnets behind the left participant, expressed as { *networkA/netmaskA* *networkB/netmaskB* [...] } If both a **leftsubnets=** and **rightsubnets=** is defined, all combinations of subnet tunnels will be instantiated. You cannot use **leftsubnet** and **leftsubnets** together. For examples see *testing/pluto/multinet-**.

leftprotoport

allowed protocols and ports over connection, also called Port Selectors. The argument is in the form *protocol*, which can be a number or a name that will be looked up in */etc/protocols*, such as *leftprotoport=icmp*, or in the form of *protocol/port*, such as *tcp/smtp*. Ports can be defined as a number (eg. 25) or as a name (eg *smtp*) which will be looked up in */etc/services*. A special keyword **%any** can be used to allow all ports of a certain protocol. The most common use of this option is for L2TP connections to only allow I2tp packets (UDP port 1701), eg:

leftprotoport=17/1701. Some clients, notably older Windows XP and some Mac OSX clients, use a random high port as source port. In those cases *rightprotoport=17/%any* can be used to allow all UDP traffic on the connection. Note that this option is part of the proposal, so it cannot be arbitrarily left out if one end does not care about the traffic selection over this connection - both peers have to agree. The Port Selectors show up in the output of *ipsec eroute* and *ipsec auto --status* eg: "*I2tp*": 193.110.157.131[@aivd.xelernace.com]:7/1701...%any:17/1701 This option only filters outbound traffic. Inbound traffic selection must still be based on firewall rules activated by an *updown* script. The variables \$PLUTO_MY_PROTOCOL, \$PLUTO_PEER_PROTOCOL, \$PLUTO_MY_PORT, and \$PLUTO_PEER_PORT are available for use in *updown* scripts. Older workarounds for bugs involved a setting of 17/0 to denote *any single UDP*

port (not UDP port 0). Some clients, most notably OSX, uses a random high port, instead of port 1705 for L2TP.

leftnexthop

next-hop gateway IP address for the left participant's connection to the public network; defaults to **%direct** (meaning *right*). If the value is to be overridden by the **left=%defaultroute** method (see above), an explicit value must *not* be given. If that method is not being used, but **leftnexthop** is **%defaultroute**, and **interfaces=%defaultroute** is used in the **config setup** section, the next-hop gateway address of the default-route interface will be used. The magic value **%direct** signifies a value to be filled in (by automatic keying) with the peer's address. Relevant only locally, other end need not agree on it.

leftsourceip

the IP address for this host to use when transmitting a packet to the other side of this link. Relevant only locally, the other end need not agree. This option is used to make the gateway itself use its internal IP, which is part of the **leftsubnet**, to communicate to the **rightsubnet** or **right**. Otherwise, it will use its **nearest** IP address, which is its public IP address. This option is mostly used when defining subnet-subnet connections, so that the gateways can talk to each other and the subnet at the other end, without the need to build additional host-subnet, subnet-host and host-host tunnels. Both IPv4 and IPv6 addresses are supported.

leftupdown

what "updown" script to run to adjust routing and/or firewalling when the status of the connection changes (default **ipsec _updown**). May include positional parameters separated by white space (although this requires enclosing the whole string in quotes); including shell metacharacters is unwise. An example to enable routing when using the NETKEY stack, one can use:

```
leftupdown="ipsec _updown --route yes"
```

See [**ipsec_pluto**\(8\)](#) for details. Relevant only locally, other end need not agree on it.

leftfirewall

This option is obsolete and should not be used anymore.

If one or both security gateways are doing forwarding firewalling (possibly including masquerading), and this is specified using the **firewall** parameters, tunnels established with IPsec are exempted from it so that packets can flow unchanged through the tunnels. (This means that all subnets connected in this manner must have distinct, non-overlapping subnet address blocks.) This is done by the default **updown** script (see [**ipsec_pluto**\(8\)](#)).

The implementation of this makes certain assumptions about firewall setup, and the availability of the *Linux Advanced Routing* tools. In situations calling for more control, it may be preferable for the user to supply his own **updown** script, which makes the appropriate adjustments for his system.

CONN PARAMETERS: AUTOMATIC KEYING

The following parameters are relevant only to automatic keying, and are ignored in manual keying. Unless otherwise noted, for a connection to work, in general it is necessary for the two ends to agree exactly on the values of these parameters.

auto

what operation, if any, should be done automatically at IPsec startup; currently-accepted values are **add** (signifying an **ipsec auto --add**), **route** (signifying that plus an **ipsec auto --route**),

start (signifying that plus an **ipsec auto --up**), **manual** (signifying an **ipsec manual --up**), and **ignore** (also the default) (signifying no automatic startup operation). See the **config setup** discussion below. Relevant only locally, other end need not agree on it (but in general, for an intended-to-be-permanent connection, both ends should use **auto=start** to ensure that any reboot causes immediate renegotiation).

authby

how the two security gateways should authenticate each other; acceptable values are **secret** for shared secrets, **rsasig** for RSA digital signatures (the default), **secret|rsasig** for either, and **never** if negotiation is never to be attempted or accepted (useful for shunt-only conns). Digital signatures are superior in every way to shared secrets.

ike

IKE encryption/authentication algorithm to be used for the connection (phase 1 aka ISAKMP SA). The format is "*cipher-hash;modpgroup, cipher-hash;modpgroup, ...*" Any left out option will be filled in with all allowed default options. Multiple proposals are separated by a comma. If an **ike=** line is specified, no other received proposals will be accepted. Formerly there was a distinction (by using a "!" symbol) between "strict mode" or not. That mode has been obsoleted. If an **ike=** option is specified, the mode is always strict, meaning no other received proposals will be accepted. Some examples are **ike=3des-sha1,aes-sha1, ike=aes, ike=aes128-md5;modp2048, ike=aes128-sha1;dh22, ike=3des-md5;modp1024,aes-sha1;modp1536** or **ike=modp1536**. The options must be suitable as a value of **ipsec_spi**(8)'s **--ike** option. The default is to use IKE, and to allow all combinations of:

cipher:	3des or aes
hash:	sha1 or md5
pfs group (DHgroup):	modp1024 or modp1536

If Openswan was compiled with extra INSECURE and BROKEN options, then the des (1des) and null cipher, as well as modp768 are available. This turns your VPN into a joke. Do not enable these options.

If openswan was compiled with USE_MODP_RFC5114 support, then Diffie-Hellman groups 22, 23 and 24 are also implemented as per RFC-5114. Instead of the modp key syntax, use the "dh" keyword, for example *ike=3des-sha1;dh23*

phase2

Sets the type of SA that will be produced. Valid options are: **esp** for encryption (the default), and **ah** for authentication only.

phase2alg

Specifies the algorithms that will be offered/accepted for a phase2 negotiation. If not specified, a secure set of defaults will be used. Sets are separated using comma's.

The default values are the same as for **ike=**. Note also that not all ciphers available to the kernel (eg through CryptoAPI) are necessarily supported here.

The format for ESP is ENC-AUTH followed by an optional PFSgroup. For instance, "3des-md5" or "aes256-sha1;modp2048" or "aes-sha1,aes-md5".

For RFC-5114 DH groups, use the "dh" keyword, eg "aes256-sha1;dh23"

The format for AH is AUTH followed by an optional PFSgroup. For instance, "md5" or "sha1;modp1536".

A special case is AES CCM, which uses the syntax of "phase2alg=aes_ccm_a-152-null"

sha2_truncbug

The default hash truncation for sha2_256 is 128 bits. Linux implemented the draft version which stated 96 bits. This option enables using the bad 96 bits version to interop with older linux kernels (unpatched version 2.6.33 and older) and openswan versions before 2.6.38. Currently the accepted values are **no**, (the default) signifying default IETF truncation of 128 bits, or **yes**, signifying 96 bits broken Linux kernel style truncation.

esp

This option is obsolete. Please use **phase2alg** instead.

ah

AH authentication algorithm to be used for the connection, e.g here. **hmac-md5** The options must be suitable as a value of **ipsec_spi**(8)'s **--ah** option. The default is not to use AH. If for some (invalid) reason you still think you need AH, please use esp with the null encryption cipher instead. Note also that not all ciphers available to the kernel (eg through CryptoAPI) are necessarily supported here.

ikev2

IKEv2 (RFC4309) settings to be used. Currently the accepted values are **permit**, (the default) signifying no IKEv2 should be transmitted, but will be accepted if the other ends initiates to us with IKEv2; **never** or **no** signifying no IKEv2 negotiation should be transmitted or accepted; **propose** or **yes** signifying that we permit IKEv2, and also use it as the default to initiate; **insist**, signifying we only accept and receive IKEv2 - IKEv1 negotiations will be rejected.

If the ikev2= setting is set to **permit** or **propose**, Openswan will try and detect a "bid down" attack from IKEv2 to IKEv1. Since there is no standard for transmitting the IKEv2 capability with IKEv1, Openswan uses a special Vendor ID "CAN-IKEv2". If a fall back from IKEv2 to IKEv1 was detected, and the IKEv1 negotiation contains Vendor ID "CAN-IKEv2", Openswan will immediately attempt and IKEv2 rekey and refuse to use the IKEv1 connection. With an ikev2= setting of **insist**, no IKEv1 negotiation is allowed, and no bid down attack is possible.

sareftrack

Set the method of tracking reply packets with SArefs when using an SAref compatible stack. Currently only the *mas* stack supports this. Acceptable values are **yes** (the default), **no** or **conntrack**. This option is ignored when SArefs are not supported. This option is passed as PLUTO_SAREF_TRACKING to the *updown* script which makes the actual decisions whether to perform any iptables/ip_conntrack manipulation. A value of yes means that an IPSEC mangle table will be created. This table will be used to match reply packets. A value of conntrack means that additionally, subsequent packets using this connection will be marked as well, reducing the lookups needed to find the proper SAref by using the ip_conntrack state. A value of no means no IPSEC mangle table is created, and SAref tracking is left to a third-party (kernel) module. In case of a third party module, the SArefs can be relayed using the HAVE_STATSD deamon.

leftid

how the left participant should be identified for authentication; defaults to **left**. Can be an IP address (in any **ipsec_ttoaddr**(3) syntax) or a fully-qualified domain name preceded by @ (which is used as a literal string and not resolved). The magic value **%fromcert** causes the ID to be set to a DN taken from a certificate that is loaded. Prior to 2.5.16, this was the default if a certificate was specified. The magic value **%onone** sets the ID to no ID. This is included for completeness, as the ID may have been set in the default conn, and one wishes for it to default instead of being explicitly set. The magic value **%myid** stands for the current setting of *myid*. This is set in **config setup** or by **ipsec_whack**(8)), or, if not set, it is the IP address in

%defaultroute (if that is supported by a TXT record in its reverse domain), or otherwise it is the system's hostname (if that is supported by a TXT record in its forward domain), or otherwise it is undefined.

leftrsasigkey

the left participant's public key for RSA signature authentication, in RFC 2537 format using **ipsec_todata**(3) encoding. The magic value **%none** means the same as not specifying a value (useful to override a default). The value **%dnsondemand** (the default) means the key is to be fetched from DNS at the time it is needed. The value **%dnsload** means the key is to be fetched from DNS at the time the connection description is read from *ipsec.conf*; currently this will be treated as **%none** if **right=%any** or **right=%opportunistic**. The value **%dns** is currently treated as **%dnsload** but will change to **%dnsondemand** in the future. The identity used for the left participant must be a specific host, not **%any** or another magic value. The value **%cert** will load the information required from a certificate defined in **%leftcert** and automatically define **leftid** for you. **Caution:** if two connection descriptions specify different public keys for the same **leftid**, confusion and madness will ensue.

leftrsasigkey2

if present, a second public key. Either key can authenticate the signature, allowing for key rollover.

leftcert

If you are using **leftrsasigkey=%cert** this defines the certificate you would like to use. It should point to a X.509 encoded certificate file. If you do not specify a full pathname, by default it will look in /etc/ipsec.d/certs. If openswan has been compiled with **USE_LIBNSS=true**, then openswan will also check the NSS database for RSA keys. These can be software or hardware.

leftca

specifies the authorized Certificate Authority (CA) that signed the certificate of the peer. If undefined, it defaults to the CA that signed the certificate specified in **leftcert**. The special **rightca=%same** is implied when not specifying a **rightca** and means that only peers with certificates signed by the same CA as the **leftca** will be allowed. This option is only useful in complex multi CA certificate situations. When using a single CA, it can be safely omitted for both left and right.

leftsendcert

This option configures when Openswan will send X.509 certificates to the remote host. Acceptable values are **yes|always** (signifying that we should always send a certificate), **ifasked** (signifying that we should send a certificate if the remote end asks for it), and **no|never** (signifying that we will never send a X.509 certificate). The default for this option is **ifasked** which may break compatibility with other vendor's IPSec implementations, such as Cisco and SafeNet. If you find that you are getting errors about no ID/Key found, you likely need to set this to **always**. This per-conn option replaces the obsolete global **nocrsend** option.

leftxauthserver

Left is an XAUTH server. This can use PAM for authentication or md5 passwords in /etc/ipsec.d/passwd. These are additional credentials to verify the user identity, and should not be confused with the XAUTH **group secret**, which is just a regular PSK defined in *ipsec.secrets*. The other side of the connection should be configured as **rightxauthclient**. XAUTH connections cannot rekey, so **rekey=no** should be specified in this conn. For further details on how to compile and use XAUTH, see README.XAUTH. Acceptable values are **yes** or **no** (the default).

leftxauthclient

Left is an XAUTH client. The xauth connection will have to be started interactively and cannot be configured using **auto=start**. Instead, it has to be started from the commandline using *ipsec auto --up connname*. You will then be prompted for the username and password. To setup an

XAUTH connection non-interactively, which defeats the whole purpose of XAUTH, but is regularly requested by users, it is possible to use a whack command - *ipsec whack --name baduser --ipsecgroup-xauth --xauthname badusername --xauthpass password --initiate* The other side of the connection should be configured as **rightxauthserver**. Acceptable values are **yes** or **no** (the default).

leftxauthusername

The XAUTH username associated with this XAUTH connection. The XAUTH password can be configured in the *ipsec.secrets* file.

leftmodecfgserver

Left is a Mode Config server. It can push network configuration to the client. Acceptable values are **yes** or **no** (the default).

leftmodecfgclient

Left is a Mode Config client. It can receive network configuration from the server. Acceptable values are **yes** or **no** (the default).

modecfgpull

Pull the Mode Config network information from the server. Acceptable values are **yes** or **no** (the default).

modecfgdns1, modecfgdns2, modecfgwins1, modecfgwins2

Specify the IP address for DNS or WINS servers for the client to use.

remote_peer_type

Set the remote peer type. This can enable additional processing during the IKE negotiation. Acceptable values are **cisco** or **ietf** (the default). When set to cisco, support for Cisco IPsec gateway redirection and Cisco obtained DNS and domainname are enabled. This includes automatically updating (and restoring) /etc/resolv.conf. These options require that XAUTH is also enabled on this connection.

nm_configured

Mark this connection as controlled by Network Manager. Acceptable values are **yes** or **no** (the default). Currently, setting this to yes will cause openswan to skip reconfiguring resolv.conf when used with XAUTH and ModeConfig.

forceencaps

In some cases, for example when ESP packets are filtered or when a broken IPsec peer does not properly recognise NAT, it can be useful to force RFC-3948 encapsulation. **forceencaps=yes** forces the NAT detection code to lie and tell the remote peer that RFC-3948 encapsulation (ESP in UDP port 4500 packets) is required. For this option to have any effect, the setup section option **nat_traversal=yes** needs to be set. Acceptable values are **yes** or **no** (the default).

overlapip

a boolean (yes/no) that determines, when *subnet=vhos: is used, if the virtual IP claimed by this states created from this connection can with states created from other connections.

Note that connection instances created by the Opportunistic Encryption or PKIX (x.509) instantiation system are distinct internally. They will inherit this policy bit.

The default is no.

This feature is only available with kernel drivers that support SAs to overlapping conns. At present only the (klips)mast protocol stack supports this feature.

dpddelay

Set the delay (in seconds) between Dead Peer Detection (RFC 3706) keepalives (R_U_THERE, R_U_THERE_ACK) that are sent for this connection (default 30 seconds). If dpddelay is set,

`dpdtimeout` also needs to be set.

dpdtimeout

Set the length of time (in seconds) we will idle without hearing either an R_U_THERE poll from our peer, or an R_U_THERE_ACK reply. After this period has elapsed with no response and no traffic, we will declare the peer dead, and remove the SA (default 120 seconds). If `dpdtimeout` is set, `dpdaction` also needs to be set.

dpdaction

When a DPD enabled peer is declared dead, what action should be taken. **hold** (default) means the eroute will be put into %hold status, while **clear** means the eroute and SA with both be cleared. **restart** means the the SA will immediately be renegotiated, and **restart_by_peer** means that *ALL* SA's to the dead peer will renegotiated.

`dpdaction=clear` is really only useful on the server of a Road Warrior config.

pfs

whether Perfect Forward Secrecy of keys is desired on the connection's keying channel (with PFS, penetration of the key-exchange protocol does not compromise keys negotiated earlier); Since there is no reason to ever refuse PFS, Openswan will allow a connection defined with **pfs=no** to use PFS anyway. Acceptable values are **yes** (the default) and **no**.

pfsgroup

This option is obsoleted, please use `phase2alg` if you need the pfs to be different from `phase1` (the default) using: `phase2alg=aes128-md5;modp1024`

aggrmode

Use Aggressive Mode instead of Main Mode. Aggressive Mode is less secure, and vulnerable to Denial Of Service attacks. It is also vulnerable to brute force attacks with software such as **ikecrack**. It should not be used, and it should especially not be used with XAUTH and group secrets (PSK). If the remote system administrator insists on staying irresponsible, enable this option.

Aggressive Mode is further limited to only proposals with one DH group as there is no room to negotiate the DH group. Therefor it is mandatory for Aggressive Mode connections that both **ike=** and **phase2alg=** options are specified with only fully specified proposal using one DH group. Acceptable values are **yes** or **no** (the default).

The ISAKMP SA is created in exchange 1 in aggressive mode. Openswan has to send the exponent during that exchange, so it has to know what DH group to use before starting. This is why you can not have multiple DH groups in aggressive mode. In IKEv2, which uses a similar method to IKEv1 Aggressive Mode, there is a message to convey the DH group is wrong, and so an IKEv2 connection can actually recover from picking the wrong DH group by restarting its negotiation.

salifetime

how long a particular instance of a connection (a set of encryption/authentication keys for user packets) should last, from successful negotiation to expiry; acceptable values are an integer optionally followed by **s** (a time in seconds) or a decimal number followed by **m**, **h**, or **d** (a time in minutes, hours, or days respectively) (default **8h**, maximum **24h**). Normally, the connection is renegotiated (via the keying channel) before it expires. The two ends need not exactly agree on **salifetime**, although if they do not, there will be some clutter of superseded connections on the end which thinks the lifetime is longer.

The keywords "keylife" and "lifetime" are aliases for "salifetime."

rekey

whether a connection should be renegotiated when it is about to expire; acceptable values are **yes** (the default) and **no**. The two ends need not agree, but while a value of **no** prevents Pluto from requesting renegotiation, it does not prevent responding to renegotiation requested from the other end, so **no** will be largely ineffective unless both ends agree on it.

rekeymargin

how long before connection expiry or keying-channel expiry should attempts to negotiate a replacement begin; acceptable values as for **salifetime** (default **9m**). Relevant only locally, other end need not agree on it.

rekeyfuzz

maximum percentage by which **rekeymargin** should be randomly increased to randomize rekeying intervals (important for hosts with many connections); acceptable values are an integer, which may exceed 100, followed by a '%' (default set by [ipsec_pluto](#)(8), currently **100%**). The value of **rekeymargin**, after this random increase, must not exceed **salifetime**. The value **0%** will suppress time randomization. Relevant only locally, other end need not agree on it.

keyingtries

how many attempts (a whole number or **%forever**) should be made to negotiate a connection, or a replacement for one, before giving up (default **%forever**). The value **%forever** means "never give up" (obsolete: this can be written 0). Relevant only locally, other end need not agree on it.

ikelifetime

how long the keying channel of a connection (buzzphrase: "ISAKMP SA") should last before being renegotiated; acceptable values as for **keylife** (default set by [ipsec_pluto](#)(8), currently **1h**, maximum **24h**). The two-ends-disagree case is similar to that of **keylife**.

compress

whether IPComp compression of content is proposed on the connection (link-level compression does not work on encrypted data, so to be effective, compression must be done *before* encryption); acceptable values are **yes** and **no** (the default). The two ends need not agree. A value of **yes** causes IPsec to propose both compressed and uncompressed, and prefer compressed. A value of **no** prevents IPsec from proposing compression; a proposal to compress will still be accepted.

metric

Set the metric for the routes to the ipsecX or mastX interface. This makes it possible to do host failover from another interface to ipsec using route management. This value is passed to the _updown scripts as PLUTO_METRIC. This option is only available with KLIPS or MAST on Linux. Acceptable values are positive numbers, with the default being **1**.

disablearrivalcheck

whether KLIPS's normal tunnel-exit check (that a packet emerging from a tunnel has plausible addresses in its header) should be disabled; acceptable values are **yes** and **no** (the default). Tunnel-exit checks improve security and do not break any normal configuration. Relevant only locally, other end need not agree on it.

failureshunt

what to do with packets when negotiation fails. The default is **none**: no shunt; **passthrough**, **drop**, and **reject** have the obvious meanings.

CONN PARAMETERS: MANUAL KEYING

This command was obsoleted around the same time that Al Gore invented the internet. ipsec manual was used in the jurassic period to load static keys into the kernel. There are no rational reasons to use this, and it is not supported anymore. If you need to create static SAs, then you can use **ipsec spi** and **ipsec eroute** when using KLIPS or **ip xfrm** or **setkey** when using NETKEY.

No rational person uses static keys. They are not easier to use. REPEAT: they are not easier to use.

Config Sections

At present, the only **config** section known to the IPsec software is the one named **setup**, which contains information used when the software is being started (see [**ipsec_setup\(8\)**](#)). Here's an example:

```
config setup

interfaces="ipsec0=eth1 ipsec1=ppp0"

klipsdebug=none

plutodebug=control

protostack=auto

manualstart=
```

Parameters are optional unless marked "(required)".

The currently-accepted *parameter* names in a **config setup** section are:

myid

the identity to be used for **%myid**. **%myid** is used in the implicit policy group conns and can be used as an identity in explicit conns. If unspecified, **%myid** is set to the IP address in **%defaultroute** (if that is supported by a TXT record in its reverse domain), or otherwise the system's hostname (if that is supported by a TXT record in its forward domain), or otherwise it is undefined. An explicit value generally starts with "@".

protostack

decide which protocol stack is going to be used. Valid values are "auto", "klips", "netkey" and "mast". The "mast" stack is a variation for the klips stack.

interfaces

virtual and physical interfaces for IPsec to use: a single *virtual=physical* pair, a (quoted!) list of pairs separated by white space, or **%none**. One of the pairs may be written as **%defaultroute**, which means: find the interface *d* that the default route points to, and then act as if the value was "**ipsec0=d**". **%defaultroute** is the default; **%none** must be used to denote no interfaces, or when using the NETKEY stack. If **%defaultroute** is used (implicitly or explicitly) information about the default route and its interface is noted for use by [**ipsec_manual\(8\)**](#) and [**ipsec_auto\(8\)**](#).)

listen

IP address to listen on (default depends on **interfaces=** setting). Currently only accepts one IP address.

nat_traversal

whether to accept/offer to support NAT (NAPT, also known as "IP Masquerade") workaround for IPsec. Acceptable values are: **yes** and **no** (the default). This parameter may eventually become per-connection.

disable_port_floating

whether to enable the newer NAT-T standards for port floating. Acceptable values are **no** (the default) and **yes**.

force_keepalive

whether to force sending NAT-T keep-alives to support NAT which are sent to prevent the NAT router from closing its port when there is not enough traffic on the IPsec connection. Acceptable values are: **yes** and **no** (the default). This parameter may eventually become per-connection.

keep_alive

The delay (in seconds) for NAT-T keep-alive packets, if these are enabled using **force_keepalive**. This parameter may eventually become per-connection.

virtual_private

contains the networks that are allowed as subnet= for the remote client. In other words, the address ranges that may live behind a NAT router through which a client connects. This value is usually set to all the RFC-1918 address space, excluding the space used in the local subnet behind the NAT (An IP address cannot live at two places at once). IPv4 address ranges are denoted as %v4:a.b.c.d/mm and IPv6 is denoted as %v6:aaaa::bbbb:cccc:ddd:eeee/mm. One can exclude subnets by using the !. For example, if the VPN server is giving access to 192.168.1.0/24, this option should be set to:

`virtual_private=%v4:10.0.0.0/8,%v4:192.168.0.0/16,%v4:172.16.0.0/12,%v4:!192.168.1.0/24.`

This parameter is only needed on the server side and not on the client side that resides behind the NAT router, as the client will just use its IP address for the inner IP setting. This parameter may eventually become per-connection.

oe

a boolean (yes/no) that determines if Opportunistic Encryption will be enabled. Opportunistic Encryption is the term to describe using IPsec tunnels without prearrangement. It uses IPSECKEY or TXT records to announce public RSA keys for certain IP's or identities.

For a complete description see /doc/draft-richardson-ipsec-opportunistic.txt, doc/opportunism-spec.txt and doc/opportunism.howto. See also the IETF BTNS working group and RFC4025.

The default is no.

This feature is only available with kernel drivers that support the caching of packets (%hold eroutes or equivalent) that allows us to respond to a packet from an unknown IP address. At present only the (klips)masm protocol stack supports this feature.

nhelpers

how many *pluto helpers* are started to help with cryptographic operations. Pluto will start (*n*-1) of them, where *n* is the number of CPU's you have (including hyperthreaded CPU's). A value of 0 forces pluto to do all operations in the main process. A value of -1 tells pluto to perform the above calculation. Any other value forces the number to that amount.

crlcheckinterval

interval, specified in seconds, after which pluto will verify loaded X.509 CRL's for expiration. If any of the CRL's is expired, or if they previously failed to get updated, a new attempt at updating the CRL is made. The first attempt to update a CRL is started at two times the crlcheckinterval. If set to 0, which is also the default value if this option is not specified, CRL updating is disabled.

strictcrlpolicy

if not set, pluto is tolerant about missing or expired X.509 Certificate Revocation Lists (CRL's), and will allow peer certificates as long as they do not appear on an expired CRL. When this option is enabled, all connections with an expired or missing CRL will be denied. Active connections will be terminated at rekey time. This setup is more secure, but also dangerous. If the CRL is fetched through an IPsec tunnel with a CRL that expired, the entire VPN server will be dead in the water until a new CRL is manually transferred to the machine (if it allows non-IPsec connections).

Acceptable values are **yes** or **no** (the default).

forwardcontrol

This option is obsolete and ignored. Please use **net.ipv4.ip_forward = 0** in /etc/sysctl.conf instead to control the ip forwarding behaviour.

rp_filter

This option is obsolete and ignored. Please use the **net.ipv4.conf/[iface]/rp_filter = 0** options in /etc/sysctl.conf instead. This option is badly documented; it must be 0 in many cases for ipsec to function.

syslog

the **syslog**(2) "facility" name and priority to use for startup/shutdown log messages, default **daemon.error**.

klipsdebug

how much KLIPS debugging output should be logged. An empty value, or the magic value **none**, means no debugging output (the default). The magic value **all** means full output. Otherwise only the specified types of output (a quoted list, names separated by white space) are enabled; for details on available debugging types, see **ipsec_klipsdebug**(8). This KLIPS option has no effect on NETKEY, Windows or BSD stacks.

plutodebug

how much Pluto debugging output should be logged. An empty value, or the magic value **none**, means no debugging output (the default). The magic value **all** means full output. Otherwise only the specified types of output (a quoted list, names without the **--debug-** prefix, separated by white space) are enabled; for details on available debugging types, see **ipsec_pluto**(8).

uniqueids

whether a particular participant ID should be kept unique, with any new (automatically keyed) connection using an ID from a different IP address deemed to replace all old ones using that ID. Acceptable values are **yes** (the default) and **no**. Participant IDs normally are unique, so a new (automatically-keyed) connection using the same ID is almost invariably intended to replace an old one.

plutorestartoncrash

prevent pluto from restarting after it crashed. This option should only be used when debugging a crasher. It will prevent overwriting a core file on a new start, or a cascade of core files. This option is also required if used with plutostderlog= to avoid clearing the logs of the crasher.

Values can be yes (the default) or no.

plutoopts

additional options to pass to pluto upon startup. See **ipsec_pluto**(8).

plutostderlog

do not use syslog, but rather log to stderr, and direct stderr to the argument file.

pluto

whether to start Pluto or not; Values are **yes** (the default) or **no** (useful only in special circumstances).

plutowait

should Pluto wait for each negotiation attempt that is part of startup to finish before proceeding with the next? Values are **yes** or **no** (the default).

prepluto

shell command to run before starting Pluto (e.g., to decrypt an encrypted copy of the *ipsec.secrets* file). It's run in a very simple way; complexities like I/O redirection are best hidden within a script. Any output is redirected for logging, so running interactive commands is difficult unless they use /dev/tty or equivalent for their interaction. Default is none.

postpluto

shell command to run after starting Pluto (e.g., to remove a decrypted copy of the *ipsec.secrets* file). It's run in a very simple way; complexities like I/O redirection are best hidden within a script. Any output is redirected for logging, so running interactive commands is difficult unless they use /dev/tty or equivalent for their interaction. Default is none.

dumpdir

in what directory should things started by *setup* (notably the Pluto daemon) be allowed to dump core? The empty value (the default) means they are not allowed to.

fragicmp

whether a tunnel's need to fragment a packet should be reported back with an ICMP message, in an attempt to make the sender lower his PMTU estimate; acceptable values are **yes** (the default) and **no**. This KLIPS option has no effect on NETKEY, Windows or BSD stacks.

hidetos

whether a tunnel packet's TOS field should be set to 0 rather than copied from the user packet inside; acceptable values are **yes** (the default) and **no**. This KLIPS option has no effect on NETKEY, Windows or BSD stacks.

overridemtu

value that the MTU of the ipsecn **interface(s)** should be set to, overriding IPsec's (large) default. This parameter is needed only in special situations. This KLIPS option has no effect on NETKEY, Windows or BSD stacks.

Implicit Conns

The system automatically defines several conns to implement default policy groups. Each can be overridden by explicitly defining a new conn with the same name. If the new conn has **auto=ignore**, the definition is suppressed.

Here are the automatically supplied definitions.

```
conn clear
type=passthrough
authby=never
left=%defaultroute
right=%group
auto=route
conn clear-or-private
type=passthrough
left=%defaultroute
leftid=%myid
```

right=%opportunisticgroup

failureshunt=passthrough

keyingtries=3

ikelifetime=1h

salifetime=1h

rekey=no

auto=route

conn private-or-clear

type=tunnel

left=%defaultroute

leftid=%myid

right=%opportunisticgroup

failureshunt=passthrough

keyingtries=3

ikelifetime=1h

salifetime=1h

rekey=no

auto=route

conn private

type=tunnel

left=%defaultroute

leftid=%myid

right=%opportunisticgroup

failureshunt=drop

keyingtries=3

ikelifetime=1h

salifetime=1h

rekey=no

auto=route

conn block

```
type=reject
```

```
authby=never
```

```
left=%defaultroute
```

```
right=%group
```

```
auto=route
```

```
# default policy
```

```
conn packetdefault
```

```
type=tunnel
```

```
left=%defaultroute
```

```
leftid=%myid
```

```
left=0.0.0.0/0
```

```
right=%opportunistic
```

```
failureshunt=passthrough
```

```
keyingtries=3
```

```
ikelifetime=1h
```

```
salifetime=1h
```

```
rekey=no
```

```
auto=route
```

These conns are *not* affected by anything in **conn %default**. They will only work if **%defaultroute** works. The **leftid** will be the interfaces IP address; this requires that reverse DNS records be set up properly.

The implicit conns are defined after all others. It is appropriate and reasonable to use **also=private-or-clear** (for example) in any other opportunistic conn.

Policy Group Files

The optional files under /etc/ipsec.d/policy, including

```
/etc/ipsec.d/policies/clear
/etc/ipsec.d/policies/clear-or-private
/etc/ipsec.d/policies/private-or-clear
/etc/ipsec.d/policies/private
/etc/ipsec.d/policies/block
```

may contain policy group configuration information to supplement *ipsec.conf*. Their contents are not security-sensitive.

These files are text files. Each consists of a list of CIDR blocks, one per line. White space followed by # followed by anything to the end of the line is a comment and is ignored, as are empty lines.

A connection in ipsec.conf which has **right=%group** or **right=%opportunisticgroup** is a policy group connection. When a policy group file of the same name is loaded, with

ipsec auto --rereadgroups

or at system start, the connection is instantiated such that each CIDR block serves as an instance's **right** value. The system treats the resulting instances as normal connections.

For example, given a suitable connection definition **private**, and the file /etc/ipsec.d/policy/private with an entry 192.0.2.3, the system creates a connection instance **private#192.0.2.3**. This connection inherits all details from **private**, except that its right client is 192.0.2.3.

Default Policy Groups

The standard Openswan install includes several policy groups which provide a way of classifying possible peers into IPsec security classes: **private** (talk encrypted only), **private-or-clear** (prefer encryption), **clear-or-private** (respond to requests for encryption), **clear** and **block**. Implicit policy groups apply to the local host only, and are implemented by the **IMPLICIT CONNECTIONS** described above.

CHOOSING A CONNECTION [THIS SECTION IS EXTREMELY OUT OF DATE]

When choosing a connection to apply to an outbound packet caught with a **%trap**, the system prefers the one with the most specific eroute that includes the packet's source and destination IP addresses. Source subnets are examined before destination subnets. For initiating, only routed connections are considered. For responding, unrouted but added connections are considered.

When choosing a connection to use to respond to a negotiation which doesn't match an ordinary conn, an opportunistic connection may be instantiated. Eventually, its instance will be /32 -> /32, but for earlier stages of the negotiation, there will not be enough information about the client subnets to complete the instantiation.

Files

```
/etc/ipsec.conf
/etc/ipsec.d/policies/clear
/etc/ipsec.d/policies/clear-or-private
/etc/ipsec.d/policies/private-or-clear
/etc/ipsec.d/policies/private
/etc/ipsec.d/policies/block
```

Bugs

Before reporting new bugs, please ensure you are using the latest version of Openswan, and if not using KLIPS, please ensure you are using the latest kernel code for your IPsec stack.

When **type** or **failureshunt** is set to **drop** or **reject**, Openswan blocks outbound packets using eroutes, but assumes inbound blocking is handled by the firewall. Openswan offers firewall hooks via an "updown" script. However, the default **ipsec_updown** provides no help in controlling a modern firewall.

Including attributes of the keying channel (authentication methods, **ikelifetime**, etc.) as an attribute of a connection, rather than of a participant pair, is dubious and incurs limitations.

The use of **%any** with the **protoport=** option is ambiguous. Should the SA permits any port through or should the SA negotiate any single port through? The first is a basic conn with a wildcard. The second is a template. The second is the current behaviour, and it's wrong for quite a number of uses involving TCP. The keyword **%one** may be introduced in the future to separate these two cases.

ipsec_manual is not nearly as generous about the syntax of subnets, addresses, etc. as the usual Openswan user interfaces. Four-component dotted-decimal must be used for all addresses. It *is* smart enough to translate bit-count netmasks to dotted-decimal form.

It would be good to have a line-continuation syntax, especially for the very long lines involved in RSA signature keys.

First packet caching is only implemented for the KLIPS(NG) and MAST stacks. NETKEY returns POSIX-breaking responses, visible as *connect: Resource temporarily unavailable* errors. This affects Opportunistic Encryption and DPD. Functionality on the BSD and Windows stacks is unknown.

Some state information is only available when using KLIPS, and will return errors on other IPsec stacks. These include *ipsec eroute*, *ipsec spi* and *ipsec look*.

Multiple L2TP clients behind the same NAT router, and multiple L2TP clients behind different NAT routers using the same Virtual IP is currently only working for the KLIPSNG stack.

The ability to specify different identities, **authby**, and public keys for different automatic-keyed connections between the same participants is misleading; this doesn't work dependably because the identity of the participants is not known early enough. This is especially awkward for the "Road Warrior" case, where the remote IP address is specified as 0.0.0.0, and that is considered to be the "participant" for such connections.

In principle it might be necessary to control MTU on an interface-by-interface basis, rather than with the single global override that **overridemu** provides. This feature is planned for a future release.

A number of features which *could* be implemented in both manual and automatic keying actually are not yet implemented for manual keying. This is unlikely to be fixed any time soon.

If conns are to be added before DNS is available, **left=FQDN**, **leftnexttop=FQDN**, and **leftrsasigkey=%dns.onload** will fail. **ipsec_pluto**(8) does not actually use the public key for our side of a conn but it isn't generally known at a add-time which side is ours (Road Warrior and Opportunistic conns are currently exceptions).

The **myid** option does not affect explicit **ipsec auto --add** or **ipsec auto --replace** commands for implicit conn.

ipsec__updown(8) - Linux man page

Name

ipsec__updown - kernel and routing manipulation script

Synopsis

_updown is invoked by pluto when it has brought up a new connection. This script is used to insert the appropriate routing entries for IPsec operation on some kernel IPsec stacks, such as KLIPS and MAST, and may do other necessary work that is kernel or user specific, such as defining custom firewall rules. The interface to the script is documented in the pluto man page.

Variables

The *_updown* is passed along a number of variables which can be used to act differently based on the information:

PLUTO_VERSION

indicates what version of this interface is being used. This document describes version 1.1. This is upwardly compatible with version 1.0.

PLUTO_VERB

specifies the name of the operation to be performed, which can be one of **prepare-host**, **prepare-client**, **up-host**, **up-client**, **down-host** or **down-client**. If the address family for security gateway to security gateway communications is IPv6, then a suffix of -v6 is added to this verb.

PLUTO_CONNECTION

is the name of the connection for which we are routing.

PLUTO_NEXT_HOP

is the next hop to which packets bound for the peer must be sent.

PLUTO_INTERFACE

is the name of the ipsec interface to be used.

PLUTO_ME

is the IP address of our host.

PLUTO_MY_CLIENT

is the IP address / count of our client subnet. If the client is just the host, this will be the host's own IP address / max (where max is 32 for IPv4 and 128 for IPv6).

PLUTO_MY_CLIENT_NET

is the IP address of our client net. If the client is just the host, this will be the host's own IP address.

PLUTO_MY_CLIENT_MASK

is the mask for our client net. If the client is just the host, this will be 255.255.255.255.

PLUTO_PEER

is the IP address of our peer.

PLUTO_PEER_CLIENT

is the IP address / count of the peer's client subnet. If the client is just the peer, this will be the peer's own IP address / max (where max is 32 for IPv4 and 128 for IPv6).

PLUTO_PEER_CLIENT_NET

is the IP address of the peer's client net. If the client is just the peer, this will be the peer's own IP address.

PLUTO_PEER_CLIENT_MASK

is the mask for the peer's client net. If the client is just the peer, this will be 255.255.255.255.

PLUTO_MY_PROTOCOL

lists the protocols allowed over this IPsec SA.

PLUTO_PEER_PROTOCOL

lists the protocols the peer allows over this IPsec SA.

PLUTO_MY_PORT

lists the ports allowed over this IPsec SA.

PLUTO_PEER_PORT

lists the ports the peer allows over this IPsec SA.

PLUTO_MY_ID

lists our id.

PLUTO_PEER_ID

lists our peer's id.

PLUTO_PEER_CA

lists the peer's CA.

History

Man page written for the Linux FreeS/WAN project <<http://www.freeswan.org/>> by Michael Richardson. Original program written by Henry Spencer.

ipsec_policy(8) - Linux man page

Name

ipsec_policy - show ipsec policy information

Synopsis

```
# detect what stack is used
ipsec policy --detect-stack

# display policy information
ipsec policy [ --all | [ --inbound | --outbound | --forward ] ] \
    [ --stack=name ] [ --read=file ] [ --debug ]

# provide usage information
ipsec policy --usage
ipsec policy --help
```

Description

policy displays the incoming, outgoing, and forwarding packet policies of the system. It is a wrapper around existing klips and netkey data, but presented in a less terse form.

Options

--detect-stack

Only display the stack that Openswan is using. Possible results are.

klips

KLIPS is the Openswan ipsec kernel module. This stack type indicates that KLIPS is not running in *mast* mode (see next option), but rather in the default mode. In this mode, KLIPS outgoing packet policy is dictated by *eroutes*. See the **ipsec_eroute** man page for further details.

mast

This is a mode of the Openswan ipsec kernel module, KLIPS . In this mode outgoing packet routing policies are dictated by iptables, and Linux kernel policy routing. This mode is selected by using "protostack=mast" setting in *ipsec.conf*.

netkey

This stack indicates that Openswan is controlling the Linux kernel built-in ipsec functionally.

--all

Show inbound, outbound, and forward policies. This is the default.

--inbound --in

Show only inbound policy.

--outbound --out

 Show only outbound policy.

--forward --fwd

 Show only forward policy.

--stack=<name>

 Skip autodetection and force read policy from this stack. See help on **--detect-stack** (above) for valid options and their descriptions.

--read=<file>

 This option overrides what file would be read to gather the policy information. It could be used to read policy information from a snapshot obtained from a running system.

In the case of the klips or mast stack, this file is the output of the

/proc/net/ipsec/spi/all file.

--help

 Output help.

--debug

 Output debug info.

Files

/proc/net/ipsec/spi/all

Bugs

Does not support netkey yet.

ipsec_selinux(8) - Linux man page

Name

ipsec_selinux - Security Enhanced Linux Policy for the ipsec processes

Description

Security-Enhanced Linux secures the ipsec processes via flexible mandatory access control.

The ipsec processes execute with the `ipsec_t` SELinux type. You can check if you have these processes running by executing the `ps` command with the `-Z` qualifier.

For example:

```
ps -eZ | grep ipsec_t
```

Entrypoints

The `ipsec_t` SELinux type can be entered via the "ipsec_exec_t" file type. The default entrypoint paths for the `ipsec_t` domain are the following:"

```
/usr/lib(64)?/ipsec/spi, /usr/lib(64)?/ipsec/pluto, /usr/lib(64)?/ipsec/eroute,  
/usr/lib(64)?/ipsec/klipsdebug, /usr/local/lib(64)?/ipsec/spi,  
/usr/local/lib(64)?/ipsec/pluto, /usr/local/lib(64)?/ipsec/eroute,  
/usr/local/lib(64)?/ipsec/klipsdebug, /usr/libexec/ipsec/spi, /usr/libexec/ipsec/pluto,  
/usr/libexec/ipsec/eroute, /usr/libexec/ipsec/klipsdebug
```

Process Types

SELinux defines process types (domains) for each process running on the system

You can see the context of a process using the `-Z` option to `ps`

Policy governs the access confined processes have to files. SELinux ipsec policy is very flexible allowing users to setup their ipsec processes in as secure a method as possible.

The following process types are defined for ipsec:

ipsec_t, ipsec_mgmt_t

Note: **semanage permissive -a ipsec_t**

can be used to make the process type `ipsec_t` permissive. Permissive process types are not denied access by SELinux. AVC messages will still be generated.

File Contexts

SELinux requires files to have an extended attribute to define the file type.

You can see the context of a file using the **-Z** option to **ls**

Policy governs the access confined processes have to these files. SELinux ipsec policy is very flexible allowing users to setup their ipsec processes in as secure a method as possible.

The following file types are defined for ipsec:

ipsec_conf_file_t

- Set files with the ipsec_conf_file_t type, if you want to treat the files as ipsec conf content.

ipsec_exec_t

- Set files with the ipsec_exec_t type, if you want to transition an executable to the ipsec_t domain.

ipsec_initrc_exec_t

- Set files with the ipsec_initrc_exec_t type, if you want to transition an executable to the ipsec_initrc_t domain.

ipsec_key_file_t

- Set files with the ipsec_key_file_t type, if you want to treat the files as ipsec key content.

ipsec_log_t

- Set files with the ipsec_log_t type, if you want to treat the data as ipsec log data, usually stored under the /var/log directory.

ipsec_mgmt_exec_t

- Set files with the ipsec_mgmt_exec_t type, if you want to transition an executable to the ipsec_mgmt_t domain.

ipsec_mgmt_lock_t

- Set files with the ipsec_mgmt_lock_t type, if you want to treat the files as ipsec mgmt lock data, stored under the /var/lock directory

ipsec_mgmt_var_run_t

- Set files with the ipsec_mgmt_var_run_t type, if you want to store the ipsec mgmt files under the /run directory.

ipsec_tmp_t

- Set files with the ipsec_tmp_t type, if you want to store ipsec temporary files in the /tmp directories.

ipsec_var_run_t

- Set files with the ipsec_var_run_t type, if you want to store the ipsec files under the /run directory.

Note: File context can be temporarily modified with the chcon command. If you want to permanently change the file context you need to use the **semanage fcontext** command. This will modify the SELinux labeling database. You will need to use **restorecon** to apply the labels.

Port Types

SELinux defines port types to represent TCP and UDP ports.

You can see the types associated with a port by using the following command:

semanage port -l

Policy governs the access confined processes have to these ports. SELinux ipsec policy is very flexible allowing users to setup their ipsec processes in as secure a method as possible.

The following port types are defined for ipsec:

ipsecnat_port_t

Default Defined Ports:

tcp 4500 udp 4500

Managed Files

The SELinux process type ipsec_t can manage files labeled with the following file types. The paths listed are the default paths for these file types. Note the processes UID still need to have DAC permissions.

initrc_tmp_t

ipsec_key_file_t

/etc/ipsec.d(/.*)?

/etc/racoon/certs(/.*)?

/etc/ipsec.secrets

/etc/racoon/psk.txt

ipsec_tmp_t

ipsec_var_run_t

/var/racoon(/.*)?

/var/run/pluto(/.*)?

/var/run/racoon.pid

mnt_t

/mnt(/[^/]*)

/mnt(/[^/]*)?

/rhev(/[^/]*)?

/media(/[^/]*)

/media(/[^/]*)?

/etc/rhgb(/.*)?

/media/.hal-.*

/net

/afs

/misc

/rhev

net_conf_t

/etc/ntp??.conf.*

/etc/yp.conf.*

/etc/denyhosts.*

/etc/hosts.deny.*

/etc/resolv.conf.*

/etc/ntp/step-tickers.*

```
/etc/sysconfig/networking(.*)?  
/etc/sysconfig/network-scripts(.*)?  
/etc/sysconfig/network-scripts/*resolv.conf  
/etc/hosts  
/etc/ethers  
root_t  
/  
/initrd  
security_t  
tmp_t  
/tmp  
/usr/tmp  
/var/tmp  
/var/tmp/vi.recover
```

Commands

semanage fcontext can also be used to manipulate default file context mappings.

semanage permissive can also be used to manipulate whether or not a process type is permissive.

semanage module can also be used to enable/disable/install/remove policy modules.

semanage port can also be used to manipulate the port definitions

system-config-selinux is a GUI tool available to customize SELinux policy settings.

NAME

iptables-apply – a safer way to update iptables remotely

SYNOPSIS

iptables-apply [-hV] [-t timeout] [-w savefile] {[rulesfile]/-c [runcmd]}

DESCRIPTION

iptables-apply will try to apply a new rulesfile (as output by iptables-save, read by iptables-restore) or run a command to configure iptables and then prompt the user whether the changes are okay. If the new iptables rules cut the existing connection, the user will not be able to answer affirmatively. In this case, the script rolls back to the previous working iptables rules after the timeout expires.

Successfully applied rules can also be written to savefile and later used to roll back to this state. This can be used to implement a store last good configuration mechanism when experimenting with an iptables setup script: iptables-apply -w /etc/network/iptables.up.rules -c /etc/network/iptables.up.run

When called as ip6tables-apply, the script will use ip6tables-save/-restore and IPv6 default values instead. Default value for rulesfile is '/etc/network/iptables.up.rules'.

OPTIONS

-t seconds, --timeout seconds

Sets the timeout in seconds after which the script will roll back to the previous ruleset (default: 10).

-w savefile, --write savefile

Specify the savefile where successfully applied rules will be written to (default if empty string is given: /etc/network/iptables.up.rules).

-c runcmd, --command runcmd

Run command runcmd to configure iptables instead of applying a rulesfile (default: /etc/network/iptables.up.run).

-h, --help

Display usage information.

-V, --version

Display version information.

NAME

xtables-nft — iptables using nftables kernel api

DESCRIPTION

xtables-nft are versions of iptables that use the nftables API. This is a set of tools to help the system administrator migrate the ruleset from **iptables(8)**, **ip6tables(8)**, **arptables(8)**, and **ebtables(8)** to **nftables(8)**.

The **xtables-nft** set is composed of several commands:

- **iptables-nft**
- **iptables-nft-save**
- **iptables-nft-restore**
- **ip6tables-nft**
- **ip6tables-nft-save**
- **ip6tables-nft-restore**
- **arptables-nft**
- **ebtables-nft**

These tools use the libxtables framework extensions and hook to the nf_tables kernel subsystem using the **nft_compat** module.

USAGE

The xtables-nft tools allow you to manage the nf_tables backend using the native syntax of **iptables(8)**, **ip6tables(8)**, **arptables(8)**, and **ebtables(8)**.

You should use the xtables-nft tools exactly the same way as you would use the corresponding original tools.

Adding a rule will result in that rule being added to the nf_tables kernel subsystem instead. Listing the ruleset will use the nf_tables backend as well.

When these tools were designed, the main idea was to replace each legacy binary with a symlink to the xtables-nft program, for example:

```
/sbin/iptables -> /usr/sbin/iptables-nft-multi
/sbin/ip6tables -> /usr/sbin/ip6tables-nft-multi
/sbin/arptables -> /usr/sbin/arptables-nft-multi
/sbin/ebtables -> /usr/sbin/ebtables-nft-multi
```

The iptables version string will indicate whether the legacy API (get/setsockopt) or the new nf_tables api is used:

```
iptables -V
iptables v1.7 (nf_tables)
```

DIFFERENCES TO LEGACY IPTABLES

Because the xtables-nft tools use the nf_tables kernel API, rule additions and deletions are always atomic. Unlike iptables-legacy, iptables-nft -A ... will NOT need to retrieve the current ruleset from the kernel, change it, and re-load the altered ruleset. Instead, iptables-nft will tell the kernel to add one rule. For this reason, the iptables-legacy --wait option is a no-op in iptables-nft.

Use of the xtables-nft tools allow monitoring ruleset changes using the **xtables-monitor(8)** command.

When using `-j TRACE` to debug packet traversal to the ruleset, note that you will need to use **xtables-monitor(8)** in `--trace` mode to obtain monitoring trace events.

EXAMPLES

One basic example is creating the skeleton ruleset in nf_tables from the xtables-nft tools, in a fresh machine:

```
root@machine:~# iptables-nft -L
[...]
root@machine:~# ip6tables-nft -L
[...]
root@machine:~# arptables-nft -L
[...]
root@machine:~# ebtables-nft -L
[...]
root@machine:~# nft list ruleset
table ip filter {
    chain INPUT {
        type filter hook input priority 0; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority 0; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority 0; policy accept;
    }
}
table ip6 filter {
    chain INPUT {
        type filter hook input priority 0; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority 0; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority 0; policy accept;
    }
}
table bridge filter {
    chain INPUT {
        type filter hook input priority -200; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority -200; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority -200; policy accept;
    }
}
```

```

}
table arp filter {
    chain INPUT {
        type filter hook input priority 0; policy accept;
    }

    chain FORWARD {
        type filter hook forward priority 0; policy accept;
    }

    chain OUTPUT {
        type filter hook output priority 0; policy accept;
    }
}

```

(please note that in fresh machines, listing the ruleset for the first time results in all tables an chain being created).

To migrate your complete filter ruleset, in the case of **iptables(8)**, you would use:

```

root@machine:~# iptables-legacy-save > myruleset # reads from x_tables
root@machine:~# iptables-nft-restore myruleset # writes to nf_tables
or
root@machine:~# iptables-legacy-save | iptables-translate-restore | less

```

to see how rules would look like in the nft **nft(8)** syntax.

LIMITATIONS

You should use **Linux kernel >= 4.17**.

The CLUSTERIP target is not supported.

To get up-to-date information about this, please head to <http://wiki.nftables.org/>.

NAME

iptables/**ip6tables** — administration tool for IPv4/IPv6 packet filtering and NAT

SYNOPSIS

```
iptables [-t table] {-A|-C|-D} chain rule-specification
ip6tables [-t table] {-A|-C|-D} chain rule-specification
iptables [-t table] -I chain [rulenumber] rule-specification
iptables [-t table] -R chain rulenumber rule-specification
iptables [-t table] -D chain rulenumber
iptables [-t table] -S [chain [rulenumber]]
iptables [-t table] {-F|-L|-Z} [chain [rulenumber]] [options...]
iptables [-t table] -N chain
iptables [-t table] -X [chain]
iptables [-t table] -P chain target
iptables [-t table] -E old-chain-name new-chain-name
rule-specification = [matches...] [target]
match = -m matchname [per-match-options]
target = -j targetname [per-target-options]
```

DESCRIPTION

Iptables and **ip6tables** are used to set up, maintain, and inspect the tables of IPv4 and IPv6 packet filter rules in the Linux kernel. Several different tables may be defined. Each table contains a number of built-in chains and may also contain user-defined chains.

Each chain is a list of rules which can match a set of packets. Each rule specifies what to do with a packet that matches. This is called a ‘target’, which may be a jump to a user-defined chain in the same table.

TARGETS

A firewall rule specifies criteria for a packet and a target. If the packet does not match, the next rule in the chain is examined; if it does match, then the next rule is specified by the value of the target, which can be the name of a user-defined chain, one of the targets described in **iptables-extensions(8)**, or one of the special values **ACCEPT**, **DROP** or **RETURN**.

ACCEPT means to let the packet through. **DROP** means to drop the packet on the floor. **RETURN** means stop traversing this chain and resume at the next rule in the previous (calling) chain. If the end of a built-in chain is reached or a rule in a built-in chain with target **RETURN** is matched, the target specified by the chain policy determines the fate of the packet.

TABLES

There are currently five independent tables (which tables are present at any time depends on the kernel configuration options and which modules are present).

-t, --table table

This option specifies the packet matching table which the command should operate on. If the kernel is configured with automatic module loading, an attempt will be made to load the appropriate module for that table if it is not already there.

The tables are as follows:

filter: This is the default table (if no **-t** option is passed). It contains the built-in chains **INPUT** (for packets destined to local sockets), **FORWARD** (for packets being routed through the box), and **OUTPUT** (for locally-generated packets).

nat: This table is consulted when a packet that creates a new connection is encountered. It consists of four built-ins: **PREROUTING** (for altering packets as soon as they come in),

INPUT (for altering packets destined for local sockets), **OUTPUT** (for altering locally-generated packets before routing), and **POSTROUTING** (for altering packets as they are about to go out). IPv6 NAT support is available since kernel 3.7.

mangle:

This table is used for specialized packet alteration. Until kernel 2.4.17 it had two built-in chains: **PREROUTING** (for altering incoming packets before routing) and **OUTPUT** (for altering locally-generated packets before routing). Since kernel 2.4.18, three other built-in chains are also supported: **INPUT** (for packets coming into the box itself), **FORWARD** (for altering packets being routed through the box), and **POSTROUTING** (for altering packets as they are about to go out).

raw: This table is used mainly for configuring exemptions from connection tracking in combination with the NOTRACK target. It registers at the netfilter hooks with higher priority and is thus called before ip_conntrack, or any other IP tables. It provides the following built-in chains: **PREROUTING** (for packets arriving via any network interface) **OUTPUT** (for packets generated by local processes)

security:

This table is used for Mandatory Access Control (MAC) networking rules, such as those enabled by the **SECMARK** and **CONNSECMARK** targets. Mandatory Access Control is implemented by Linux Security Modules such as SELinux. The security table is called after the filter table, allowing any Discretionary Access Control (DAC) rules in the filter table to take effect before MAC rules. This table provides the following built-in chains: **INPUT** (for packets coming into the box itself), **OUTPUT** (for altering locally-generated packets before routing), and **FORWARD** (for altering packets being routed through the box).

OPTIONS

The options that are recognized by **iptables** and **ip6tables** can be divided into several different groups.

COMMANDS

These options specify the desired action to perform. Only one of them can be specified on the command line unless otherwise stated below. For long versions of the command and option names, you need to use only enough letters to ensure that **iptables** can differentiate it from all other options.

-A, --append *chain rule-specification*

Append one or more rules to the end of the selected chain. When the source and/or destination names resolve to more than one address, a rule will be added for each possible address combination.

-C, --check *chain rule-specification*

Check whether a rule matching the specification does exist in the selected chain. This command uses the same logic as **-D** to find a matching entry, but does not alter the existing iptables configuration and uses its exit code to indicate success or failure.

-D, --delete *chain rule-specification*

-D, --delete *chain rulenum*

Delete one or more rules from the selected chain. There are two versions of this command: the rule can be specified as a number in the chain (starting at 1 for the first rule) or a rule to match.

-I, --insert *chain [rulenum] rule-specification*

Insert one or more rules in the selected chain as the given rule number. So, if the rule number is 1, the rule or rules are inserted at the head of the chain. This is also the default if no rule number is specified.

-R, --replace *chain rulenum rule-specification*

Replace a rule in the selected chain. If the source and/or destination names resolve to multiple addresses, the command will fail. Rules are numbered starting at 1.

-L, --list [chain]

List all rules in the selected chain. If no chain is selected, all chains are listed. Like every other iptables command, it applies to the specified table (filter is the default), so NAT rules get listed by `iptables -t nat -n -L`

Please note that it is often used with the `-n` option, in order to avoid long reverse DNS lookups. It is legal to specify the `-Z` (zero) option as well, in which case the chain(s) will be atomically listed and zeroed. The exact output is affected by the other arguments given. The exact rules are suppressed until you use

`iptables -L -v`
or `iptables-save(8)`.

-S, --list-rules [chain]

Print all rules in the selected chain. If no chain is selected, all chains are printed like `iptables-save`. Like every other iptables command, it applies to the specified table (filter is the default).

-F, --flush [chain]

Flush the selected chain (all the chains in the table if none is given). This is equivalent to deleting all the rules one by one.

-Z, --zero [chain [rulenum]]

Zero the packet and byte counters in all chains, or only the given chain, or only the given rule in a chain. It is legal to specify the `-L, --list` (list) option as well, to see the counters immediately before they are cleared. (See above.)

-N, --new-chain chain

Create a new user-defined chain by the given name. There must be no target of that name already.

-X, --delete-chain [chain]

Delete the optional user-defined chain specified. There must be no references to the chain. If there are, you must delete or replace the referring rules before the chain can be deleted. The chain must be empty, i.e. not contain any rules. If no argument is given, it will attempt to delete every non-built-in chain in the table.

-P, --policy chain target

Set the policy for the built-in (non-user-defined) chain to the given target. The policy target must be either **ACCEPT** or **DROP**.

-E, --rename-chain old-chain new-chain

Rename the user specified chain to the user supplied name. This is cosmetic, and has no effect on the structure of the table.

-h Help. Give a (currently very brief) description of the command syntax.**PARAMETERS**

The following parameters make up a rule specification (as used in the add, delete, insert, replace and append commands).

-4, --ipv4

This option has no effect in `iptables` and `iptables-restore`. If a rule using the `-4` option is inserted with (and only with) `ip6tables-restore`, it will be silently ignored. Any other uses will throw an error. This option allows IPv4 and IPv6 rules in a single rule file for use with both `iptables-restore` and `ip6tables-restore`.

-6, --ipv6

If a rule using the `-6` option is inserted with (and only with) `iptables-restore`, it will be silently ignored. Any other uses will throw an error. This option allows IPv4 and IPv6 rules in a single rule file for use with both `iptables-restore` and `ip6tables-restore`. This option has no effect in `ip6tables` and `ip6tables-restore`.

[!] -p, --protocol protocol

The protocol of the rule or of the packet to check. The specified protocol can be one of **tcp**, **udp**, **udplite**, **icmp**, **icmpv6**, **esp**, **ah**, **sctp**, **mh** or the special keyword "**all**", or it can be a numeric

value, representing one of these protocols or a different one. A protocol name from /etc/protocols is also allowed. A "!" argument before the protocol inverts the test. The number zero is equivalent to **all**. "all" will match with all protocols and is taken as default when this option is omitted. Note that, in ip6tables, IPv6 extension headers except **esp** are not allowed. **esp** and **ipv6-nonext** can be used with Kernel version 2.6.11 or later. The number zero is equivalent to **all**, which means that you cannot test the protocol field for the value 0 directly. To match on a HBH header, even if it were the last, you cannot use **-p 0**, but always need **-m hbh**.

[!] **-s, --source** *address[/mask][,...]*

Source specification. *Address* can be either a network name, a hostname, a network IP address (with */mask*), or a plain IP address. Hostnames will be resolved once only, before the rule is submitted to the kernel. Please note that specifying any name to be resolved with a remote query such as DNS is a really bad idea. The *mask* can be either an ipv4 network mask (for iptables) or a plain number, specifying the number of 1's at the left side of the network mask. Thus, an iptables mask of 24 is equivalent to 255.255.255.0. A "!" argument before the address specification inverts the sense of the address. The flag **--src** is an alias for this option. Multiple addresses can be specified, but this will **expand to multiple rules** (when adding with **-A**), or will cause multiple rules to be deleted (with **-D**).

[!] **-d, --destination** *address[/mask][,...]*

Destination specification. See the description of the **-s** (source) flag for a detailed description of the syntax. The flag **--dst** is an alias for this option.

-m, --match *match*

Specifies a match to use, that is, an extension module that tests for a specific property. The set of matches make up the condition under which a target is invoked. Matches are evaluated first to last as specified on the command line and work in short-circuit fashion, i.e. if one extension yields false, evaluation will stop.

-j, --jump *target*

This specifies the target of the rule; i.e., what to do if the packet matches it. The target can be a user-defined chain (other than the one this rule is in), one of the special builtin targets which decide the fate of the packet immediately, or an extension (see **EXTENSIONS** below). If this option is omitted in a rule (and **-g** is not used), then matching the rule will have no effect on the packet's fate, but the counters on the rule will be incremented.

-g, --goto *chain*

This specifies that the processing should continue in a user specified chain. Unlike the **--jump** option return will not continue processing in this chain but instead in the chain that called us via **--jump**.

[!] **-i, --in-interface** *name*

Name of an interface via which a packet was received (only for packets entering the **INPUT**, **FORWARD** and **PREROUTING** chains). When the "!" argument is used before the interface name, the sense is inverted. If the interface name ends in a "+", then any interface which begins with this name will match. If this option is omitted, any interface name will match.

[!] **-o, --out-interface** *name*

Name of an interface via which a packet is going to be sent (for packets entering the **FORWARD**, **OUTPUT** and **POSTROUTING** chains). When the "!" argument is used before the interface name, the sense is inverted. If the interface name ends in a "+", then any interface which begins with this name will match. If this option is omitted, any interface name will match.

[!] **-f, --fragment**

This means that the rule only refers to second and further IPv4 fragments of fragmented packets. Since there is no way to tell the source or destination ports of such a packet (or ICMP type), such a packet will not match any rules which specify them. When the "!" argument precedes the **-f** flag, the rule will only match head fragments, or unfragmented packets. This option is IPv4 specific, it is not available in ip6tables.

-c, --set-counters *packets bytes*

This enables the administrator to initialize the packet and byte counters of a rule (during **INSERT**, **APPEND**, **REPLACE** operations).

OTHER OPTIONS

The following additional options can be specified:

-v, --verbose

Verbose output. This option makes the list command show the interface name, the rule options (if any), and the TOS masks. The packet and byte counters are also listed, with the suffix 'K', 'M' or 'G' for 1000, 1,000,000 and 1,000,000,000 multipliers respectively (but see the **-x** flag to change this). For appending, insertion, deletion and replacement, this causes detailed information on the rule or rules to be printed. **-v** may be specified multiple times to possibly emit more detailed debug statements.

-w, --wait [*seconds*]

Wait for the xtables lock. To prevent multiple instances of the program from running concurrently, an attempt will be made to obtain an exclusive lock at launch. By default, the program will exit if the lock cannot be obtained. This option will make the program wait (indefinitely or for optional *seconds*) until the exclusive lock can be obtained.

-W, --wait-interval *microseconds*

Interval to wait per each iteration. When running latency sensitive applications, waiting for the xtables lock for extended durations may not be acceptable. This option will make each iteration take the amount of time specified. The default interval is 1 second. This option only works with **-w**.

-n, --numeric

Numeric output. IP addresses and port numbers will be printed in numeric format. By default, the program will try to display them as host names, network names, or services (whenever applicable).

-x, --exact

Expand numbers. Display the exact value of the packet and byte counters, instead of only the rounded number in K's (multiples of 1000) M's (multiples of 1000K) or G's (multiples of 1000M). This option is only relevant for the **-L** command.

--line-numbers

When listing rules, add line numbers to the beginning of each rule, corresponding to that rule's position in the chain.

--modprobe=*command*

When adding or inserting rules into a chain, use *command* to load any necessary modules (targets, match extensions, etc).

LOCK FILE

iptables uses the */run/xtables.lock* file to take an exclusive lock at launch.

The **XTABLES_LOCKFILE** environment variable can be used to override the default setting.

MATCH AND TARGET EXTENSIONS

iptables can use extended packet matching and target modules. A list of these is available in the **iptables-extensions(8)** manpage.

DIAGNOSTICS

Various error messages are printed to standard error. The exit code is 0 for correct functioning. Errors which appear to be caused by invalid or abused command line parameters cause an exit code of 2, and other errors cause an exit code of 1.

BUGS

Bugs? What's this? ;-) Well, you might want to have a look at <http://bugzilla.netfilter.org/>

COMPATIBILITY WITH IPCHAINS

This **iptables** is very similar to ipchains by Rusty Russell. The main difference is that the chains **INPUT** and **OUTPUT** are only traversed for packets coming into the local host and originating from the local host respectively. Hence every packet only passes through one of the three chains (except loopback traffic, which involves both INPUT and OUTPUT chains); previously a forwarded packet would pass through all three.

The other main difference is that **-i** refers to the input interface; **-o** refers to the output interface, and both are available for packets entering the **FORWARD** chain.

The various forms of NAT have been separated out; **iptables** is a pure packet filter when using the default 'filter' table, with optional extension modules. This should simplify much of the previous confusion over the combination of IP masquerading and packet filtering seen previously. So the following options are handled differently:

-j MASQ
-M -S
-M -L

There are several other changes in iptables.

AUTHORS

Rusty Russell originally wrote iptables, in early consultation with Michael Neuling.

Marc Boucher made Rusty abandon ipnatctl by lobbying for a generic packet selection framework in iptables, then wrote the mangle table, the owner match, the mark stuff, and ran around doing cool stuff everywhere.

James Morris wrote the TOS target, and tos match.

Jozsef Kadlecik wrote the REJECT target.

Harald Welte wrote the ULOG and NFQUEUE target, the new libiptc, as well as the TTL, DSCP, ECN matches and targets.

The Netfilter Core Team is: Jozsef Kadlecik, Pablo Neira Ayuso, Eric Leblond, Florian Westphal and Arturo Borrero Gonzalez. Emeritus Core Team members are: Marc Boucher, Martin Josefsson, Yasuyuki Kozakai, James Morris, Harald Welte and Rusty Russell.

Man page originally written by Herve Eychenne <rv@wallfire.org>.

VERSION

This manual page applies to iptables/ip6tables 1.8.7.

NAME

iptunnel – Create and manage IP tunnels

SYNOPSIS

```
iptunnel { add | change | del | show } [ NAME ]
[ mode { ipip | gre | sit } ] [ remote ADDR ] [ local ADDR ]
[ [i|o]seq ] [ [i|o]key KEY ] [ [i|o]csum ]
[ ttl TTL ] [ tos TOS ] [ nopmtudisc ] [ dev PHYS_DEV ]
```

iptunnel -V | --version

Where: NAME := STRING

```
ADDR := { IP_ADDRESS | any }
TOS := { NUMBER | inherit }
TTL := { 1..255 | inherit }
KEY := { DOTTED_QUAD | NUMBER }
```

DESCRIPTION

iptunnel can be used to add, change, delete and show IP tunnels on the machine.

OPTIONS

help Show the help text.

show List existing IP tunnels.

{ **add** | **change** | **del** } [NAME]

Specify an action (**add**, **change** or **delete** an IP tunnel) to be executed by **iptunnel** on the tunnel named **NAME**, which must be a string. You must specify one action.

mode PROTOCOL

Specify the **PROTOCOL** to be used for the IP tunnel. It can be **ipip** for TCP/IP, **gre** for Cisco GRE tunnel (RFCs 1701 and 1702), or **sit** for IPv6-in-IPv4 tunneling.

remote ADDR

Set the remote (i.e., destination) address of the tunnel. **ADDR** must be an IP address or the word **any**.

local ADDR

Set the local (i.e., source) address of the tunnel. **ADDR** must be an IP address or the word **any**.

iseq Require that all incoming packets are serialized. Only applicable for **GRE** tunnels.

oseq Enable serialization (sequencing) for all outgoing packets. Only applicable for**GRE** tunnels.

ikey KEY

Specify the input key for the Cisco GRE tunnel. **KEY** must be either in dotted quad (dotted decimal) or a number. Only applicable for**GRE** tunnels.

okey KEY

Same as **ikey**, but set the output key instead. Only applicable for **GRE** tunnels.

icsum Require that all incoming packets have the correct checksum. Only applicable for **GRE** tunnels.

osum Calculate checksums for all outgoing packets. Only applicable for **GRE** tunnels.

ttl TTL

Specify the **Time-To-Live** value for the IP tunnel. **TTL** must be a value between **1** and **255**, or the word **inherit**, which causes the field to be copied from the original IP header.

tos TOS

Specify the **Type-Of-Service** value for the IP tunnel. **T OS** must be a value between **1** and **255**, or the word **inherit**, which causes the field to be copied from the original IP header.

nopmtudisc

Disable **Path MTU Discovery** on this tunnel. Note that a fixed **ttl** is incompatible with this option.

dev PHYS_DEV

Bind the tunnel to the device **PHYS_DEV**.

NAME

journalctl – Query the systemd journal

SYNOPSIS

journalctl [OPTIONS...] [MATCHES...]

DESCRIPTION

journalctl may be used to query the contents of the **systemd(1)** journal as written by **systemd-journald.service(8)**.

If called without parameters, it will show the full contents of the journal, starting with the oldest entry collected.

If one or more match arguments are passed, the output is filtered accordingly. A match is in the format "**FIELD=VALUE**", e.g. "**_SYSTEMD_UNIT=httpd.service**", referring to the components of a structured journal entry. See **systemd.journal-fields(7)** for a list of well-known fields. If multiple matches are specified matching different fields, the log entries are filtered by both, i.e. the resulting output will show only entries matching all the specified matches of this kind. If two matches apply to the same field, then they are automatically matched as alternatives, i.e. the resulting output will show entries matching any of the specified matches for the same field. Finally, the character "+" may appear as a separate word between other terms on the command line. This causes all matches before and after to be combined in a disjunction (i.e. logical OR).

It is also possible to filter the entries by specifying an absolute file path as an argument. The file path may be a file or a symbolic link and the file must exist at the time of the query. If a file path refers to an executable binary, an "**_EXE=**" match for the canonicalized binary path is added to the query. If a file path refers to an executable script, a "**_COMM=**" match for the script name is added to the query. If a file path refers to a device node, "**_KERNEL_DEVICE=**" matches for the kernel name of the device and for each of its ancestor devices is added to the query. Symbolic links are dereferenced, kernel names are synthesized, and parent devices are identified from the environment at the time of the query. In general, a device node is the best proxy for an actual device, as log entries do not usually contain fields that identify an actual device. For the resulting log entries to be correct for the actual device, the relevant parts of the environment at the time the entry was logged, in particular the actual device corresponding to the device node, must have been the same as those at the time of the query. Because device nodes generally change their corresponding devices across reboots, specifying a device node path causes the resulting entries to be restricted to those from the current boot.

Additional constraints may be added using options **--boot**, **--unit=**, etc., to further limit what entries will be shown (logical AND).

Output is interleaved from all accessible journal files, whether they are rotated or currently being written, and regardless of whether they belong to the system itself or are accessible user journals. The **--header** option can be used to identify which files *are* being shown.

The set of journal files which will be used can be modified using the **--user**, **--system**, **--directory**, and **--file** options, see below.

All users are granted access to their private per-user journals. However, by default, only root and users who are members of a few special groups are granted access to the system journal and the journals of other users. Members of the groups "systemd-journal", "adm", and "wheel" can read all journal files. Note that the two latter groups traditionally have additional privileges specified by the distribution. Members of the "wheel" group can often perform administrative tasks.

The output is paged through **less** by default, and long lines are "truncated" to screen width. The hidden part can be viewed by using the left-arrow and right-arrow keys. Paging can be disabled; see the **--no-pager** option and the "Environment" section below.

When outputting to a tty, lines are colored according to priority: lines of level ERROR and higher are colored red; lines of level NOTICE and higher are highlighted; lines of level DEBUG are colored lighter grey; other lines are displayed normally.

OPTIONS

The following options are understood:

--no-full, --full, -l

Ellipsize fields when they do not fit in available columns. The default is to show full fields, allowing them to wrap or be truncated by the pager, if one is used.

The old options **-l**/**--full** are not useful anymore, except to undo **--no-full**.

-a, --all

Show all fields in full, even if they include unprintable characters or are very long. By default, fields with unprintable characters are abbreviated as "blob data". (Note that the pager may escape unprintable characters again.)

-f, --follow

Show only the most recent journal entries, and continuously print new entries as they are appended to the journal.

-e, --pager-end

Immediately jump to the end of the journal inside the implied pager tool. This implies **-n1000** to guarantee that the pager will not buffer logs of unbounded size. This may be overridden with an explicit **-n** with some other numeric value, while **-null** will disable this cap. Note that this option is only supported for the **less(1)** pager.

--n, --lines=

Show the most recent journal events and limit the number of events shown. If **--follow** is used, this option is implied. The argument is a positive integer or "all" to disable line limiting. The default value is 10 if no argument is given.

--no-tail

Show all stored output lines, even in follow mode. Undoes the effect of **--lines=**.

-r, --reverse

Reverse output so that the newest entries are displayed first.

-o, --output=

Controls the formatting of the journal entries that are shown. Takes one of the following options:

short

is the default and generates an output that is mostly identical to the formatting of classic syslog files, showing one line per journal entry.

short-full

is very similar, but shows timestamps in the format the **--since=** and **--until=** options accept. Unlike the timestamp information shown in **short** output mode this mode includes weekday, year and timezone information in the output, and is locale-independent.

short-iso

is very similar, but shows ISO 8601 wallclock timestamps.

short-iso-precise

as for **short-iso** but includes full microsecond precision.

short-precise

is very similar, but shows classic syslog timestamps with full microsecond precision.

short-monotonic

is very similar, but shows monotonic timestamps instead of wallclock timestamps.

short-unix

is very similar, but shows seconds passed since January 1st 1970 UTC instead of wallclock timestamps ("UNIX time"). The time is shown with microsecond accuracy.

verbose

shows the full-structured entry items with all fields.

export

serializes the journal into a binary (but mostly text-based) stream suitable for backups and network transfer (see [Journal Export Format^{\[1\]}](#) for more information). To import the binary stream back into native journald format use [systemd-journal-remote\(8\)](#).

json

formats entries as JSON objects, separated by newline characters (see [Journal JSON Format^{\[2\]}](#) for more information). Field values are generally encoded as JSON strings, with three exceptions:

1. Fields larger than 4096 bytes are encoded as **null** values. (This may be turned off by passing **--all**, but be aware that this may allocate overly long JSON objects.)
2. Journal entries permit non-unique fields within the same log entry. JSON does not allow non-unique fields within objects. Due to this, if a non-unique field is encountered a JSON array is used as field value, listing all field values as elements.
3. Fields containing non-printable or non-UTF8 bytes are encoded as arrays containing the raw bytes individually formatted as unsigned numbers.

Note that this encoding is reversible (with the exception of the size limit).

json-pretty

formats entries as JSON data structures, but formats them in multiple lines in order to make them more readable by humans.

json-sse

formats entries as JSON data structures, but wraps them in a format suitable for [Server-Sent Events^{\[3\]}](#).

json-seq

formats entries as JSON data structures, but prefixes them with an ASCII Record Separator character (0x1E) and suffixes them with an ASCII Line Feed character (0x0A), in accordance with [JavaScript Object Notation \(JSON\) Text Sequences^{\[4\]}](#) ("application/json-seq").

cat

generates a very terse output, only showing the actual message of each journal entry with no metadata, not even a timestamp. If combined with the **--output-fields=** option will output the listed fields for each log record, instead of the message.

with-unit

similar to short-full, but prefixes the unit and user unit names instead of the traditional syslog identifier. Useful when using templated instances, as it will include the arguments in the unit names.

--output-fields=

A comma separated list of the fields which should be included in the output. This has an effect only for the output modes which would normally show all fields (**verbose**, **export**, **json**, **json-pretty**, **json-sse** and **json-seq**), as well as on **cat**. For the former, the "**__CURSOR**", "**__REALTIME_TIMESTAMP**", "**__MONOTONIC_TIMESTAMP**", and "**_BOOT_ID**" fields are always printed.

--utc

Express time in Coordinated Universal Time (UTC).

--no-hostname

Don't show the hostname field of log messages originating from the local host. This switch has an effect only on the **short** family of output modes (see above).

Note: this option does not remove occurrences of the hostname from log entries themselves, so it does not prevent the hostname from being visible in the logs.

-x, --catalog

Augment log lines with explanation texts from the message catalog. This will add explanatory help texts to log messages in the output where this is available. These short help texts will explain the context of an error or log event, possible solutions, as well as pointers to support forums, developer documentation, and any other relevant manuals. Note that help texts are not available for all messages, but only for selected ones. For more information on the message catalog, please refer to the [Message Catalog Developer Documentation](#)^[5].

Note: when attaching **journalctl** output to bug reports, please do *not* use **-x**.

-q, --quiet

Suppresses all informational messages (i.e. "— Journal begins at ...", "— Reboot —"), any warning messages regarding inaccessible system journals when run as a normal user.

-m, --merge

Show entries interleaved from all available journals, including remote ones.

-b [[ID][±offset]|all], --boot=[ID][±offset]|all

Show messages from a specific boot. This will add a match for "_BOOT_ID=".

The argument may be empty, in which case logs for the current boot will be shown.

If the boot ID is omitted, a positive *offset* will look up the boots starting from the beginning of the journal, and an equal-or-less-than zero *offset* will look up boots starting from the end of the journal. Thus, **1** means the first boot found in the journal in chronological order, **2** the second and so on; while **-0** is the last boot, **-1** the boot before last, and so on. An empty *offset* is equivalent to specifying **-0**, except when the current boot is not the last boot (e.g. because **--directory** was specified to look at logs from a different machine).

If the 32-character *ID* is specified, it may optionally be followed by *offset* which identifies the boot relative to the one given by boot *ID*. Negative values mean earlier boots and positive values mean later boots. If *offset* is not specified, a value of zero is assumed, and the logs for the boot given by *ID* are shown.

The special argument **all** can be used to negate the effect of an earlier use of **-b**.

--list-boots

Show a tabular list of boot numbers (relative to the current boot), their IDs, and the timestamps of the first and last message pertaining to the boot.

-k, --dmesg

Show only kernel messages. This implies **-b** and adds the match "_TRANSPORT=kernel".

-t, --identifier=SYSLOG_IDENTIFIER

Show messages for the specified syslog identifier *SYSLOG_IDENTIFIER*.

This parameter can be specified multiple times.

-u, --unit=UNIT|PATTERN

Show messages for the specified systemd unit *UNIT* (such as a service unit), or for any of the units matched by *PATTERN*. If a pattern is specified, a list of unit names found in the journal is compared with the specified pattern and all that match are used. For each unit name, a match is added for messages from the unit ("_SYSTEMD_UNIT=*UNIT*"), along with additional matches for messages from systemd and messages about core dumps for the specified unit. A match is also added for "_SYSTEMD_SLICE=*UNIT*", such that if the provided *UNIT* is a **systemd.slice(5)** unit, all logs of children of the slice will be shown.

This parameter can be specified multiple times.

--user-unit=

Show messages for the specified user session unit. This will add a match for messages from the unit ("`_SYSTEMD_USER_UNIT=`" and "`_UID=`") and additional matches for messages from session systemd and messages about core dumps for the specified unit. A match is also added for "`_SYSTEMD_USER_SLICE=UNIT`", such that if the provided `UNIT` is a **systemd.slice(5)** unit, all logs of children of the unit will be shown.

This parameter can be specified multiple times.

-p, --priority=

Filter output by message priorities or priority ranges. Takes either a single numeric or textual log level (i.e. between 0/"emerg" and 7/"debug"), or a range of numeric/text log levels in the form FROM..TO. The log levels are the usual syslog log levels as documented in **syslog(3)**, i.e. "emerg" (0), "alert" (1), "crit" (2), "err" (3), "warning" (4), "notice" (5), "info" (6), "debug" (7). If a single log level is specified, all messages with this log level or a lower (hence more important) log level are shown. If a range is specified, all messages within the range are shown, including both the start and the end value of the range. This will add "PRIORITY=" matches for the specified priorities.

--facility=

Filter output by syslog facility. Takes a comma-separated list of numbers or facility names. The names are the usual syslog facilities as documented in **syslog(3)**. **--facility=help** may be used to display a list of known facility names and exit.

-g, --grep=

Filter output to entries where the `MESSAGE=` field matches the specified regular expression. PERL-compatible regular expressions are used, see **pcre2pattern(3)** for a detailed description of the syntax.

If the pattern is all lowercase, matching is case insensitive. Otherwise, matching is case sensitive. This can be overridden with the **--case-sensitive** option, see below.

--case-sensitive[=BOOLEAN]

Make pattern matching case sensitive or case insensitive.

-c, --cursor=

Start showing entries from the location in the journal specified by the passed cursor.

--cursor-file=FILE

If `FILE` exists and contains a cursor, start showing entries *after* this location. Otherwise the show entries according the other given options. At the end, write the cursor of the last entry to `FILE`. Use this option to continually read the journal by sequentially calling **journalctl**.

--after-cursor=

Start showing entries from the location in the journal *after* the location specified by the passed cursor. The cursor is shown when the **--show-cursor** option is used.

--show-cursor

The cursor is shown after the last entry after two dashes:

```
-- cursor: s=0639...
```

The format of the cursor is private and subject to change.

-S, --since=, -U, --until=

Start showing entries on or newer than the specified date, or on or older than the specified date, respectively. Date specifications should be of the format "2012-10-30 18:17:16". If the time part is omitted, "00:00:00" is assumed. If only the seconds component is omitted, ":00" is assumed. If the date component is omitted, the current day is assumed. Alternatively the strings "yesterday", "today", "tomorrow" are understood, which refer to 00:00:00 of the day before the current day, the current day, or the day after the current day, respectively. "now" refers to the current time. Finally, relative times may be specified, prefixed with "-" or "+", referring to times before or after the current time,

respectively. For complete time and date specification, see **systemd.time(7)**. Note that **--output=short-full** prints timestamps that follow precisely this format.

-F, --field=

Print all possible data values the specified field can take in all entries of the journal.

-N, --fields

Print all field names currently used in all entries of the journal.

--system, --user

Show messages from system services and the kernel (with **--system**). Show messages from service of current user (with **--user**). If neither is specified, show all messages that the user can see.

-M, --machine=

Show messages from a running, local container. Specify a container name to connect to.

-D DIR, --directory=DIR

Takes a directory path as argument. If specified, journalctl will operate on the specified journal directory *DIR* instead of the default runtime and system journal paths.

--file=GLOB

Takes a file glob as an argument. If specified, journalctl will operate on the specified journal files matching *GLOB* instead of the default runtime and system journal paths. May be specified multiple times, in which case files will be suitably interleaved.

--root=ROOT

Takes a directory path as an argument. If specified, **journalctl** will operate on journal directories and catalog file hierarchy underneath the specified directory instead of the root directory (e.g.

--update-catalog will create *ROOT*/var/lib/systemd/catalog/database, and journal files under *ROOT*/run/journal/ or *ROOT*/var/log/journal/ will be displayed).

--image=IMAGE

Takes a path to a disk image file or block device node. If specified, **journalctl** will operate on the file system in the indicated disk image. This is similar to **--root=** but operates on file systems stored in disk images or block devices, thus providing an easy way to extract log data from disk images. The disk image should either contain just a file system or a set of file systems within a GPT partition table, following the [Discoverable Partitions Specification](#)^[6]. For further information on supported disk images, see **systemd-nspawn(1)**'s switch of the same name.

--namespace=NAMESPACE

Takes a journal namespace identifier string as argument. If not specified the data collected by the default namespace is shown. If specified shows the log data of the specified namespace instead. If the namespace is specified as "*" data from all namespaces is shown, interleaved. If the namespace identifier is prefixed with "+" data from the specified namespace and the default namespace is shown, interleaved, but no other. For details about journal namespaces see **systemd-journald.service(8)**.

--header

Instead of showing journal contents, show internal header information of the journal fields accessed.

This option is particularly useful when trying to identify out-of-order journal entries, as happens for example when the machine is booted with the wrong system time.

--disk-usage

Shows the current disk usage of all journal files. This shows the sum of the disk usage of all archived and active journal files.

--vacuum-size=, --vacuum-time=, --vacuum-files=

Removes the oldest archived journal files until the disk space they use falls below the specified size (specified with the usual "K", "M", "G" and "T" suffixes), or all archived journal files contain no data older than the specified timespan (specified with the usual "s", "m", "h", "days", "months", "weeks" and "years" suffixes), or no more than the specified number of separate journal files remain. Note that running **--vacuum-size=** has only an indirect effect on the output shown by **--disk-usage**, as the

latter includes active journal files, while the vacuuming operation only operates on archived journal files. Similarly, **--vacuum-files=** might not actually reduce the number of journal files to below the specified number, as it will not remove active journal files.

--vacuum-size=, **--vacuum-time=** and **--vacuum-files=** may be combined in a single invocation to enforce any combination of a size, a time and a number of files limit on the archived journal files. Specifying any of these three parameters as zero is equivalent to not enforcing the specific limit, and is thus redundant.

These three switches may also be combined with **--rotate** into one command. If so, all active files are rotated first, and the requested vacuuming operation is executed right after. The rotation has the effect that all currently active files are archived (and potentially new, empty journal files opened as replacement), and hence the vacuuming operation has the greatest effect as it can take all log data written so far into account.

--list-catalog [128-bit-ID...]

List the contents of the message catalog as a table of message IDs, plus their short description strings.

If any *128-bit-IDs* are specified, only those entries are shown.

--dump-catalog [128-bit-ID...]

Show the contents of the message catalog, with entries separated by a line consisting of two dashes and the ID (the format is the same as .catalog files).

If any *128-bit-IDs* are specified, only those entries are shown.

--update-catalog

Update the message catalog index. This command needs to be executed each time new catalog files are installed, removed, or updated to rebuild the binary catalog index.

--setup-keys

Instead of showing journal contents, generate a new key pair for Forward Secure Sealing (FSS). This will generate a sealing key and a verification key. The sealing key is stored in the journal data directory and shall remain on the host. The verification key should be stored externally. Refer to the **Seal=** option in **journald.conf(5)** for information on Forward Secure Sealing and for a link to a refereed scholarly paper detailing the cryptographic theory it is based on.

--force

When **--setup-keys** is passed and Forward Secure Sealing (FSS) has already been configured, recreate FSS keys.

--interval=

Specifies the change interval for the sealing key when generating an FSS key pair with **--setup-keys**. Shorter intervals increase CPU consumption but shorten the time range of undetectable journal alterations. Defaults to 15min.

--verify

Check the journal file for internal consistency. If the file has been generated with FSS enabled and the FSS verification key has been specified with **--verify-key=**, authenticity of the journal file is verified.

--verify-key=

Specifies the FSS verification key to use for the **--verify** operation.

--sync

Asks the journal daemon to write all yet unwritten journal data to the backing file system and synchronize all journals. This call does not return until the synchronization operation is complete. This command guarantees that any log messages written before its invocation are safely stored on disk at the time it returns.

--flush

Asks the journal daemon to flush any log data stored in `/run/log/journal/` into `/var/log/journal/`, if persistent storage is enabled. This call does not return until the operation is complete. Note that this call is idempotent: the data is only flushed from `/run/log/journal/` into `/var/log/journal/` once during system runtime (but see **--relinquish-var** below), and this command exits cleanly without executing any operation if this has already happened. This command effectively guarantees that all data is flushed to `/var/log/journal/` at the time it returns.

--relinquish-var

Asks the journal daemon for the reverse operation to **--flush**: if requested the daemon will write further log data to `/run/log/journal/` and stops writing to `/var/log/journal/`. A subsequent call to **--flush** causes the log output to switch back to `/var/log/journal/`, see above.

--smart-relinquish-var

Similar to **--relinquish-var** but executes no operation if the root file system and `/var/lib/journal/` reside on the same mount point. This operation is used during system shutdown in order to make the journal daemon stop writing data to `/var/log/journal/` in case that directory is located on a mount point that needs to be unmounted.

--rotate

Asks the journal daemon to rotate journal files. This call does not return until the rotation operation is complete. Journal file rotation has the effect that all currently active journal files are marked as archived and renamed, so that they are never written to in future. New (empty) journal files are then created in their place. This operation may be combined with **--vacuum-size=**, **--vacuum-time=** and **--vacuum-file=** into a single command, see above.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

--no-pager

Do not pipe output into a pager.

EXIT STATUS

On success, 0 is returned; otherwise, a non-zero failure code is returned.

ENVIRONMENT

\$SYSTEMD_LOG_LEVEL

The maximum log level of emitted messages (messages with a higher log level, i.e. less important ones, will be suppressed). Either one of (in order of decreasing importance) **emerg**, **alert**, **crit**, **err**, **warning**, **notice**, **info**, **debug**, or an integer in the range 0...7. See **syslog(3)** for more information.

\$SYSTEMD_LOG_COLOR

A boolean. If true, messages written to the tty will be colored according to priority.

This setting is only useful when messages are written directly to the terminal, because **journalctl(1)** and other tools that display logs will color messages based on the log level on their own.

\$SYSTEMD_LOG_TIME

A boolean. If true, console log messages will be prefixed with a timestamp.

This setting is only useful when messages are written directly to the terminal or a file, because **journalctl(1)** and other tools that display logs will attach timestamps based on the entry metadata on their own.

\$SYSTEMD_LOG_LOCATION

A boolean. If true, messages will be prefixed with a filename and line number in the source code where the message originates.

Note that the log location is often attached as metadata to journal entries anyway. Including it directly

in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TID

A boolean. If true, messages will be prefixed with the current numerical thread ID (TID).

Note that the this information is attached as metadata to journal entries anyway. Including it directly in the message text can nevertheless be convenient when debugging programs.

\$SYSTEMD_LOG_TARGET

The destination for log messages. One of **console** (log to the attached tty), **console-prefixed** (log to the attached tty but with prefixes encoding the log level and "facility", see [syslog\(3\)](#)), **kmsg** (log to the kernel circular log buffer), **journal** (log to the journal), **journal-or-kmsg** (log to the journal if available, and to kmsg otherwise), **auto** (determine the appropriate log target automatically, the default), **null** (disable log output).

\$SYSTEMD_PAGER

Pager to use when **--no-pager** is not given; overrides **\$PAGER**. If neither **\$SYSTEMD_PAGER** nor **\$PAGER** are set, a set of well-known pager implementations are tried in turn, including **less(1)** and **more(1)**, until one is found. If no pager implementation is discovered no pager is invoked. Setting this environment variable to an empty string or the value "cat" is equivalent to passing **--no-pager**.

\$SYSTEMD_LESS

Override the options passed to **less** (by default "FRSXMK").

Users might want to change two options in particular:

K

This option instructs the pager to exit immediately when Ctrl+C is pressed. To allow **less** to handle Ctrl+C itself to switch back to the pager command prompt, unset this option.

If the value of **\$SYSTEMD_LESS** does not include "K", and the pager that is invoked is **less**, Ctrl+C will be ignored by the executable, and needs to be handled by the pager.

X

This option instructs the pager to not send termcap initialization and deinitialization strings to the terminal. It is set by default to allow command output to remain visible in the terminal even after the pager exits. Nevertheless, this prevents some pager functionality from working, in particular paged output cannot be scrolled with the mouse.

See **less(1)** for more discussion.

\$SYSTEMD_LESSCHARSET

Override the charset passed to **less** (by default "utf-8", if the invoking terminal is determined to be UTF-8 compatible).

\$SYSTEMD_PAGERSECURE

Takes a boolean argument. When true, the "secure" mode of the pager is enabled; if false, disabled. If **\$SYSTEMD_PAGERSECURE** is not set at all, secure mode is enabled if the effective UID is not the same as the owner of the login session, see **geteuid(2)** and **sd_pid_get_owner_uid(3)**. In secure mode, **LESSSECURE=1** will be set when invoking the pager, and the pager shall disable commands that open or create new files or start new subprocesses. When **\$SYSTEMD_PAGERSECURE** is not set at all, pagers which are not known to implement secure mode will not be used. (Currently only **less(1)** implements secure mode.)

Note: when commands are invoked with elevated privileges, for example under **sudo(8)** or **pkexec(1)**, care must be taken to ensure that unintended interactive features are not enabled. "Secure" mode for the pager may be enabled automatically as described above. Setting **SYSTEMD_PAGERSECURE=0** or not removing it from the inherited environment allows the user to invoke arbitrary commands. Note that if the **\$SYSTEMD_PAGER** or **\$PAGER** variables are to be honoured,

\$SYSTEMD_PAGERSECURE must be set too. It might be reasonable to completely disable the pager using **--no-pager** instead.

\$SYSTEMD_COLORS

Takes a boolean argument. When true, **systemd** and related utilities will use colors in their output, otherwise the output will be monochrome. Additionally, the variable can take one of the following special values: "16", "256" to restrict the use of colors to the base 16 or 256 ANSI colors, respectively. This can be specified to override the automatic decision based on **\$TERM** and what the console is connected to.

\$SYSTEMD_URLIFY

The value must be a boolean. Controls whether clickable links should be generated in the output for terminal emulators supporting this. This can be specified to override the decision that **systemd** makes based on **\$TERM** and other conditions.

EXAMPLES

Without arguments, all collected logs are shown unfiltered:

```
journalctl
```

With one match specified, all entries with a field matching the expression are shown:

```
journalctl _SYSTEMD_UNIT=avahi-daemon.service
```

```
journalctl _SYSTEMD_CGROUP=/user.slice/user-42.slice/session-c1.scope
```

If two different fields are matched, only entries matching both expressions at the same time are shown:

```
journalctl _SYSTEMD_UNIT=avahi-daemon.service _PID=28097
```

If two matches refer to the same field, all entries matching either expression are shown:

```
journalctl _SYSTEMD_UNIT=avahi-daemon.service _SYSTEMD_UNIT=dbus.service
```

If the separator "+" is used, two expressions may be combined in a logical OR. The following will show all messages from the Avahi service process with the PID 28097 plus all messages from the D-Bus service (from any of its processes):

```
journalctl _SYSTEMD_UNIT=avahi-daemon.service _PID=28097 + _SYSTEMD_UNIT=dbus.service
```

To show all fields emitted *by* a unit and *about* the unit, option **-u**/**--unit=** should be used. **journalctl -u name** expands to a complex filter similar to

```
_SYSTEMD_UNIT=name.service
+ UNIT=name.service _PID=1
+ OBJECT_SYSTEMD_UNIT=name.service _UID=0
+ COREDUMP_UNIT=name.service _UID=0 MESSAGE_ID=fc2e22bc6ee647b6b90729ab34a250b1
```

(see **systemd.journal-fields(7)** for an explanation of those patterns).

Show all logs generated by the D-Bus executable:

```
journalctl /usr/bin/dbus-daemon
```

Show all kernel logs from previous boot:

```
journalctl -k -b -1
```

Show a live log display from a system service apache.service:

```
journalctl -f -u apache
```

NAME

journald.conf, journald.conf.d, journald@.conf – Journal service configuration files

SYNOPSIS

```
/etc/systemd/journald.conf
/etc/systemd/journald.conf.d/*.conf
/run/systemd/journald.conf.d/*.conf
/usr/lib/systemd/journald.conf.d/*.conf
/etc/systemd/journald@NAMESPACE.conf
/etc/systemd/journald@NAMESPACE.conf.d/*.conf
/run/systemd/journald@NAMESPACE.conf.d/*.conf
/usr/lib/systemd/journald@NAMESPACE.conf.d/*.conf
```

DESCRIPTION

These files configure various parameters of the systemd journal service, **systemd-journald.service(8)**. See **systemd.syntax(7)** for a general description of the syntax.

The **systemd-journald** instance managing the default namespace is configured by `/etc/systemd/journald.conf` and associated drop-ins. Instances managing other namespaces read `/etc/systemd/journald@NAMESPACE.conf` and associated drop-ins with the namespace identifier filled in. This allows each namespace to carry a distinct configuration. See **systemd-journald.service(8)** for details about journal namespaces.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in `/etc/systemd/` contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from `/usr/lib/systemd/*.conf.d/`, `/usr/local/lib/systemd/*.conf.d/`, and `/etc/systemd/*.conf.d/`. Those drop-ins have higher precedence and override the main configuration file. Files in the `*.conf.d/` configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under `/usr/`. Files in `/etc/` are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to `/dev/null` in the configuration directory in `/etc/`, with the same filename as the vendor configuration file.

OPTIONS

All options are configured in the [Journal] section:

Storage=

Controls where to store journal data. One of "volatile", "persistent", "auto" and "none". If "volatile", journal log data will be stored only in memory, i.e. below the `/run/log/journal` hierarchy (which is created if needed). If "persistent", data will be stored preferably on disk, i.e. below the `/var/log/journal` hierarchy (which is created if needed), with a fallback to `/run/log/journal` (which is created if needed), during early boot and if the disk is not writable. "auto" behaves like "persistent" if the `/var/log/journal` directory exists, and "volatile" otherwise (the existence of the directory controls the storage mode).

"none" turns off all storage, all log data received will be dropped (but forwarding to other targets, such as the console, the kernel log buffer, or a syslog socket will still work). Defaults to "auto" in the default journal namespace, and "persistent" in all others.

Note that journald will initially use volatile storage, until a call to **journalctl --flush** (or sending **SIGUSR1** to journald) will cause it to switch to persistent logging (under the conditions mentioned above). This is done automatically on boot via "systemd-journal-flush.service".

Note that when this option is changed to "volatile", existing persistent data is not removed. In the other direction, **journalctl(1)** with the **--flush** option may be used to move volatile data to persistent storage.

Compress=

Can take a boolean value. If enabled (the default), data objects that shall be stored in the journal and are larger than the default threshold of 512 bytes are compressed before they are written to the file system. It can also be set to a number of bytes to specify the compression threshold directly. Suffixes like K, M, and G can be used to specify larger units.

Seal=

Takes a boolean value. If enabled (the default), and a sealing key is available (as created by **journalctl(1)**'s **--setup-keys** command), Forward Secure Sealing (FSS) for all persistent journal files is enabled. FSS is based on [Seekable Sequential Key Generators^{\[1\]}](#) by G. A. Marson and B. Poettering (doi:10.1007/978-3-642-40203-6_7) and may be used to protect journal files from unnoticed alteration.

SplitMode=

Controls whether to split up journal files per user, either "uid" or "none". Split journal files are primarily useful for access control: on UNIX/Linux access control is managed per file, and the journal daemon will assign users read access to their journal files. If "uid", all regular users (with UID outside the range of system users, dynamic service users, and the nobody user) will each get their own journal files, and system users will log to the system journal. See [Users, Groups, UIDs and GIDs on systemd systems^{\[2\]}](#) for more details about UID ranges. If "none", journal files are not split up by user and all messages are instead stored in the single system journal. In this mode unprivileged users generally do not have access to their own log data. Note that splitting up journal files by user is only available for journals stored persistently. If journals are stored on volatile storage (see *Storage=* above), only a single journal file is used. Defaults to "uid".

RateLimitIntervalSec=, RateLimitBurst=

Configures the rate limiting that is applied to all messages generated on the system. If, in the time interval defined by *RateLimitIntervalSec=*, more messages than specified in *RateLimitBurst=* are logged by a service, all further messages within the interval are dropped until the interval is over. A message about the number of dropped messages is generated. This rate limiting is applied per-service, so that two services which log do not interfere with each other's limits. Defaults to 10000 messages in 30s. The time specification for *RateLimitIntervalSec=* may be specified in the following units: "s", "min", "h", "ms", "us". To turn off any kind of rate limiting, set either value to 0.

Note that the effective rate limit is multiplied by a factor derived from the available free disk space for the journal. Currently, this factor is calculated using the base 2 logarithm.

Table 1. Example *RateLimitBurst=* rate modifications by the available disk space

Available Disk Space	Burst Multiplier
<= 1MB	1
<= 16MB	2
<= 256MB	3
<= 4GB	4
<= 64GB	5
<= 1TB	6

If a service provides rate limits for itself through *LogRateLimitIntervalSec*= and/or *LogRateLimitBurst*= in **systemd.exec**(5), those values will override the settings specified here.

SystemMaxUse=, *SystemKeepFree*=, *SystemMaxFileSize*=, *SystemMaxFiles*=, *RuntimeMaxUse*=, *RuntimeKeepFree*=, *RuntimeMaxFileSize*=, *RuntimeMaxFiles*=

Enforce size limits on the journal files stored. The options prefixed with "System" apply to the journal files when stored on a persistent file system, more specifically /var/log/journal. The options prefixed with "Runtime" apply to the journal files when stored on a volatile in-memory file system, more specifically /run/log/journal. The former is used only when /var/ is mounted, writable, and the directory /var/log/journal exists. Otherwise, only the latter applies. Note that this means that during early boot and if the administrator disabled persistent logging, only the latter options apply, while the former apply if persistent logging is enabled and the system is fully booted up. **journaldctl** and **systemd-journald** ignore all files with names not ending with ".journal" or ".journal~", so only such files, located in the appropriate directories, are taken into account when calculating current disk usage.

SystemMaxUse= and *RuntimeMaxUse*= control how much disk space the journal may use up at most. *SystemKeepFree*= and *RuntimeKeepFree*= control how much disk space **systemd-journald** shall leave free for other uses. **systemd-journald** will respect both limits and use the smaller of the two values.

The first pair defaults to 10% and the second to 15% of the size of the respective file system, but each value is capped to 4G. If the file system is nearly full and either *SystemKeepFree*= or *RuntimeKeepFree*= are violated when **systemd-journald** is started, the limit will be raised to the percentage that is actually free. This means that if there was enough free space before and journal files were created, and subsequently something else causes the file system to fill up, **journald** will stop using more space, but it will not be removing existing files to reduce the footprint again, either. Also note that only archived files are deleted to reduce the space occupied by journal files. This means that, in effect, there might still be more space used than *SystemMaxUse*= or *RuntimeMaxUse*= limit after a vacuuming operation is complete.

SystemMaxFileSize= and *RuntimeMaxFileSize*= control how large individual journal files may grow at most. This influences the granularity in which disk space is made available through rotation, i.e. deletion of historic data. Defaults to one eighth of the values configured with *SystemMaxUse*= and *RuntimeMaxUse*=, so that usually seven rotated journal files are kept as history.

Specify values in bytes or use K, M, G, T, P, E as units for the specified sizes (equal to 1024, 1024², ... bytes). Note that size limits are enforced synchronously when journal files are extended, and no explicit rotation step triggered by time is needed.

SystemMaxFiles= and *RuntimeMaxFiles*= control how many individual journal files to keep at most. Note that only archived files are deleted to reduce the number of files until this limit is reached; active files will stay around. This means that, in effect, there might still be more journal files around in total than this limit after a vacuuming operation is complete. This setting defaults to 100.

MaxFileSec=

The maximum time to store entries in a single journal file before rotating to the next one. Normally, time-based rotation should not be required as size-based rotation with options such as *SystemMaxFileSize*= should be sufficient to ensure that journal files do not grow without bounds.

However, to ensure that not too much data is lost at once when old journal files are deleted, it might make sense to change this value from the default of one month. Set to 0 to turn off this feature. This setting takes time values which may be suffixed with the units "year", "month", "week", "day", "h" or "m" to override the default time unit of seconds.

MaxRetentionSec=

The maximum time to store journal entries. This controls whether journal files containing entries older than the specified time span are deleted. Normally, time-based deletion of old journal files should not be required as size-based deletion with options such as *SystemMaxUse=* should be sufficient to ensure that journal files do not grow without bounds. However, to enforce data retention policies, it might make sense to change this value from the default of 0 (which turns off this feature). This setting also takes time values which may be suffixed with the units "year", "month", "week", "day", "h" or "m" to override the default time unit of seconds.

SyncIntervalSec=

The timeout before synchronizing journal files to disk. After syncing, journal files are placed in the OFFLINE state. Note that syncing is unconditionally done immediately after a log message of priority CRIT, ALERT or EMERG has been logged. This setting hence applies only to messages of the levels ERR, WARNING, NOTICE, INFO, DEBUG. The default timeout is 5 minutes.

ForwardToSyslog=, *ForwardToKMsg=*, *ForwardToConsole=*, *ForwardToWall=*

Control whether log messages received by the journal daemon shall be forwarded to a traditional syslog daemon, to the kernel log buffer (kmsg), to the system console, or sent as wall messages to all logged-in users. These options take boolean arguments. If forwarding to syslog is enabled but nothing reads messages from the socket, forwarding to syslog has no effect. By default, only forwarding to syslog and wall is enabled. These settings may be overridden at boot time with the kernel command line options "systemd.journald.forward_to_syslog", "systemd.journald.forward_to_kmsg", "systemd.journald.forward_to_console", and "systemd.journald.forward_to_wall". If the option name is specified without "=" and the following argument, true is assumed. Otherwise, the argument is parsed as a boolean.

When forwarding to the console, the TTY to log to can be changed with *TTYPath=*, described below.

When forwarding to the kernel log buffer (kmsg), make sure to select a suitably large size for the log buffer, for example by adding "log_buf_len=8M" to the kernel command line. **systemd** will automatically disable kernel's rate-limiting applied to userspace processes (equivalent to setting "printk.devkmsg=on").

MaxLevelStore=, *MaxLevelSyslog=*, *MaxLevelKMsg=*, *MaxLevelConsole=*, *MaxLevelWall=*

Controls the maximum log level of messages that are stored in the journal, forwarded to syslog, kmsg, the console or wall (if that is enabled, see above). As argument, takes one of "emerg", "alert", "crit", "err", "warning", "notice", "info", "debug", or integer values in the range of 0–7 (corresponding to the same levels). Messages equal or below the log level specified are stored/forwarded, messages above are dropped. Defaults to "debug" for *MaxLevelStore=* and *MaxLevelSyslog=*, to ensure that all messages are stored in the journal and forwarded to syslog. Defaults to "notice" for *MaxLevelKMsg=*, "info" for *MaxLevelConsole=*, and "emerg" for *MaxLevelWall=*. These settings may be overridden at boot time with the kernel command line options "systemd.journald.max_level_store=", "systemd.journald.max_level_syslog=", "systemd.journald.max_level_kmsg=", "systemd.journald.max_level_console=", "systemd.journald.max_level_wall=".

ReadKMsg=

Takes a boolean value. If enabled **systemd-journal** processes /dev/kmsg messages generated by the kernel. In the default journal namespace this option is enabled by default, it is disabled in all others.

Audit=

Takes a boolean value. If enabled **systemd-journal** will turn on kernel auditing on start-up. If disabled it will turn it off. If unset it will neither enable nor disable it, leaving the previous state unchanged. Note that this option does not control whether **systemd-journald** collects generated audit

records, it just controls whether it tells the kernel to generate them. This means if another tool turns on auditing even if **systemd-journald** left it off, it will still collect the generated messages. Defaults to off.

TTYPath=

Change the console TTY to use if *ForwardToConsole=yes* is used. Defaults to /dev/console.

LineMax=

The maximum line length to permit when converting stream logs into record logs. When a systemd unit's standard output/error are connected to the journal via a stream socket, the data read is split into individual log records at newline ("\\n", ASCII 10) and **NUL** characters. If no such delimiter is read for the specified number of bytes a hard log record boundary is artificially inserted, breaking up overly long lines into multiple log records. Selecting overly large values increases the possible memory usage of the Journal daemon for each stream client, as in the worst case the journal daemon needs to buffer the specified number of bytes in memory before it can flush a new log record to disk. Also note that permitting overly large line maximum line lengths affects compatibility with traditional log protocols as log records might not fit anymore into a single **AF_UNIX** or **AF_INET** datagram. Takes a size in bytes. If the value is suffixed with K, M, G or T, the specified size is parsed as Kilobytes, Megabytes, Gigabytes, or Terabytes (with the base 1024), respectively. Defaults to 48K, which is relatively large but still small enough so that log records likely fit into network datagrams along with extra room for metadata. Note that values below 79 are not accepted and will be bumped to 79.

FORWARDING TO TRADITIONAL SYSLOG DAEMONS

Journal events can be transferred to a different logging daemon in two different ways. With the first method, messages are immediately forwarded to a socket (/run/systemd/journal/syslog), where the traditional syslog daemon can read them. This method is controlled by the *ForwardToSyslog=* option. With a second method, a syslog daemon behaves like a normal journal client, and reads messages from the journal files, similarly to **journalctl(1)**. With this, messages do not have to be read immediately, which allows a logging daemon which is only started late in boot to access all messages since the start of the system. In addition, full structured meta-data is available to it. This method of course is available only if the messages are stored in a journal file at all. So it will not work if *Storage=none* is set. It should be noted that usually the *second* method is used by syslog daemons, so the *Storage=* option, and not the *ForwardToSyslog=* option, is relevant for them.

NAME

journald.conf, journald.conf.d, journald@.conf – Journal service configuration files

SYNOPSIS

```
/etc/systemd/journald.conf
/etc/systemd/journald.conf.d/*.conf
/run/systemd/journald.conf.d/*.conf
/usr/lib/systemd/journald.conf.d/*.conf
/etc/systemd/journald@NAMESPACE.conf
/etc/systemd/journald@NAMESPACE.conf.d/*.conf
/run/systemd/journald@NAMESPACE.conf.d/*.conf
/usr/lib/systemd/journald@NAMESPACE.conf.d/*.conf
```

DESCRIPTION

These files configure various parameters of the systemd journal service, **systemd-journald.service(8)**. See **systemd.syntax(7)** for a general description of the syntax.

The **systemd-journald** instance managing the default namespace is configured by `/etc/systemd/journald.conf` and associated drop-ins. Instances managing other namespaces read `/etc/systemd/journald@NAMESPACE.conf` and associated drop-ins with the namespace identifier filled in. This allows each namespace to carry a distinct configuration. See **systemd-journald.service(8)** for details about journal namespaces.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in `/etc/systemd/` contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from `/usr/lib/systemd/*.conf.d/`, `/usr/local/lib/systemd/*.conf.d/`, and `/etc/systemd/*.conf.d/`. Those drop-ins have higher precedence and override the main configuration file. Files in the `*.conf.d/` configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under `/usr/`. Files in `/etc/` are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to `/dev/null` in the configuration directory in `/etc/`, with the same filename as the vendor configuration file.

OPTIONS

All options are configured in the [Journal] section:

Storage=

Controls where to store journal data. One of "volatile", "persistent", "auto" and "none". If "volatile", journal log data will be stored only in memory, i.e. below the `/run/log/journal` hierarchy (which is created if needed). If "persistent", data will be stored preferably on disk, i.e. below the `/var/log/journal` hierarchy (which is created if needed), with a fallback to `/run/log/journal` (which is created if needed), during early boot and if the disk is not writable. "auto" behaves like "persistent" if the `/var/log/journal` directory exists, and "volatile" otherwise (the existence of the directory controls the storage mode).

"none" turns off all storage, all log data received will be dropped (but forwarding to other targets, such as the console, the kernel log buffer, or a syslog socket will still work). Defaults to "auto" in the default journal namespace, and "persistent" in all others.

Note that journald will initially use volatile storage, until a call to **journalctl --flush** (or sending **SIGUSR1** to journald) will cause it to switch to persistent logging (under the conditions mentioned above). This is done automatically on boot via "systemd-journal-flush.service".

Note that when this option is changed to "volatile", existing persistent data is not removed. In the other direction, **journalctl(1)** with the **--flush** option may be used to move volatile data to persistent storage.

Compress=

Can take a boolean value. If enabled (the default), data objects that shall be stored in the journal and are larger than the default threshold of 512 bytes are compressed before they are written to the file system. It can also be set to a number of bytes to specify the compression threshold directly. Suffixes like K, M, and G can be used to specify larger units.

Seal=

Takes a boolean value. If enabled (the default), and a sealing key is available (as created by **journalctl(1)**'s **--setup-keys** command), Forward Secure Sealing (FSS) for all persistent journal files is enabled. FSS is based on [Seekable Sequential Key Generators^{\[1\]}](#) by G. A. Marson and B. Poettering (doi:10.1007/978-3-642-40203-6_7) and may be used to protect journal files from unnoticed alteration.

SplitMode=

Controls whether to split up journal files per user, either "uid" or "none". Split journal files are primarily useful for access control: on UNIX/Linux access control is managed per file, and the journal daemon will assign users read access to their journal files. If "uid", all regular users (with UID outside the range of system users, dynamic service users, and the nobody user) will each get their own journal files, and system users will log to the system journal. See [Users, Groups, UIDs and GIDs on systemd systems^{\[2\]}](#) for more details about UID ranges. If "none", journal files are not split up by user and all messages are instead stored in the single system journal. In this mode unprivileged users generally do not have access to their own log data. Note that splitting up journal files by user is only available for journals stored persistently. If journals are stored on volatile storage (see *Storage=* above), only a single journal file is used. Defaults to "uid".

RateLimitIntervalSec=, RateLimitBurst=

Configures the rate limiting that is applied to all messages generated on the system. If, in the time interval defined by *RateLimitIntervalSec=*, more messages than specified in *RateLimitBurst=* are logged by a service, all further messages within the interval are dropped until the interval is over. A message about the number of dropped messages is generated. This rate limiting is applied per-service, so that two services which log do not interfere with each other's limits. Defaults to 10000 messages in 30s. The time specification for *RateLimitIntervalSec=* may be specified in the following units: "s", "min", "h", "ms", "us". To turn off any kind of rate limiting, set either value to 0.

Note that the effective rate limit is multiplied by a factor derived from the available free disk space for the journal. Currently, this factor is calculated using the base 2 logarithm.

Table 1. Example *RateLimitBurst=* rate modifications by the available disk space

Available Disk Space	Burst Multiplier
<= 1MB	1
<= 16MB	2
<= 256MB	3
<= 4GB	4
<= 64GB	5
<= 1TB	6

If a service provides rate limits for itself through *LogRateLimitIntervalSec*= and/or *LogRateLimitBurst*= in **systemd.exec(5)**, those values will override the settings specified here.

SystemMaxUse=, *SystemKeepFree*=, *SystemMaxFileSize*=, *SystemMaxFiles*=, *RuntimeMaxUse*=, *RuntimeKeepFree*=, *RuntimeMaxFileSize*=, *RuntimeMaxFiles*=

Enforce size limits on the journal files stored. The options prefixed with "System" apply to the journal files when stored on a persistent file system, more specifically /var/log/journal. The options prefixed with "Runtime" apply to the journal files when stored on a volatile in-memory file system, more specifically /run/log/journal. The former is used only when /var/ is mounted, writable, and the directory /var/log/journal exists. Otherwise, only the latter applies. Note that this means that during early boot and if the administrator disabled persistent logging, only the latter options apply, while the former apply if persistent logging is enabled and the system is fully booted up. **journalctl** and **systemd-journald** ignore all files with names not ending with ".journal" or ".journal~", so only such files, located in the appropriate directories, are taken into account when calculating current disk usage.

SystemMaxUse= and *RuntimeMaxUse*= control how much disk space the journal may use up at most. *SystemKeepFree*= and *RuntimeKeepFree*= control how much disk space **systemd-journald** shall leave free for other uses. **systemd-journald** will respect both limits and use the smaller of the two values.

The first pair defaults to 10% and the second to 15% of the size of the respective file system, but each value is capped to 4G. If the file system is nearly full and either *SystemKeepFree*= or *RuntimeKeepFree*= are violated when **systemd-journald** is started, the limit will be raised to the percentage that is actually free. This means that if there was enough free space before and journal files were created, and subsequently something else causes the file system to fill up, **journald** will stop using more space, but it will not be removing existing files to reduce the footprint again, either. Also note that only archived files are deleted to reduce the space occupied by journal files. This means that, in effect, there might still be more space used than *SystemMaxUse*= or *RuntimeMaxUse*= limit after a vacuuming operation is complete.

SystemMaxFileSize= and *RuntimeMaxFileSize*= control how large individual journal files may grow at most. This influences the granularity in which disk space is made available through rotation, i.e. deletion of historic data. Defaults to one eighth of the values configured with *SystemMaxUse*= and *RuntimeMaxUse*=, so that usually seven rotated journal files are kept as history.

Specify values in bytes or use K, M, G, T, P, E as units for the specified sizes (equal to 1024, 1024², ... bytes). Note that size limits are enforced synchronously when journal files are extended, and no explicit rotation step triggered by time is needed.

SystemMaxFiles= and *RuntimeMaxFiles*= control how many individual journal files to keep at most. Note that only archived files are deleted to reduce the number of files until this limit is reached; active files will stay around. This means that, in effect, there might still be more journal files around in total than this limit after a vacuuming operation is complete. This setting defaults to 100.

MaxFileSec=

The maximum time to store entries in a single journal file before rotating to the next one. Normally, time-based rotation should not be required as size-based rotation with options such as *SystemMaxFileSize*= should be sufficient to ensure that journal files do not grow without bounds.

However, to ensure that not too much data is lost at once when old journal files are deleted, it might make sense to change this value from the default of one month. Set to 0 to turn off this feature. This setting takes time values which may be suffixed with the units "year", "month", "week", "day", "h" or "m" to override the default time unit of seconds.

MaxRetentionSec=

The maximum time to store journal entries. This controls whether journal files containing entries older than the specified time span are deleted. Normally, time-based deletion of old journal files should not be required as size-based deletion with options such as *SystemMaxUse=* should be sufficient to ensure that journal files do not grow without bounds. However, to enforce data retention policies, it might make sense to change this value from the default of 0 (which turns off this feature). This setting also takes time values which may be suffixed with the units "year", "month", "week", "day", "h" or "m" to override the default time unit of seconds.

SyncIntervalSec=

The timeout before synchronizing journal files to disk. After syncing, journal files are placed in the OFFLINE state. Note that syncing is unconditionally done immediately after a log message of priority CRIT, ALERT or EMERG has been logged. This setting hence applies only to messages of the levels ERR, WARNING, NOTICE, INFO, DEBUG. The default timeout is 5 minutes.

ForwardToSyslog=, *ForwardToKMsg=*, *ForwardToConsole=*, *ForwardToWall=*

Control whether log messages received by the journal daemon shall be forwarded to a traditional syslog daemon, to the kernel log buffer (kmsg), to the system console, or sent as wall messages to all logged-in users. These options take boolean arguments. If forwarding to syslog is enabled but nothing reads messages from the socket, forwarding to syslog has no effect. By default, only forwarding to syslog and wall is enabled. These settings may be overridden at boot time with the kernel command line options "systemd.journald.forward_to_syslog", "systemd.journald.forward_to_kmsg", "systemd.journald.forward_to_console", and "systemd.journald.forward_to_wall". If the option name is specified without "=" and the following argument, true is assumed. Otherwise, the argument is parsed as a boolean.

When forwarding to the console, the TTY to log to can be changed with *TTYPath=*, described below.

When forwarding to the kernel log buffer (kmsg), make sure to select a suitably large size for the log buffer, for example by adding "log_buf_len=8M" to the kernel command line. **systemd** will automatically disable kernel's rate-limiting applied to userspace processes (equivalent to setting "printk.devkmsg=on").

MaxLevelStore=, *MaxLevelSyslog=*, *MaxLevelKMsg=*, *MaxLevelConsole=*, *MaxLevelWall=*

Controls the maximum log level of messages that are stored in the journal, forwarded to syslog, kmsg, the console or wall (if that is enabled, see above). As argument, takes one of "emerg", "alert", "crit", "err", "warning", "notice", "info", "debug", or integer values in the range of 0–7 (corresponding to the same levels). Messages equal or below the log level specified are stored/forwarded, messages above are dropped. Defaults to "debug" for *MaxLevelStore=* and *MaxLevelSyslog=*, to ensure that all messages are stored in the journal and forwarded to syslog. Defaults to "notice" for *MaxLevelKMsg=*, "info" for *MaxLevelConsole=*, and "emerg" for *MaxLevelWall=*. These settings may be overridden at boot time with the kernel command line options "systemd.journald.max_level_store=", "systemd.journald.max_level_syslog=", "systemd.journald.max_level_kmsg=", "systemd.journald.max_level_console=", "systemd.journald.max_level_wall=".

ReadKMsg=

Takes a boolean value. If enabled **systemd-journal** processes /dev/kmsg messages generated by the kernel. In the default journal namespace this option is enabled by default, it is disabled in all others.

Audit=

Takes a boolean value. If enabled **systemd-journal** will turn on kernel auditing on start-up. If disabled it will turn it off. If unset it will neither enable nor disable it, leaving the previous state unchanged. Note that this option does not control whether **systemd-journald** collects generated audit

records, it just controls whether it tells the kernel to generate them. This means if another tool turns on auditing even if **systemd-journald** left it off, it will still collect the generated messages. Defaults to off.

TTYPath=

Change the console TTY to use if *ForwardToConsole=yes* is used. Defaults to /dev/console.

LineMax=

The maximum line length to permit when converting stream logs into record logs. When a systemd unit's standard output/error are connected to the journal via a stream socket, the data read is split into individual log records at newline ("\n", ASCII 10) and **NUL** characters. If no such delimiter is read for the specified number of bytes a hard log record boundary is artificially inserted, breaking up overly long lines into multiple log records. Selecting overly large values increases the possible memory usage of the Journal daemon for each stream client, as in the worst case the journal daemon needs to buffer the specified number of bytes in memory before it can flush a new log record to disk. Also note that permitting overly large line maximum line lengths affects compatibility with traditional log protocols as log records might not fit anymore into a single **AF_UNIX** or **AF_INET** datagram. Takes a size in bytes. If the value is suffixed with K, M, G or T, the specified size is parsed as Kilobytes, Megabytes, Gigabytes, or Terabytes (with the base 1024), respectively. Defaults to 48K, which is relatively large but still small enough so that log records likely fit into network datagrams along with extra room for metadata. Note that values below 79 are not accepted and will be bumped to 79.

FORWARDING TO TRADITIONAL SYSLOG DAEMONS

Journal events can be transferred to a different logging daemon in two different ways. With the first method, messages are immediately forwarded to a socket (/run/systemd/journal/syslog), where the traditional syslog daemon can read them. This method is controlled by the *ForwardToSyslog=* option. With a second method, a syslog daemon behaves like a normal journal client, and reads messages from the journal files, similarly to **journalctl(1)**. With this, messages do not have to be read immediately, which allows a logging daemon which is only started late in boot to access all messages since the start of the system. In addition, full structured meta-data is available to it. This method of course is available only if the messages are stored in a journal file at all. So it will not work if *Storage=none* is set. It should be noted that usually the *second* method is used by syslog daemons, so the *Storage=* option, and not the *ForwardToSyslog=* option, is relevant for them.

NAME

journald.conf, journald.conf.d, journald@.conf – Journal service configuration files

SYNOPSIS

```
/etc/systemd/journald.conf
/etc/systemd/journald.conf.d/*.conf
/run/systemd/journald.conf.d/*.conf
/usr/lib/systemd/journald.conf.d/*.conf
/etc/systemd/journald@NAMESPACE.conf
/etc/systemd/journald@NAMESPACE.conf.d/*.conf
/run/systemd/journald@NAMESPACE.conf.d/*.conf
/usr/lib/systemd/journald@NAMESPACE.conf.d/*.conf
```

DESCRIPTION

These files configure various parameters of the systemd journal service, **systemd-journald.service(8)**. See **systemd.syntax(7)** for a general description of the syntax.

The **systemd-journald** instance managing the default namespace is configured by `/etc/systemd/journald.conf` and associated drop-ins. Instances managing other namespaces read `/etc/systemd/journald@NAMESPACE.conf` and associated drop-ins with the namespace identifier filled in. This allows each namespace to carry a distinct configuration. See **systemd-journald.service(8)** for details about journal namespaces.

CONFIGURATION DIRECTORIES AND PRECEDENCE

The default configuration is set during compilation, so configuration is only needed when it is necessary to deviate from those defaults. Initially, the main configuration file in `/etc/systemd/` contains commented out entries showing the defaults as a guide to the administrator. Local overrides can be created by editing this file or by creating drop-ins, as described below. Using drop-ins for local configuration is recommended over modifications to the main configuration file.

In addition to the "main" configuration file, drop-in configuration snippets are read from `/usr/lib/systemd/*.conf.d/`, `/usr/local/lib/systemd/*.conf.d/`, and `/etc/systemd/*.conf.d/`. Those drop-ins have higher precedence and override the main configuration file. Files in the `*.conf.d/` configuration subdirectories are sorted by their filename in lexicographic order, regardless of in which of the subdirectories they reside. When multiple files specify the same option, for options which accept just a single value, the entry in the file sorted last takes precedence, and for options which accept a list of values, entries are collected as they occur in the sorted files.

When packages need to customize the configuration, they can install drop-ins under `/usr/`. Files in `/etc/` are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. Drop-ins have to be used to override package drop-ins, since the main configuration file has lower precedence. It is recommended to prefix all filenames in those subdirectories with a two-digit number and a dash, to simplify the ordering of the files.

To disable a configuration file supplied by the vendor, the recommended way is to place a symlink to `/dev/null` in the configuration directory in `/etc/`, with the same filename as the vendor configuration file.

OPTIONS

All options are configured in the [Journal] section:

Storage=

Controls where to store journal data. One of "volatile", "persistent", "auto" and "none". If "volatile", journal log data will be stored only in memory, i.e. below the `/run/log/journal` hierarchy (which is created if needed). If "persistent", data will be stored preferably on disk, i.e. below the `/var/log/journal` hierarchy (which is created if needed), with a fallback to `/run/log/journal` (which is created if needed), during early boot and if the disk is not writable. "auto" behaves like "persistent" if the `/var/log/journal` directory exists, and "volatile" otherwise (the existence of the directory controls the storage mode).

"none" turns off all storage, all log data received will be dropped (but forwarding to other targets, such as the console, the kernel log buffer, or a syslog socket will still work). Defaults to "auto" in the default journal namespace, and "persistent" in all others.

Note that journald will initially use volatile storage, until a call to **journalctl --flush** (or sending **SIGUSR1** to journald) will cause it to switch to persistent logging (under the conditions mentioned above). This is done automatically on boot via "systemd-journal-flush.service".

Note that when this option is changed to "volatile", existing persistent data is not removed. In the other direction, **journald(1)** with the **--flush** option may be used to move volatile data to persistent storage.

Compress=

Can take a boolean value. If enabled (the default), data objects that shall be stored in the journal and are larger than the default threshold of 512 bytes are compressed before they are written to the file system. It can also be set to a number of bytes to specify the compression threshold directly. Suffixes like K, M, and G can be used to specify larger units.

Seal=

Takes a boolean value. If enabled (the default), and a sealing key is available (as created by **journald(1)**'s **--setup-keys** command), Forward Secure Sealing (FSS) for all persistent journal files is enabled. FSS is based on [Seekable Sequential Key Generators^{\[1\]}](#) by G. A. Marson and B. Poettering (doi:10.1007/978-3-642-40203-6_7) and may be used to protect journal files from unnoticed alteration.

SplitMode=

Controls whether to split up journal files per user, either "uid" or "none". Split journal files are primarily useful for access control: on UNIX/Linux access control is managed per file, and the journal daemon will assign users read access to their journal files. If "uid", all regular users (with UID outside the range of system users, dynamic service users, and the nobody user) will each get their own journal files, and system users will log to the system journal. See [Users, Groups, UIDs and GIDs on systemd systems^{\[2\]}](#) for more details about UID ranges. If "none", journal files are not split up by user and all messages are instead stored in the single system journal. In this mode unprivileged users generally do not have access to their own log data. Note that splitting up journal files by user is only available for journals stored persistently. If journals are stored on volatile storage (see *Storage=* above), only a single journal file is used. Defaults to "uid".

RateLimitIntervalSec=, RateLimitBurst=

Configures the rate limiting that is applied to all messages generated on the system. If, in the time interval defined by *RateLimitIntervalSec=*, more messages than specified in *RateLimitBurst=* are logged by a service, all further messages within the interval are dropped until the interval is over. A message about the number of dropped messages is generated. This rate limiting is applied per-service, so that two services which log do not interfere with each other's limits. Defaults to 10000 messages in 30s. The time specification for *RateLimitIntervalSec=* may be specified in the following units: "s", "min", "h", "ms", "us". To turn off any kind of rate limiting, set either value to 0.

Note that the effective rate limit is multiplied by a factor derived from the available free disk space for the journal. Currently, this factor is calculated using the base 2 logarithm.

Table 1. Example *RateLimitBurst=* rate modifications by the available disk space

Available Disk Space	Burst Multiplier
<= 1MB	1
<= 16MB	2
<= 256MB	3
<= 4GB	4
<= 64GB	5
<= 1TB	6

If a service provides rate limits for itself through *LogRateLimitIntervalSec*= and/or *LogRateLimitBurst*= in **systemd.exec(5)**, those values will override the settings specified here.

SystemMaxUse=, *SystemKeepFree*=, *SystemMaxFileSize*=, *SystemMaxFiles*=, *RuntimeMaxUse*=, *RuntimeKeepFree*=, *RuntimeMaxFileSize*=, *RuntimeMaxFiles*=

Enforce size limits on the journal files stored. The options prefixed with "System" apply to the journal files when stored on a persistent file system, more specifically /var/log/journal. The options prefixed with "Runtime" apply to the journal files when stored on a volatile in-memory file system, more specifically /run/log/journal. The former is used only when /var/ is mounted, writable, and the directory /var/log/journal exists. Otherwise, only the latter applies. Note that this means that during early boot and if the administrator disabled persistent logging, only the latter options apply, while the former apply if persistent logging is enabled and the system is fully booted up. **journaldctl** and **systemd-journald** ignore all files with names not ending with ".journal" or ".journal~", so only such files, located in the appropriate directories, are taken into account when calculating current disk usage.

SystemMaxUse= and *RuntimeMaxUse*= control how much disk space the journal may use up at most. *SystemKeepFree*= and *RuntimeKeepFree*= control how much disk space **systemd-journald** shall leave free for other uses. **systemd-journald** will respect both limits and use the smaller of the two values.

The first pair defaults to 10% and the second to 15% of the size of the respective file system, but each value is capped to 4G. If the file system is nearly full and either *SystemKeepFree*= or *RuntimeKeepFree*= are violated when **systemd-journald** is started, the limit will be raised to the percentage that is actually free. This means that if there was enough free space before and journal files were created, and subsequently something else causes the file system to fill up, **journald** will stop using more space, but it will not be removing existing files to reduce the footprint again, either. Also note that only archived files are deleted to reduce the space occupied by journal files. This means that, in effect, there might still be more space used than *SystemMaxUse*= or *RuntimeMaxUse*= limit after a vacuuming operation is complete.

SystemMaxFileSize= and *RuntimeMaxFileSize*= control how large individual journal files may grow at most. This influences the granularity in which disk space is made available through rotation, i.e. deletion of historic data. Defaults to one eighth of the values configured with *SystemMaxUse*= and *RuntimeMaxUse*=, so that usually seven rotated journal files are kept as history.

Specify values in bytes or use K, M, G, T, P, E as units for the specified sizes (equal to 1024, 1024², ... bytes). Note that size limits are enforced synchronously when journal files are extended, and no explicit rotation step triggered by time is needed.

SystemMaxFiles= and *RuntimeMaxFiles*= control how many individual journal files to keep at most. Note that only archived files are deleted to reduce the number of files until this limit is reached; active files will stay around. This means that, in effect, there might still be more journal files around in total than this limit after a vacuuming operation is complete. This setting defaults to 100.

MaxFileSec=

The maximum time to store entries in a single journal file before rotating to the next one. Normally, time-based rotation should not be required as size-based rotation with options such as *SystemMaxFileSize*= should be sufficient to ensure that journal files do not grow without bounds.

However, to ensure that not too much data is lost at once when old journal files are deleted, it might make sense to change this value from the default of one month. Set to 0 to turn off this feature. This setting takes time values which may be suffixed with the units "year", "month", "week", "day", "h" or "m" to override the default time unit of seconds.

MaxRetentionSec=

The maximum time to store journal entries. This controls whether journal files containing entries older than the specified time span are deleted. Normally, time-based deletion of old journal files should not be required as size-based deletion with options such as *SystemMaxUse=* should be sufficient to ensure that journal files do not grow without bounds. However, to enforce data retention policies, it might make sense to change this value from the default of 0 (which turns off this feature). This setting also takes time values which may be suffixed with the units "year", "month", "week", "day", "h" or "m" to override the default time unit of seconds.

SyncIntervalSec=

The timeout before synchronizing journal files to disk. After syncing, journal files are placed in the OFFLINE state. Note that syncing is unconditionally done immediately after a log message of priority CRIT, ALERT or EMERG has been logged. This setting hence applies only to messages of the levels ERR, WARNING, NOTICE, INFO, DEBUG. The default timeout is 5 minutes.

ForwardToSyslog=, *ForwardToKMsg=*, *ForwardToConsole=*, *ForwardToWall=*

Control whether log messages received by the journal daemon shall be forwarded to a traditional syslog daemon, to the kernel log buffer (kmsg), to the system console, or sent as wall messages to all logged-in users. These options take boolean arguments. If forwarding to syslog is enabled but nothing reads messages from the socket, forwarding to syslog has no effect. By default, only forwarding to syslog and wall is enabled. These settings may be overridden at boot time with the kernel command line options "systemd.journald.forward_to_syslog", "systemd.journald.forward_to_kmsg", "systemd.journald.forward_to_console", and "systemd.journald.forward_to_wall". If the option name is specified without "=" and the following argument, true is assumed. Otherwise, the argument is parsed as a boolean.

When forwarding to the console, the TTY to log to can be changed with *TTYPath=*, described below.

When forwarding to the kernel log buffer (kmsg), make sure to select a suitably large size for the log buffer, for example by adding "log_buf_len=8M" to the kernel command line. **systemd** will automatically disable kernel's rate-limiting applied to userspace processes (equivalent to setting "printk.devkmsg=on").

MaxLevelStore=, *MaxLevelSyslog=*, *MaxLevelKMsg=*, *MaxLevelConsole=*, *MaxLevelWall=*

Controls the maximum log level of messages that are stored in the journal, forwarded to syslog, kmsg, the console or wall (if that is enabled, see above). As argument, takes one of "emerg", "alert", "crit", "err", "warning", "notice", "info", "debug", or integer values in the range of 0–7 (corresponding to the same levels). Messages equal or below the log level specified are stored/forwarded, messages above are dropped. Defaults to "debug" for *MaxLevelStore=* and *MaxLevelSyslog=*, to ensure that all messages are stored in the journal and forwarded to syslog. Defaults to "notice" for *MaxLevelKMsg=*, "info" for *MaxLevelConsole=*, and "emerg" for *MaxLevelWall=*. These settings may be overridden at boot time with the kernel command line options "systemd.journald.max_level_store=", "systemd.journald.max_level_syslog=", "systemd.journald.max_level_kmsg=", "systemd.journald.max_level_console=", "systemd.journald.max_level_wall=".

ReadKMsg=

Takes a boolean value. If enabled **systemd-journal** processes /dev/kmsg messages generated by the kernel. In the default journal namespace this option is enabled by default, it is disabled in all others.

Audit=

Takes a boolean value. If enabled **systemd-journal** will turn on kernel auditing on start-up. If disabled it will turn it off. If unset it will neither enable nor disable it, leaving the previous state unchanged. Note that this option does not control whether **systemd-journald** collects generated audit

records, it just controls whether it tells the kernel to generate them. This means if another tool turns on auditing even if **systemd-journald** left it off, it will still collect the generated messages. Defaults to off.

TTYPath=

Change the console TTY to use if *ForwardToConsole=yes* is used. Defaults to /dev/console.

LineMax=

The maximum line length to permit when converting stream logs into record logs. When a systemd unit's standard output/error are connected to the journal via a stream socket, the data read is split into individual log records at newline ("\n", ASCII 10) and **NUL** characters. If no such delimiter is read for the specified number of bytes a hard log record boundary is artificially inserted, breaking up overly long lines into multiple log records. Selecting overly large values increases the possible memory usage of the Journal daemon for each stream client, as in the worst case the journal daemon needs to buffer the specified number of bytes in memory before it can flush a new log record to disk. Also note that permitting overly large line maximum line lengths affects compatibility with traditional log protocols as log records might not fit anymore into a single **AF_UNIX** or **AF_INET** datagram. Takes a size in bytes. If the value is suffixed with K, M, G or T, the specified size is parsed as Kilobytes, Megabytes, Gigabytes, or Terabytes (with the base 1024), respectively. Defaults to 48K, which is relatively large but still small enough so that log records likely fit into network datagrams along with extra room for metadata. Note that values below 79 are not accepted and will be bumped to 79.

FORWARDING TO TRADITIONAL SYSLOG DAEMONS

Journal events can be transferred to a different logging daemon in two different ways. With the first method, messages are immediately forwarded to a socket (/run/systemd/journal/syslog), where the traditional syslog daemon can read them. This method is controlled by the *ForwardToSyslog=* option. With a second method, a syslog daemon behaves like a normal journal client, and reads messages from the journal files, similarly to **journalctl(1)**. With this, messages do not have to be read immediately, which allows a logging daemon which is only started late in boot to access all messages since the start of the system. In addition, full structured meta-data is available to it. This method of course is available only if the messages are stored in a journal file at all. So it will not work if *Storage=none* is set. It should be noted that usually the *second* method is used by syslog daemons, so the *Storage=* option, and not the *ForwardToSyslog=* option, is relevant for them.

NAME

kill – send a signal to a process

SYNOPSIS

kill [options] <pid> [...]

DESCRIPTION

The default signal for kill is TERM. Use **-l** or **-L** to list available signals. Particularly useful signals include HUP, INT, KILL, STOP, CONT, and 0. Alternate signals may be specified in three ways: **-9**, **-SIGKILL** or **-KILL**. Negative PID values may be used to choose whole process groups; see the PGID column in ps command output. A PID of **-1** is special; it indicates all processes except the kill process itself and init.

OPTIONS

<pid> [...]

Send signal to every <pid> listed.

-<signal>

-s <signal>

--signal <signal>

Specify the **signal** to be sent. The signal can be specified by using name or number. The behavior of signals is explained in **signal(7)** manual page.

-q, --queue value

Use **sigqueue(3)** rather than **kill(2)** and the value argument is used to specify an integer to be sent with the signal. If the receiving process has installed a handler for this signal using the SA_SIGINFO flag to **sigaction(2)**, then it can obtain this data via the si_value field of the siginfo_t structure.

-l, --list [signal]

List signal names. This option has optional argument, which will convert signal number to signal name, or other way round.

-L, --table

List signal names in a nice table.

NOTES

Your shell (command line interpreter) may have a built-in kill command. You may need to run the command described here as /bin/kill to solve the conflict.

EXAMPLES

kill -9 -1

Kill all processes you can kill.

kill -l 11

Translate number 11 into a signal name.

kill -L List the available signal choices in a nice table.

kill 123 543 2341 3453

Send the default signal, SIGTERM, to all those processes.

SEE ALSO

kill(2), killall(1), nice(1), pkill(1), renice(1), signal(7), sigqueue(3), skill(1)

STANDARDS

This command meets appropriate standards. The **-L** flag is Linux-specific.

AUTHOR

Albert Cahalan <albert@users.sf.net> wrote kill in 1999 to replace a bsutils one that was not standards compliant. The util-linux one might also work correctly.

REPORTING BUGS

Please send bug reports to <procps@freelists.org>

NAME

kill – send signal to a process

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <signal.h>
int kill(pid_t pid, int sig);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
kill():
    _POSIX_C_SOURCE
```

DESCRIPTION

The **kill()** system call can be used to send any signal to any process group or process.

If *pid* is positive, then signal *sig* is sent to the process with the ID specified by *pid*.

If *pid* equals 0, then *sig* is sent to every process in the process group of the calling process.

If *pid* equals -1, then *sig* is sent to every process for which the calling process has permission to send signals, except for process 1 (*init*), but see below.

If *pid* is less than -1, then *sig* is sent to every process in the process group whose ID is *-pid*.

If *sig* is 0, then no signal is sent, but existence and permission checks are still performed; this can be used to check for the existence of a process ID or process group ID that the caller is permitted to signal.

For a process to have permission to send a signal, it must either be privileged (under Linux: have the **CAP_KILL** capability in the user namespace of the target process), or the real or effective user ID of the sending process must equal the real or saved set-user-ID of the target process. In the case of **SIGCONT**, it suffices when the sending and receiving processes belong to the same session. (Historically, the rules were different; see NOTES.)

RETURN VALUE

On success (at least one signal was sent), zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL

An invalid signal was specified.

EPERM

The calling process does not have permission to send the signal to any of the target processes.

ESRCH

The target process or process group does not exist. Note that an existing process might be a zombie, a process that has terminated execution, but has not yet been **wait(2)**ed for.

STANDARDS

POSIX.1-2001, POSIX.1-2008, SVr4, 4.3BSD.

NOTES

The only signals that can be sent to process ID 1, the *init* process, are those for which *init* has explicitly installed signal handlers. This is done to assure the system is not brought down accidentally.

POSIX.1 requires that *kill(-1,sig)* send *sig* to all processes that the calling process may send signals to, except possibly for some implementation-defined system processes. Linux allows a process to signal itself, but on Linux the call *kill(-1,sig)* does not signal the calling process.

POSIX.1 requires that if a process sends a signal to itself, and the sending thread does not have the signal blocked, and no other thread has it unblocked or is waiting for it in **sigwait(3)**, at least one unblocked signal must be delivered to the sending thread before the **kill()** returns.

Linux notes

Across different kernel versions, Linux has enforced different rules for the permissions required for an unprivileged process to send a signal to another process. In Linux 1.0 to 1.2.2, a signal could be sent if the effective user ID of the sender matched effective user ID of the target, or the real user ID of the sender matched the real user ID of the target. From Linux 1.2.3 until 1.3.77, a signal could be sent if the effective user ID of the sender matched either the real or effective user ID of the target. The current rules, which conform to POSIX.1, were adopted in Linux 1.3.78.

BUGS

In Linux 2.6 up to and including Linux 2.6.7, there was a bug that meant that when sending signals to a process group, **kill()** failed with the error **EPEERM** if the caller did not have permission to send the signal to *any* (rather than *all*) of the members of the process group. Notwithstanding this error return, the signal was still delivered to all of the processes for which the caller had permission to signal.

NAME

killall – kill processes by name

SYNOPSIS

```
killall [-Z, --context pattern] [-e, --exact] [-g, --process-group] [-i, --interactive] [-n, --ns PID]
[-o, --older-than TIME] [-q, --quiet] [-r, --regexp] [-s, --signal SIGNAL, -SIGNAL] [-u, --user
user] [-v, --verbose] [-w, --wait] [-y, --younger-than TIME] [-I, --ignore-case] [-V, --version]
[--] name ...
killall -l
killall -V, --version
```

DESCRIPTION

killall sends a signal to all processes running any of the specified commands. If no signal name is specified, SIGTERM is sent.

Signals can be specified either by name (e.g. **-HUP** or **-SIGHUP**) or by number (e.g. **-1**) or by option **-s**.

If the command name is not regular expression (option **-r**) and contains a slash (/), processes executing that particular file will be selected for killing, independent of their name.

killall returns a zero return code if at least one process has been killed for each listed command, or no commands were listed and at least one process matched the **-u** and **-Z** search criteria. **killall** returns non-zero otherwise.

A **killall** process never kills itself (but may kill other **killall** processes).

OPTIONS**-e, --exact**

Require an exact match for very long names. If a command name is longer than 15 characters, the full name may be unavailable (i.e. it is swapped out). In this case, **killall** will kill everything that matches within the first 15 characters. With **-e**, such entries are skipped. **killall** prints a message for each skipped entry if **-v** is specified in addition to **-e**.

-I, --ignore-case

Do case insensitive process name match.

-g, --process-group

Kill the process group to which the process belongs. The kill signal is only sent once per group, even if multiple processes belonging to the same process group were found.

-i, --interactive

Interactively ask for confirmation before killing.

-l, --list

List all known signal names.

-n, --ns

Match against the PID namespace of the given PID. The default is to match against all namespaces.

-o, --older-than

Match only processes that are older (started before) the time specified. The time is specified as a float then a unit. The units are s,m,h,d,w,M,y for seconds, minutes, hours, days, weeks, months and years respectively.

-q, --quiet

Do not complain if no processes were killed.

-r, --regexp

Interpret process name pattern as a POSIX extended regular expression, per **regex(3)**.

-s, --signal, -*SIGNAL*

Send this signal instead of SIGTERM.

-u, --user

Kill only processes the specified user owns. Command names are optional.

-v, --verbose

Report if the signal was successfully sent.

-V, --version

Display version information.

-w, --wait

Wait for all killed processes to die. **killall** checks once per second if any of the killed processes still exist and only returns if none are left. Note that **killall** may wait forever if the signal was ignored, had no effect, or if the process stays in zombie state.

-y, --younger-than

Match only processes that are younger (started after) the time specified. The time is specified as a float then a unit. The units are s,m,h,d,w,M,y for seconds, minutes, hours, days, weeks, Months and years respectively.

-Z, --context

Specify security context: kill only processes having security context that match with given extended regular expression pattern. Must precede other arguments on the command line. Command names are optional.

FILES

/proc location of the proc file system

KNOWN BUGS

Killing by file only works for executables that are kept open during execution, i.e. impure executables can't be killed this way.

Be warned that typing **killall name** may not have the desired effect on non-Linux systems, especially when done by a privileged user.

killall -w doesn't detect if a process disappears and is replaced by a new process with the same PID between scans.

If processes change their name, **killall** may not be able to match them correctly.

killall has a limit of names that can be specified on the command line. This figure is the size of an unsigned long integer multiplied by 8. For most 32 bit systems the limit is 32 and similarly for a 64 bit system the limit is usually 64.

NAME

killall5 -- send a signal to all processes.

SYNOPSIS

killall5 **-signalnumber** [**-o omitpid[,omitpid...]**] [**-o omitpid[,omitpid...]**...]

DESCRIPTION

killall5 is the SystemV killall command. It sends a signal to all processes except kernel threads and the processes in its own session, so it won't kill the shell that is running the script it was called from. Its primary (only) use is in the **rc** scripts found in the /etc/init.d directory.

OPTIONS

-o omitpid

Tells *killall5* to omit processes with that process id.

NOTES

killall5 can also be invoked as pidof, which is simply a (symbolic) link to the *killall5* program.

EXIT STATUS

The program return zero if it killed processes. It return 2 if no process were killed, and 1 if it was unable to find any processes (/proc/ is missing).

SEE ALSO

halt(8), **reboot(8)**, **pidof(8)**

AUTHOR

NAME

killpg – send signal to a process group

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <signal.h>
int killpg(int pgrp, int sig);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
killpg():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _BSD_SOURCE
```

DESCRIPTION

killpg() sends the signal *sig* to the process group *pgrp*. Seesignal(7) for a list of signals.

If *pgrp* is 0, **killpg()** sends the signal to the calling process's process group. (POSIX says: if *pgrp* is less than or equal to 1, the behavior is undefined.)

For the permissions required to send a signal to another process, see **kill(2)**.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL

sig is not a valid signal number.

EPERM

The process does not have permission to send the signal to any of the target processes. For the required permissions, see **kill(2)**.

ESRCH

No process can be found in the process group specified by *pgrp*.

ESRCH

The process group was given as 0 but the sending process does not have a process group.

STANDARDS

POSIX.1-2001, POSIX.1-2008, SVr4, 4.4BSD (**killpg()** first appeared in 4BSD).

NOTES

There are various differences between the permission checking in BSD-type systems and System V-type systems. See the POSIX rationale for**kill(3p)**. A difference not mentioned by POSIX concerns the return value **EPERM**: BSD documents that no signal is sent and **EPERM** returned when the permission check failed for at least one target process, while POSIX documents **EPERM** only when the permission check failed for all target processes.

C library/kernel differences

On Linux, **killpg()** is implemented as a library function that makes the call *kill(-pgrp, sig)*.

getpgrp(2), **kill(2)**, **signal(2)**, **capabilities(7)**, **credentials(7)**

NAME

less – opposite of more

SYNOPSIS

less –?

less --help

less -V

less --version

less [-[+]aABcCdeEfFgGiIJKLMNOPQRSTUVWXYZ]

[-b space] [-h lines] [-j line] [-k keyfile]

[-{oO} logfile] [-p pattern] [-P prompt] [-t tag]

[-T tagsfile] [-x tab,...] [-y lines] [-z lines]

[-# shift] [+ [+cmd] [--] [filename]...]

(See the OPTIONS section for alternate option syntax with long option names.)

DESCRIPTION

Less is a program similar to *more*(1), but it has many more features. *Less* does not have to read the entire input file before starting, so with large input files it starts up faster than text editors like *vi*(1). *Less* uses termcap (or terminfo on some systems), so it can run on a variety of terminals. There is even limited support for hardcopy terminals. (On a hardcopy terminal, lines which should be printed at the top of the screen are prefixed with a caret.)

Commands are based on both *more* and *vi*. Commands may be preceded by a decimal number, called N in the descriptions below. The number is used by some commands, as indicated.

COMMANDS

In the following descriptions, ^X means control-X. ESC stands for the ESCAPE key; for example ESC-v means the two character sequence "ESCAPE", then "v".

h or H Help: display a summary of these commands. If you forget all the other commands, remember this one.

SPACE or ^V or f or ^F

Scroll forward N lines, default one window (see option –z below). If N is more than the screen size, only the final screenful is displayed. Warning: some systems use ^V as a special literalization character.

z Like SPACE, but if N is specified, it becomes the new window size.

ESC-SPACE

Like SPACE, but scrolls a full screenful, even if it reaches end-of-file in the process.

ENTER or RETURN or ^N or e or ^E or j or ^J

Scroll forward N lines, default 1. The entire N lines are displayed, even if N is more than the screen size.

d or ^D Scroll forward N lines, default one half of the screen size. If N is specified, it becomes the new default for subsequent d and u commands.

b or ^B or ESC-v

Scroll backward N lines, default one window (see option –z below). If N is more than the screen size, only the final screenful is displayed.

w Like ESC-v, but if N is specified, it becomes the new window size.

y or ^Y or ^P or k or ^K

Scroll backward N lines, default 1. The entire N lines are displayed, even if N is more than the screen size. Warning: some systems use ^Y as a special job control character.

u or ^U Scroll backward N lines, default one half of the screen size. If N is specified, it becomes the new default for subsequent d and u commands.

J Like **j**, but continues to scroll beyond the end of the file.

K or Y Like **k**, but continues to scroll beyond the beginning of the file.

ESC-) or RIGHTARROW

Scroll horizontally right N characters, default half the screen width (see the **-#** option). If a number N is specified, it becomes the default for future **RIGHTARROW** and **LEFTARROW** commands. While the text is scrolled, it acts as though the **-S** option (chop lines) were in effect.

ESC-(or LEFTARROW

Scroll horizontally left N characters, default half the screen width (see the **-#** option). If a number N is specified, it becomes the default for future **RIGHTARROW** and **LEFTARROW** commands.

ESC-} or ^RIGHTARROW

Scroll horizontally right to show the end of the longest displayed line.

ESC-{ or ^LEFTARROW

Scroll horizontally left back to the first column.

r or ^R or ^L

Repaint the screen.

R Repaint the screen, discarding any buffered input. That is, reload the current file. Useful if the file is changing while it is being viewed.

F Scroll forward, and keep trying to read when the end of file is reached. Normally this command would be used when already at the end of the file. It is a way to monitor the tail of a file which is growing while it is being viewed. (The behavior is similar to the "tail -f" command.) To stop waiting for more data, enter the interrupt character (usually **^C**). On some systems you can also use **^X**.

ESC-F Like **F**, but as soon as a line is found which matches the last search pattern, the terminal bell is rung and forward scrolling stops.

g or < or ESC-<

Go to line N in the file, default 1 (beginning of file). (Warning: this may be slow if N is large.)

G or > or ESC->

Go to line N in the file, default the end of the file. (Warning: this may be slow if N is large, or if N is not specified and standard input, rather than a file, is being read.)

ESC-G Same as **G**, except if no number N is specified and the input is standard input, goes to the last line which is currently buffered.

p or % Go to a position N percent into the file. N should be between 0 and 100, and may contain a decimal point.

P Go to the line containing byte offset N in the file.

{ If a left curly bracket appears in the top line displayed on the screen, the **{** command will go to the matching right curly bracket. The matching right curly bracket is positioned on the bottom line of the screen. If there is more than one left curly bracket on the top line, a number N may be used to specify the N-th bracket on the line.

} If a right curly bracket appears in the bottom line displayed on the screen, the **}** command will go to the matching left curly bracket. The matching left curly bracket is positioned on the top line of the screen. If there is more than one right curly bracket on the top line, a number N may be used to specify the N-th bracket on the line.

(Like **{**, but applies to parentheses rather than curly brackets.

) Like **}**, but applies to parentheses rather than curly brackets.

[Like **{**, but applies to square brackets rather than curly brackets.

] Like }, but applies to square brackets rather than curly brackets.

ESC-^F Followed by two characters, acts like {, but uses the two characters as open and close brackets, respectively. For example, "ESC ^F < >" could be used to go forward to the > which matches the < in the top displayed line.

ESC-^B

Followed by two characters, acts like }, but uses the two characters as open and close brackets, respectively. For example, "ESC ^B < >" could be used to go backward to the < which matches the > in the bottom displayed line.

m Followed by any lowercase or uppercase letter, marks the first displayed line with that letter. If the status column is enabled via the -J option, the status column shows the marked line.

M Acts like m, except the last displayed line is marked rather than the first displayed line.

' (Single quote.) Followed by any lowercase or uppercase letter, returns to the position which was previously marked with that letter. Followed by another single quote, returns to the position at which the last "large" movement command was executed. Followed by a ^ or \$, jumps to the beginning or end of the file respectively. Marks are preserved when a new file is examined, so the ' command can be used to switch between input files.

^X'X Same as single quote.

ESC-m Followed by any lowercase or uppercase letter, clears the mark identified by that letter.

/pattern Search forward in the file for the N-th line containing the pattern. N defaults to 1. The pattern is a regular expression, as recognized by the regular expression library supplied by your system. The search starts at the first line displayed (but see the -a and -j options, which change this).

Certain characters are special if entered at the beginning of the pattern; they modify the type of search rather than become part of the pattern:

^N or ! Search for lines which do NOT match the pattern.

^E or * Search multiple files. That is, if the search reaches the END of the current file without finding a match, the search continues in the next file in the command line list.

^F or @

Begin the search at the first line of the FIRST file in the command line list, regardless of what is currently displayed on the screen or the settings of the -a or -j options.

^K Highlight any text which matches the pattern on the current screen, but don't move to the first match (KEEP current position).

^R Don't interpret regular expression metacharacters; that is, do a simple textual comparison.

^W WRAP around the current file. That is, if the search reaches the end of the current file without finding a match, the search continues from the first line of the current file up to the line where it started.

?pattern

Search backward in the file for the N-th line containing the pattern. The search starts at the last line displayed (but see the -a and -j options, which change this).

Certain characters are special as in the / command:

^N or ! Search for lines which do NOT match the pattern.

^E or * Search multiple files. That is, if the search reaches the beginning of the current file without finding a match, the search continues in the previous file in the command line list.

^F or @

Begin the search at the last line of the last file in the command line list, regardless of what is currently displayed on the screen or the settings of the -a or -j options.

- ^K** As in forward searches.
- ^R** As in forward searches.
- ^W** WRAP around the current file. That is, if the search reaches the beginning of the current file without finding a match, the search continues from the last line of the current file up to the line where it started.

ESC-/pattern

Same as "/*".

ESC-?pattern

Same as "?*".

- n** Repeat previous search, for N-th line containing the last pattern. If the previous search was modified by ^N, the search is made for the N-th line NOT containing the pattern. If the previous search was modified by ^E, the search continues in the next (or previous) file if not satisfied in the current file. If the previous search was modified by ^R, the search is done without using regular expressions. There is no effect if the previous search was modified by ^F or ^K.

- N** Repeat previous search, but in the reverse direction.

- ESC-n** Repeat previous search, but crossing file boundaries. The effect is as if the previous search were modified by *.

- ESC-N** Repeat previous search, but in the reverse direction and crossing file boundaries.

- ESC-u** Undo search highlighting. Turn off highlighting of strings matching the current search pattern. If highlighting is already off because of a previous ESC-u command, turn highlighting back on. Any search command will also turn highlighting back on. (Highlighting can also be disabled by toggling the -G option; in that case search commands do not turn highlighting back on.)

- ESC-U** Like ESC-u but also clears the saved search pattern. If the status column is enabled via the -J option, this clears all search matches marked in the status column.

&pattern

Display only lines which match the pattern; lines which do not match the pattern are not displayed. If pattern is empty (if you type & immediately followed by ENTER), any filtering is turned off, and all lines are displayed. While filtering is in effect, an ampersand is displayed at the beginning of the prompt, as a reminder that some lines in the file may be hidden. Multiple & commands may be entered, in which case only lines which match all of the patterns will be displayed.

Certain characters are special as in the / command:

^N or ! Display only lines which do NOT match the pattern.

^R Don't interpret regular expression metacharacters; that is, do a simple textual comparison.

:e [filename]

Examine a new file. If the filename is missing, the "current" file (see the :n and :p commands below) from the list of files in the command line is re-examined. A percent sign (%) in the filename is replaced by the name of the current file. A pound sign (#) is replaced by the name of the previously examined file. However, two consecutive percent signs are simply replaced with a single percent sign. This allows you to enter a filename that contains a percent sign in the name. Similarly, two consecutive pound signs are replaced with a single pound sign. The filename is inserted into the command line list of files so that it can be seen by subsequent :n and :p commands. If the filename consists of several files, they are all inserted into the list of files and the first one is examined. If the filename contains one or more spaces, the entire filename should be enclosed in double quotes (also see the -" option).

^X^V or E

Same as :e. Warning: some systems use ^V as a special literalization character. On such systems, you may not be able to use ^V.

- :n Examine the next file (from the list of files given in the command line). If a number N is specified, the N-th next file is examined.
- :p Examine the previous file in the command line list. If a number N is specified, the N-th previous file is examined.
- :x Examine the first file in the command line list. If a number N is specified, the N-th file in the list is examined.
- :d Remove the current file from the list of files.
- t Go to the next tag, if there were more than one matches for the current tag. See the -t option for more details about tags.
- T Go to the previous tag, if there were more than one matches for the current tag.
- = or ^G or :f Prints some information about the file being viewed, including its name and the line number and byte offset of the bottom line being displayed. If possible, it also prints the length of the file, the number of lines in the file and the percent of the file above the last displayed line.
- Followed by one of the command line option letters (see OPTIONS below), this will change the setting of that option and print a message describing the new setting. If a ^P (CONTROL-P) is entered immediately after the dash, the setting of the option is changed but no message is printed. If the option letter has a numeric value (such as -b or -h), or a string value (such as -P or -t), a new value may be entered after the option letter. If no new value is entered, a message describing the current setting is printed and nothing is changed.
- Like the - command, but takes a long option name (see OPTIONS below) rather than a single option letter. You must press ENTER or RETURN after typing the option name. A ^P immediately after the second dash suppresses printing of a message describing the new setting, as in the - command.
- + Followed by one of the command line option letters this will reset the option to its default setting and print a message describing the new setting. (The "-+X" command does the same thing as "+X" on the command line.) This does not work for string-valued options.
- + Like the --+ command, but takes a long option name rather than a single option letter.
- ! Followed by one of the command line option letters, this will reset the option to the "opposite" of its default setting and print a message describing the new setting. This does not work for numeric or string-valued options.
- ! Like the -! command, but takes a long option name rather than a single option letter.
- _ (Underscore.) Followed by one of the command line option letters, this will print a message describing the current setting of that option. The setting of the option is not changed.
- __ (Double underscore.) Like the _ (underscore) command, but takes a long option name rather than a single option letter. You must press ENTER or RETURN after typing the option name.
- +cmd Causes the specified cmd to be executed each time a new file is examined. For example, +G causes *less* to initially display each file starting at the end rather than the beginning.
- V Prints the version number of *less* being run.
- q or Q or :q or :Q or ZZ Exits *less*.

The following four commands may or may not be valid, depending on your particular installation.

- v Invokes an editor to edit the current file being viewed. The editor is taken from the environment variable VISUAL if defined, or EDITOR if VISUAL is not defined, or defaults to "vi" if neither VISUAL nor EDITOR is defined. See also the discussion of LESSEDIT under the section on PROMPTS below.

! shell-command

Invokes a shell to run the shell-command given. A percent sign (%) in the command is replaced by the name of the current file. A pound sign (#) is replaced by the name of the previously examined file. "!!" repeats the last shell command. "!" with no shell command simply invokes a shell. On Unix systems, the shell is taken from the environment variable SHELL, or defaults to "sh". On MS-DOS and OS/2 systems, the shell is the normal command processor.

| <m> shell-command

<m> represents any mark letter. Pipes a section of the input file to the given shell command. The section of the file to be piped is between the position marked by the letter and the current screen. The entire current screen is included, regardless of whether the marked position is before or after the current screen. <m> may also be ^ or \$ to indicate beginning or end of file respectively. If <m> is . or newline, the current screen is piped.

s filename

Save the input to a file. This only works if the input is a pipe, not an ordinary file.

OPTIONS

Command line options are described below. Most options may be changed while *less* is running, via the "--" command.

Most options may be given in one of two forms: either a dash followed by a single letter, or two dashes followed by a long option name. A long option name may be abbreviated as long as the abbreviation is unambiguous. For example, --quit-at-eof may be abbreviated --quit, but not --qui, since both --quit-at-eof and --quiet begin with --qui. Some long option names are in uppercase, such as --QUIT-AT-EOF, as distinct from --quit-at-eof. Such option names need only have their first letter capitalized; the remainder of the name may be in either case. For example, --Quit-at-eof is equivalent to --QUIT-AT-EOF.

Options are also taken from the environment variable "LESS". For example, to avoid typing "less -options ..." each time *less* is invoked, you might tell *csh*:

`setenv LESS "-options"`

or if you use *sh*:

`LESS="-options"; export LESS`

On MS-DOS, you don't need the quotes, but you should replace any percent signs in the options string by double percent signs.

The environment variable is parsed before the command line, so command line options override the LESS environment variable. If an option appears in the LESS variable, it can be reset to its default value on the command line by beginning the command line option with "-+".

Some options like -k or -D require a string to follow the option letter. The string for that option is considered to end when a dollar sign (\$) is found. For example, you can set two -D options on MS-DOS like this:

`LESS="Dn9.1$Ds4.1"`

If the --use-backslash option appears earlier in the options, then a dollar sign or backslash may be included literally in an option string by preceding it with a backslash. If the --use-backslash option is not in effect, then backslashes are not treated specially, and there is no way to include a dollar sign in the option string.

-? or --help

This option displays a summary of the commands accepted by *less* (the same as the h command). (Depending on how your shell interprets the question mark, it may be necessary to quote the question mark, thus: "-\?".)

-a or --search-skip-screen

By default, forward searches start at the top of the displayed screen and backwards searches start at the bottom of the displayed screen (except for repeated searches invoked by the **n** or **N** commands, which start after or before the "target" line respectively; see the **-j** option for more about the target line). The **-a** option causes forward searches to instead start at the bottom of the screen and backward searches to start at the top of the screen, thus skipping all lines displayed on the screen.

-A or --SEARCH-SKIP-SCREEN

Causes all forward searches (not just non-repeated searches) to start just after the target line, and all backward searches to start just before the target line. Thus, forward searches will skip part of the displayed screen (from the first line up to and including the target line). Similarly backwards searches will skip the displayed screen from the last line up to and including the target line. This was the default behavior in less versions prior to 441.

-bn or --buffers=n

Specifies the amount of buffer space *less* will use for each file, in units of kilobytes (1024 bytes). By default 64 KB of buffer space is used for each file (unless the file is a pipe; see the **-B** option). The **-b** option specifies instead that *n* kilobytes of buffer space should be used for each file. If *n* is **-1**, buffer space is unlimited; that is, the entire file can be read into memory.

-B or --auto-buffers

By default, when data is read from a pipe, buffers are allocated automatically as needed. If a large amount of data is read from the pipe, this can cause a large amount of memory to be allocated. The **-B** option disables this automatic allocation of buffers for pipes, so that only 64 KB (or the amount of space specified by the **-b** option) is used for the pipe. Warning: use of **-B** can result in erroneous display, since only the most recently viewed part of the piped data is kept in memory; any earlier data is lost.

-c or --clear-screen

Causes full screen repaints to be painted from the top line down. By default, full screen repaints are done by scrolling from the bottom of the screen.

-C or --CLEAR-SCREEN

Same as **-c**, for compatibility with older versions of *less*.

-d or --dumb

The **-d** option suppresses the error message normally displayed if the terminal is dumb; that is, lacks some important capability, such as the ability to clear the screen or scroll backward. The **-d** option does not otherwise change the behavior of *less* on a dumb terminal.

-Dxcolor or --color=xcolor

Changes the color of different parts of the displayed text. **x** is a single character which selects the type of text whose color is being set:

- B Binary characters.
- C Control characters.
- E Errors and informational messages.
- M Mark letters in the status column.
- N Line numbers enabled via the **-N** option.
- P Prompts.
- R The rscroll character.
- S Search results.
- W The highlight enabled via the **-w** option.
- d Bold text.

- k Blinking text.
- s Standout text.
- u Underlined text.

The uppercase letters can be used only when the `--use-color` option is enabled. When text color is specified by both an uppercase letter and a lowercase letter, the uppercase letter takes precedence. For example, error messages are normally displayed as standout text. So if both "s" and "E" are given a color, the "E" color applies to error messages, and the "s" color applies to other standout text. The "d" and "u" letters refer to bold and underline text formed by overstriking with backspaces (see the `-u` option), not to text using ANSI escape sequences with the `-R` option.

A lowercase letter may be followed by a `+` to indicate that both the normal format change and the specified color should both be used. For example, `-Dug` displays underlined text as green without underlining; the green color has replaced the usual underline formatting. But `-Du+g` displays underlined text as both green and in underlined format.

color is either a 4-bit color string or an 8-bit color string:

A 4-bit color string is zero, one or two characters, where the first character specifies the foreground color and the second specifies the background color as follows:

- b Blue
- c Cyan
- g Green
- k Black
- m Magenta
- r Red
- w White
- y Yellow

The corresponding upper-case letter denotes a brighter shade of the color. For example, `-DNGk` displays line numbers as bright green text on a black background, and `-DEbR` displays error messages as blue text on a bright red background. If either character is a `"-"` or is omitted, the corresponding color is set to that of normal text.

An 8-bit color string is one or two decimal integers separated by a dot, where the first integer specifies the foreground color and the second specifies the background color. Each integer is a value between 0 and 255 inclusive which selects a "CSI 38;5" color value (see

https://en.wikipedia.org/wiki/ANSI_escape_code#SGR_parameters) If either integer is a `"-"` or is omitted, the corresponding color is set to that of normal text. On MS-DOS versions of *less*, 8-bit color is not supported; instead, decimal values are interpreted as 4-bit CHAR_INFO.Attributes values (see

<https://docs.microsoft.com/en-us/windows/console/char-info-str>).

`-e` or `--quit-at-eof`

Causes *less* to automatically exit the second time it reaches end-of-file. By default, the only way to exit *less* is via the `"q"` command.

`-E` or `--QUIT-AT-EOF`

Causes *less* to automatically exit the first time it reaches end-of-file.

`-f` or `--force`

Forces non-regular files to be opened. (A non-regular file is a directory or a device special file.) Also suppresses the warning message when a binary file is opened. By default, *less* will refuse to open non-regular files. Note that some operating systems will not allow directories to be read, even if `-f` is set.

-F or --quit-if-one-screen

Causes *less* to automatically exit if the entire file can be displayed on the first screen.

-g or --hilite-search

Normally, *less* will highlight ALL strings which match the last search command. The **-g** option changes this behavior to highlight only the particular string which was found by the last search command. This can cause *less* to run somewhat faster than the default.

-G or --HILITE-SEARCH

The **-G** option suppresses all highlighting of strings found by search commands.

-hn or --max-back-scroll=n

Specifies a maximum number of lines to scroll backward. If it is necessary to scroll backward more than *n* lines, the screen is repainted in a forward direction instead. (If the terminal does not have the ability to scroll backward, **-h0** is implied.)

-i or --ignore-case

Causes searches to ignore case; that is, uppercase and lowercase are considered identical. This option is ignored if any uppercase letters appear in the search pattern; in other words, if a pattern contains uppercase letters, then that search does not ignore case.

-I or --IGNORE-CASE

Like **-i**, but searches ignore case even if the pattern contains uppercase letters.

-jn or --jump-target=n

Specifies a line on the screen where the "target" line is to be positioned. The target line is the line specified by any command to search for a pattern, jump to a line number, jump to a file percentage or jump to a tag. The screen line may be specified by a number: the top line on the screen is 1, the next is 2, and so on. The number may be negative to specify a line relative to the bottom of the screen: the bottom line on the screen is -1, the second to the bottom is -2, and so on. Alternately, the screen line may be specified as a fraction of the height of the screen, starting with a decimal point: .5 is in the middle of the screen, .3 is three tenths down from the first line, and so on. If the line is specified as a fraction, the actual line number is recalculated if the terminal window is resized, so that the target line remains at the specified fraction of the screen height. If any form of the **-j** option is used, repeated forward searches (invoked with "n" or "N") begin at the line immediately after the target line, and repeated backward searches begin at the target line, unless changed by **-a** or **-A**. For example, if "**-j4**" is used, the target line is the fourth line on the screen, so forward searches begin at the fifth line on the screen. However nonrepeated searches (invoked with "/" or "?") always begin at the start or end of the current screen respectively.

-J or --status-column

Displays a status column at the left edge of the screen. The status column shows the lines that matched the current search, and any lines that are marked (via the **m** or **M** command).

-kfilename or --lesskey-file=filename

Causes *less* to open and interpret the named file as a *lesskey*(1) binary file. Multiple **-k** options may be specified. If the LESSKEY or LESSKEY_SYSTEM environment variable is set, or if a lesskey file is found in a standard place (see KEY BINDINGS), it is also used as a *lesskey* file.

--lesskey-src=filename

Causes *less* to open and interpret the named file as a *lesskey*(1) source file. If the LESSKEYIN or LESSKEYIN_SYSTEM environment variable is set, or if a lesskey source file is found in a standard place (see KEY BINDINGS), it is also used as a *lesskey source* file. Prior to version 582, the *lesskey* program needed to be run to convert a *lesskey source* file to a *lesskey binary* file for *less* to use. Newer versions of *less* read the *lesskey source* file directly and ignore the binary file if the source file exists.

-K or --quit-on-intr

Causes *less* to exit immediately (with status 2) when an interrupt character (usually ^C) is typed. Normally, an interrupt character causes *less* to stop whatever it is doing and return to its command

prompt. Note that use of this option makes it impossible to return to the command prompt from the "F" command.

-L or --no-lessopen

Ignore the LESSOPEN environment variable (see the INPUT PREPROCESSOR section below). This option can be set from within *less*, but it will apply only to files opened subsequently, not to the file which is currently open.

-m or --long-prompt

Causes *less* to prompt verbosely (like *more*), with the percent into the file. By default, *less* prompts with a colon.

-M or --LONG-PROMPT

Causes *less* to prompt even more verbosely than *more*.

-n or --line-numbers

Suppresses line numbers. The default (to use line numbers) may cause *less* to run more slowly in some cases, especially with a very large input file. Suppressing line numbers with the -n option will avoid this problem. Using line numbers means: the line number will be displayed in the verbose prompt and in the = command, and the v command will pass the current line number to the editor (see also the discussion of LESSEDIT in PROMPTS below).

-N or --LINE-NUMBERS

Causes a line number to be displayed at the beginning of each line in the display.

-filename or --log-file=filename

Causes *less* to copy its input to the named file as it is being viewed. This applies only when the input file is a pipe, not an ordinary file. If the file already exists, *less* will ask for confirmation before overwriting it.

-Ofilename or --LOG-FILE=filename

The -O option is like -o, but it will overwrite an existing file without asking for confirmation.

If no log file has been specified, the -o and -O options can be used from within *less* to specify a log file. Without a file name, they will simply report the name of the log file. The "s" command is equivalent to specifying -o from within *less*.

-ppattern or --pattern=pattern

The -p option on the command line is equivalent to specifying +/pattern; that is, it tells *less* to start at the first occurrence of pattern in the file.

-Pprompt or --prompt=prompt

Provides a way to tailor the three prompt styles to your own preference. This option would normally be put in the LESS environment variable, rather than being typed in with each *less* command. Such an option must either be the last option in the LESS variable, or be terminated by a dollar sign.

-Ps followed by a string changes the default (short) prompt to that string.

-Pm changes the medium (-m) prompt.

-PM changes the long (-M) prompt.

-Ph changes the prompt for the help screen.

-P= changes the message printed by the = command.

-Pw changes the message printed while waiting for data (in the F command).

All prompt strings consist of a sequence of letters and special escape sequences. See the section on PROMPTS for more details.

-q or --quiet or --silent

Causes moderately "quiet" operation: the terminal bell is not rung if an attempt is made to scroll past the end of the file or before the beginning of the file. If the terminal has a "visual bell", it is used instead. The bell will be rung on certain other errors, such as typing an invalid character.

The default is to ring the terminal bell in all such cases.

-Q or --QUIET or --SILENT

Causes totally "quiet" operation: the terminal bell is never rung. If the terminal has a "visual bell", it is used in all cases where the terminal bell would have been rung.

-r or --raw-control-chars

Causes "raw" control characters to be displayed. The default is to display control characters using the caret notation; for example, a control-A (octal 001) is displayed as "^A". Warning: when the -r option is used, *less* cannot keep track of the actual appearance of the screen (since this depends on how the screen responds to each type of control character). Thus, various display problems may result, such as long lines being split in the wrong place.

USE OF THE -r OPTION IS NOT RECOMMENDED.

-R or --RAW-CONTROL-CHARS

Like -r, but only ANSI "color" escape sequences and OSC 8 hyperlink sequences are output in "raw" form. Unlike -r, the screen appearance is maintained correctly, provided that there are no escape sequences in the file other than these types of escape sequences. Color escape sequences are only supported when the color is changed within one line, not across lines. In other words, the beginning of each line is assumed to be normal (non-colored), regardless of any escape sequences in previous lines. For the purpose of keeping track of screen appearance, these escape sequences are assumed to not move the cursor.

OSC 8 hyperlinks are sequences of the form:

ESC] 8 ; ... \7

The terminating sequence may be either a BEL character (\7) or the two-character sequence "ESC \".

ANSI color escape sequences are sequences of the form:

ESC [... m

where the "..." is zero or more color specification characters. You can make *less* think that characters other than "m" can end ANSI color escape sequences by setting the environment variable LESSANSIENDCHARS to the list of characters which can end a color escape sequence. And you can make *less* think that characters other than the standard ones may appear between the ESC and the m by setting the environment variable LESSANSIMIDCHARS to the list of characters which can appear.

-s or --squeeze-blank-lines

Causes consecutive blank lines to be squeezed into a single blank line. This is useful when viewing *nroff* output.

-S or --chop-long-lines

Causes lines longer than the screen width to be chopped (truncated) rather than wrapped. That is, the portion of a long line that does not fit in the screen width is not displayed until you press RIGHT-ARROW. The default is to wrap long lines; that is, display the remainder on the next line.

-ttag or --tag=tag

The -t option, followed immediately by a TAG, will edit the file containing that tag. For this to work, tag information must be available; for example, there may be a file in the current directory called "tags", which was previously built by *ctags(1)* or an equivalent command. If the environment variable LESSGLOBALTAGS is set, it is taken to be the name of a command compatible with *global(1)*, and that command is executed to find the tag. (See <http://www.gnu.org/software/global/global.html>). The -t option may also be specified from within

less (using the **-** command) as a way of examining a new file. The command ":t" is equivalent to specifying **-t** from within *less*.

-T*tagsfile* or **--tag-file=tagsfile**

Specifies a tags file to be used instead of "tags".

-u or **--underline-special**

Causes backspaces and carriage returns to be treated as printable characters; that is, they are sent to the terminal when they appear in the input.

-U or **--UNDERLINE-SPECIAL**

Causes backspaces, tabs, carriage returns and "formatting characters" (as defined by Unicode) to be treated as control characters; that is, they are handled as specified by the **-r** option.

By default, if neither **-u** nor **-U** is given, backspaces which appear adjacent to an underscore character are treated specially: the underlined text is displayed using the terminal's hardware underlining capability. Also, backspaces which appear between two identical characters are treated specially: the overstruck text is printed using the terminal's hardware boldface capability. Other backspaces are deleted, along with the preceding character. Carriage returns immediately followed by a newline are deleted. Other carriage returns are handled as specified by the **-r** option. Unicode formatting characters, such as the Byte Order Mark, are sent to the terminal. Text which is overstruck or underlined can be searched for if neither **-u** nor **-U** is in effect.

-V or **--version**

Displays the version number of *less*.

-w or **--hilite-unread**

Temporarily highlights the first "new" line after a forward movement of a full page. The first "new" line is the line immediately following the line previously at the bottom of the screen. Also highlights the target line after a **g** or **p** command. The highlight is removed at the next command which causes movement. The entire line is highlighted, unless the **-J** option is in effect, in which case only the status column is highlighted.

-W or **--HILITE-UNREAD**

Like **-w**, but temporarily highlights the first new line after any forward movement command larger than one line.

-xn,... or **--tabs=n,...**

Sets tab stops. If only one *n* is specified, tab stops are set at multiples of *n*. If multiple values separated by commas are specified, tab stops are set at those positions, and then continue with the same spacing as the last two. For example, **-x9,17** will set tabs at positions 9, 17, 25, 33, etc. The default for *n* is 8.

-X or **--no-init**

Disables sending the termcap initialization and deinitialization strings to the terminal. This is sometimes desirable if the deinitialization string does something unnecessary, like clearing the screen.

-yn or **--max-forw-scroll=n**

Specifies a maximum number of lines to scroll forward. If it is necessary to scroll forward more than *n* lines, the screen is repainted instead. The **-c** or **-C** option may be used to repaint from the top of the screen if desired. By default, any forward movement causes scrolling.

-zn or **--window=n** or **-n**

Changes the default scrolling window size to *n* lines. The default is one screenful. The **z** and **w** commands can also be used to change the window size. The "z" may be omitted for compatibility with some versions of *more*. If the number *n* is negative, it indicates *n* lines less than the current screen size. For example, if the screen is 24 lines, **-z-4** sets the scrolling window to 20 lines. If the screen is resized to 40 lines, the scrolling window automatically changes to 36 lines.

–"cc or --quotes=cc

Changes the filename quoting character. This may be necessary if you are trying to name a file which contains both spaces and quote characters. Followed by a single character, this changes the quote character to that character. Filenames containing a space should then be surrounded by that character rather than by double quotes. Followed by two characters, changes the open quote to the first character, and the close quote to the second character. Filenames containing a space should then be preceded by the open quote character and followed by the close quote character. Note that even after the quote characters are changed, this option remains –" (a dash followed by a double quote).

–~ or --tilde

Normally lines after end of file are displayed as a single tilde (~). This option causes lines after end of file to be displayed as blank lines.

–# or --shift

Specifies the default number of positions to scroll horizontally in the RIGHTARROW and LEFT-ARROW commands. If the number specified is zero, it sets the default number of positions to one half of the screen width. Alternately, the number may be specified as a fraction of the width of the screen, starting with a decimal point: .5 is half of the screen width, .3 is three tenths of the screen width, and so on. If the number is specified as a fraction, the actual number of scroll positions is recalculated if the terminal window is resized, so that the actual scroll remains at the specified fraction of the screen width.

--file-size

If --file-size is specified, *less* will determine the size of the file immediately after opening the file. Normally this is not done, because it can be slow if the input file is large.

--follow-name

Normally, if the input file is renamed while an F command is executing, *less* will continue to display the contents of the original file despite its name change. If --follow-name is specified, during an F command *less* will periodically attempt to reopen the file by name. If the reopen succeeds and the file is a different file from the original (which means that a new file has been created with the same name as the original (now renamed) file), *less* will display the contents of that new file.

--incsearch

Subsequent search commands will be "incremental"; that is, *less* will advance to the next line containing the search pattern as each character of the pattern is typed in.

--line-num-width

Sets the minimum width of the line number field when the –N option is in effect. The default is 7 characters.

--mouse

Enables mouse input: scrolling the mouse wheel down moves forward in the file, scrolling the mouse wheel up moves backwards in the file, and clicking the mouse sets the "#" mark to the line where the mouse is clicked. The number of lines to scroll when the wheel is moved can be set by the --wheel-lines option. Mouse input works only on terminals which support X11 mouse reporting, and on the Windows version of *less*.

--MOUSE

Like --mouse, except the direction scrolled on mouse wheel movement is reversed.

--no-keypad

Disables sending the keypad initialization and deinitialization strings to the terminal. This is sometimes useful if the keypad strings make the numeric keypad behave in an undesirable manner.

--no-histdups

This option changes the behavior so that if a search string or file name is typed in, and the same string is already in the history list, the existing copy is removed from the history list before the

new one is added. Thus, a given string will appear only once in the history list. Normally, a string may appear multiple times.

--rscroll

This option changes the character used to mark truncated lines. It may begin with a two-character attribute indicator like LESSBINFMT does. If there is no attribute indicator, standout is used. If set to "-", truncated lines are not marked.

--save-marks

Save marks in the history file, so marks are retained across different invocations of *less*.

--status-col-width

Sets the width of the status column when the -J option is in effect. The default is 2 characters.

--use-backslash

This option changes the interpretations of options which follow this one. After the --use-backslash option, any backslash in an option string is removed and the following character is taken literally. This allows a dollar sign to be included in option strings.

--use-color

Enables the colored text in various places. The -D option can be used to change the colors. Colored text works only if the terminal supports ANSI color escape sequences (as defined in ECMA-48 SGR; see

<https://www.ecma-international.org/publications-and-standards/standards/ecma-48>).

--wheel-lines=n

Set the number of lines to scroll when the mouse wheel is scrolled and the --mouse or --MOUSE option is in effect. The default is 1 line.

-- A command line argument of "--" marks the end of option arguments. Any arguments following this are interpreted as filenames. This can be useful when viewing a file whose name begins with a "--" or "+".

+ If a command line option begins with +, the remainder of that option is taken to be an initial command to *less*. For example, +G tells *less* to start at the end of the file rather than the beginning, and +/xyz tells it to start at the first occurrence of "xyz" in the file. As a special case, +<number> acts like +<number>g; that is, it starts the display at the specified line number (however, see the caveat under the "g" command above). If the option starts with ++, the initial command applies to every file being viewed, not just the first one. The + command described previously may also be used to set (or change) an initial command for every file.

LINE EDITING

When entering a command line at the bottom of the screen (for example, a filename for the :e command, or the pattern for a search command), certain keys can be used to manipulate the command line. Most commands have an alternate form in [brackets] which can be used if a key does not exist on a particular keyboard. (Note that the forms beginning with ESC do not work in some MS-DOS and Windows systems because ESC is the line erase character.) Any of these special keys may be entered literally by preceding it with the "literal" character, either ^V or ^A. A backslash itself may also be entered literally by entering two backslashes.

LEFTARROW [ESC-h]

Move the cursor one space to the left.

RIGHTARROW [ESC-1]

Move the cursor one space to the right.

^LEFTARROW [ESC-b or ESC-LEFTARROW]

(That is, CONTROL and LEFTARROW simultaneously.) Move the cursor one word to the left.

^RIGHTARROW [ESC-w or ESC-RIGHTARROW]

(That is, CONTROL and RIGHTARROW simultaneously.) Move the cursor one word to the right.

- HOME [ESC-0]**
Move the cursor to the beginning of the line.
- END [ESC-\$]**
Move the cursor to the end of the line.
- BACKSPACE**
Delete the character to the left of the cursor, or cancel the command if the command line is empty.
- DELETE or [ESC-x]**
Delete the character under the cursor.
- ^BACKSPACE [ESC-BACKSPACE]**
(That is, CONTROL and BACKSPACE simultaneously.) Delete the word to the left of the cursor.
- ^DELETE [ESC-X or ESC-DELETE]**
(That is, CONTROL and DELETE simultaneously.) Delete the word under the cursor.
- UPARROW [ESC-k]**
Retrieve the previous command line. If you first enter some text and then press UPARROW, it will retrieve the previous command which begins with that text.
- DOWNARROW [ESC-j]**
Retrieve the next command line. If you first enter some text and then press DOWNARROW, it will retrieve the next command which begins with that text.
- TAB** Complete the partial filename to the left of the cursor. If it matches more than one filename, the first match is entered into the command line. Repeated TABs will cycle thru the other matching filenames. If the completed filename is a directory, a "/" is appended to the filename. (On MS-DOS systems, a "\" is appended.) The environment variable LESSSEPARATOR can be used to specify a different character to append to a directory name.
- BACKTAB [ESC-TAB]**
Like, TAB, but cycles in the reverse direction thru the matching filenames.
- ^L** Complete the partial filename to the left of the cursor. If it matches more than one filename, all matches are entered into the command line (if they fit).
- ^U (Unix and OS/2) or ESC (MS-DOS)**
Delete the entire command line, or cancel the command if the command line is empty. If you have changed your line-kill character in Unix to something other than ^U, that character is used instead of ^U.
- ^G** Delete the entire command line and return to the main prompt.

KEY BINDINGS

You may define your own *less* commands by creating a lesskey source file. This file specifies a set of command keys and an action associated with each key. You may also change the line-editing keys (see LINE EDITING), and to set environment variables. If the environment variable LESSKEYIN is set, *less* uses that as the name of the lesskey source file. Otherwise, *less* looks in a standard place for the lesskey source file: On Unix systems, *less* looks for a lesskey file called "\$XDG_CONFIG_HOME/lesskey" or "\$HOME/.lesskey". On MS-DOS and Windows systems, *less* looks for a lesskey file called "\$HOME/_lesskey", and if it is not found there, then looks for a lesskey file called "_lesskey" in any directory specified in the PATH environment variable. On OS/2 systems, *less* looks for a lesskey file called "\$HOME/lesskey.ini", and if it is not found, then looks for a lesskey file called "lesskey.ini" in any directory specified in the INIT environment variable, and if it not found there, then looks for a lesskey file called "lesskey.ini" in any directory specified in the PATH environment variable. See the lesskey manual page for more details.

A system-wide lesskey source file may also be set up to provide key bindings. If a key is defined in both a local lesskey file and in the system-wide file, key bindings in the local file take precedence over those in the system-wide file. If the environment variable LESSKEYIN_SYSTEM is set, *less* uses that as the name of the system-wide lesskey file. Otherwise, *less* looks in a standard place for the system-wide lesskey file: On

Unix systems, the system-wide lesskey file is /usr/local/etc/syslesskey. (However, if *less* was built with a different sysconf directory than /usr/local/etc, that directory is where the sysless file is found.) On MS-DOS and Windows systems, the system-wide lesskey file is c:\syslesskey. On OS/2 systems, the system-wide lesskey file is c:\syslesskey.ini.

Previous versions of *less* (before v582) used lesskey files with a binary format, produced by the *lesskey* program. It is no longer necessary to use the *lesskey* program.

INPUT PREPROCESSOR

You may define an "input preprocessor" for *less*. Before *less* opens a file, it first gives your input preprocessor a chance to modify the way the contents of the file are displayed. An input preprocessor is simply an executable program (or shell script), which writes the contents of the file to a different file, called the replacement file. The contents of the replacement file are then displayed in place of the contents of the original file. However, it will appear to the user as if the original file is opened; that is, *less* will display the original filename as the name of the current file.

An input preprocessor receives one command line argument, the original filename, as entered by the user. It should create the replacement file, and when finished, print the name of the replacement file to its standard output. If the input preprocessor does not output a replacement filename, *less* uses the original file, as normal. The input preprocessor is not called when viewing standard input. To set up an input preprocessor, set the LESSOPEN environment variable to a command line which will invoke your input preprocessor. This command line should include one occurrence of the string "%s", which will be replaced by the filename when the input preprocessor command is invoked.

When *less* closes a file opened in such a way, it will call another program, called the input postprocessor, which may perform any desired clean-up action (such as deleting the replacement file created by LESSOPEN). This program receives two command line arguments, the original filename as entered by the user, and the name of the replacement file. To set up an input postprocessor, set the LESSCLOSE environment variable to a command line which will invoke your input postprocessor. It may include two occurrences of the string "%s"; the first is replaced with the original name of the file and the second with the name of the replacement file, which was output by LESSOPEN.

For example, on many Unix systems, these two scripts will allow you to keep files in compressed format, but still let *less* view them directly:

```
lessopen.sh:
#!/bin/sh
case "$1" in
*.Z)   TEMPFILE=$(mktemp)
       uncompress -c $1 >$TEMPFILE 2>/dev/null
       if [ -s $TEMPFILE ]; then
           echo $TEMPFILE
       else
           rm -f $TEMPFILE
       fi
       ;;
esac

lessclose.sh:
#!/bin/sh
rm $2
```

To use these scripts, put them both where they can be executed and set LESSOPEN="lessopen.sh %s", and LESSCLOSE="lessclose.sh %s %s". More complex LESSOPEN and LESSCLOSE scripts may be written to accept other types of compressed files, and so on.

It is also possible to set up an input preprocessor to pipe the file data directly to *less*, rather than putting the data into a replacement file. This avoids the need to decompress the entire file before starting to view it. An input preprocessor that works this way is called an input pipe. An input pipe, instead of writing the name of a replacement file on its standard output, writes the entire contents of the replacement file on its

standard output. If the input pipe does not write any characters on its standard output, then there is no replacement file and *less* uses the original file, as normal. To use an input pipe, make the first character in the LESSOPEN environment variable a vertical bar (|) to signify that the input preprocessor is an input pipe. As with non-pipe input preprocessors, the command string must contain one occurrence of %s, which is replaced with the filename of the input file.

For example, on many Unix systems, this script will work like the previous example scripts:

`lesspipe.sh`:

```
#!/bin/sh
case "$1" in
*.Z)    uncompress -c $1 2>/dev/null
;;
*)      exit 1
;;
esac
exit $?
```

To use this script, put it where it can be executed and set LESSOPEN="|lesspipe.sh %s".

Note that a preprocessor cannot output an empty file, since that is interpreted as meaning there is no replacement, and the original file is used. To avoid this, if LESSOPEN starts with two vertical bars, the exit status of the script becomes meaningful. If the exit status is zero, the output is considered to be replacement text, even if it is empty. If the exit status is nonzero, any output is ignored and the original file is used. For compatibility with previous versions of *less*, if LESSOPEN starts with only one vertical bar, the exit status of the preprocessor is ignored.

When an input pipe is used, a LESSCLOSE postprocessor can be used, but it is usually not necessary since there is no replacement file to clean up. In this case, the replacement file name passed to the LESSCLOSE postprocessor is "-".

For compatibility with previous versions of *less*, the input preprocessor or pipe is not used if *less* is viewing standard input. However, if the first character of LESSOPEN is a dash (-), the input preprocessor is used on standard input as well as other files. In this case, the dash is not considered to be part of the preprocessor command. If standard input is being viewed, the input preprocessor is passed a file name consisting of a single dash. Similarly, if the first two characters of LESSOPEN are vertical bar and dash (|-) or two vertical bars and a dash (||-), the input pipe is used on standard input as well as other files. Again, in this case the dash is not considered to be part of the input pipe command.

NATIONAL CHARACTER SETS

There are three types of characters in the input file:

normal characters

can be displayed directly to the screen.

control characters

should not be displayed directly, but are expected to be found in ordinary text files (such as backspace and tab).

binary characters

should not be displayed directly and are not expected to be found in text files.

A "character set" is simply a description of which characters are to be considered normal, control, and binary. The LESSCHARSET environment variable may be used to select a character set. Possible values for LESSCHARSET are:

ascii BS, TAB, NL, CR, and formfeed are control characters, all chars with values between 32 and 126 are normal, and all others are binary.

iso8859

Selects an ISO 8859 character set. This is the same as ASCII, except characters between 160 and 255 are treated as normal characters.

latin1	Same as iso8859.
latin9	Same as iso8859.
dos	Selects a character set appropriate for MS-DOS.
ebcdic	Selects an EBCDIC character set.
IBM-1047	Selects an EBCDIC character set used by OS/390 Unix Services. This is the EBCDIC analogue of latin1. You get similar results by setting either LESSCHARSET=IBM-1047 or LC_CTYPE=en_US in your environment.
koi8-r	Selects a Russian character set.
next	Selects a character set appropriate for NeXT computers.
utf-8	Selects the UTF-8 encoding of the ISO 10646 character set. UTF-8 is special in that it supports multi-byte characters in the input file. It is the only character set that supports multi-byte characters.
windows	Selects a character set appropriate for Microsoft Windows (cp 1251).

In rare cases, it may be desired to tailor *less* to use a character set other than the ones definable by LESS-CHARSET. In this case, the environment variable LESSCHARDEF can be used to define a character set. It should be set to a string where each character in the string represents one character in the character set. The character "." is used for a normal character, "c" for control, and "b" for binary. A decimal number may be used for repetition. For example, "bccc4b." would mean character 0 is binary, 1, 2 and 3 are control, 4, 5, 6 and 7 are binary, and 8 is normal. All characters after the last are taken to be the same as the last, so characters 9 through 255 would be normal. (This is an example, and does not necessarily represent any real character set.)

This table shows the value of LESSCHARDEF which is equivalent to each of the possible values for LESS-CHARSET:

ascii	8bcccbbc18b95.b
dos	8bcccbbc12bc5b95.b.
ebcdic	5bc6bcc7bcc41b.9b7.9b5.b..8b6.10b6.b9.7b 9.8b8.17b3.3b9.7b9.8b8.6b10.b.b.b.
IBM-1047	4cbcbbc3b9cbccbccbb4c6bcc5b3cbcc4bc4bccbc 191.b
iso8859	8bcccbbc18b95.33b.
koi8-r	8bcccbbc18b95.b128.
latin1	8bcccbbc18b95.33b.
next	8bcccbbc18b95.bb125.bb

If neither LESSCHARSET nor LESSCHARDEF is set, but any of the strings "UTF-8", "UTF8", "utf-8" or "utf8" is found in the LC_ALL, LC_CTYPE or LANG environment variables, then the default character set is utf-8.

If that string is not found, but your system supports the *setlocale* interface, *less* will use *setlocale* to determine the character set. *setlocale* is controlled by setting the LANG or LC_CTYPE environment variables.

Finally, if the *setlocale* interface is also not available, the default character set is latin1.

Control and binary characters are displayed in standout (reverse video). Each such character is displayed in caret notation if possible (e.g. ^A for control-A). Caret notation is used only if inverting the 0100 bit results in a normal printable character. Otherwise, the character is displayed as a hex number in angle brackets. This format can be changed by setting the LESSBINFMT environment variable. LESSBINFMT may begin with a "*" and one character to select the display attribute: "*k" is blinking, "*d" is bold, "*u" is underlined, "*s" is standout, and "*n" is normal. If LESSBINFMT does not begin with a "*", normal attribute is assumed. The remainder of LESSBINFMT is a string which may include one printf-style escape sequence (a

% followed by x, X, o, d, etc.). For example, if LESSBINFMT is "*u[%x]", binary characters are displayed in underlined hexadecimal surrounded by brackets. The default if no LESSBINFMT is specified is "*s<%02X>". Warning: the result of expanding the character via LESSBINFMT must be less than 31 characters.

When the character set is utf-8, the LESSUTFBINFMT environment variable acts similarly to LESSBINFMT but it applies to Unicode code points that were successfully decoded but are unsuitable for display (e.g., unassigned code points). Its default value is "<U+%04IX>". Note that LESSUTFBINFMT and LESSBINFMT share their display attribute setting ("*x") so specifying one will affect both; LESSUTFBINFMT is read after LESSBINFMT so its setting, if any, will have priority. Problematic octets in a UTF-8 file (octets of a truncated sequence, octets of a complete but non-shortest form sequence, invalid octets, and stray trailing octets) are displayed individually using LESSBINFMT so as to facilitate diagnostic of how the UTF-8 file is ill-formed.

PROMPTS

The -P option allows you to tailor the prompt to your preference. The string given to the -P option replaces the specified prompt string. Certain characters in the string are interpreted specially. The prompt mechanism is rather complicated to provide flexibility, but the ordinary user need not understand the details of constructing personalized prompt strings.

A percent sign followed by a single character is expanded according to what the following character is:

- %bX Replaced by the byte offset into the current input file. The b is followed by a single character (shown as X above) which specifies the line whose byte offset is to be used. If the character is a "t", the byte offset of the top line in the display is used, an "m" means use the middle line, a "b" means use the bottom line, a "B" means use the line just after the bottom line, and a "j" means use the "target" line, as specified by the -j option.
- %B Replaced by the size of the current input file.
- %c Replaced by the column number of the text appearing in the first column of the screen.
- %dX Replaced by the page number of a line in the input file. The line to be used is determined by the X, as with the %b option.
- %D Replaced by the number of pages in the input file, or equivalently, the page number of the last line in the input file.
- %E Replaced by the name of the editor (from the VISUAL environment variable, or the EDITOR environment variable if VISUAL is not defined). See the discussion of the LESSEDIT feature below.
- %f Replaced by the name of the current input file.
- %F Replaced by the last component of the name of the current input file.
- %g Replaced by the shell-escaped name of the current input file. This is useful when the expanded string will be used in a shell command, such as in LESSEDIT.
- %i Replaced by the index of the current file in the list of input files.
- %lX Replaced by the line number of a line in the input file. The line to be used is determined by the X, as with the %b option.
- %L Replaced by the line number of the last line in the input file.
- %m Replaced by the total number of input files.
- %pX Replaced by the percent into the current input file, based on byte offsets. The line used is determined by the X as with the %b option.
- %PX Replaced by the percent into the current input file, based on line numbers. The line used is determined by the X as with the %b option.
- %s Same as %B.

- %t Causes any trailing spaces to be removed. Usually used at the end of the string, but may appear anywhere.
- %T Normally expands to the word "file". However if viewing files via a tags list using the -t option, it expands to the word "tag".
- %x Replaced by the name of the next input file in the list.

If any item is unknown (for example, the file size if input is a pipe), a question mark is printed instead.

The format of the prompt string can be changed depending on certain conditions. A question mark followed by a single character acts like an "IF": depending on the following character, a condition is evaluated. If the condition is true, any characters following the question mark and condition character, up to a period, are included in the prompt. If the condition is false, such characters are not included. A colon appearing between the question mark and the period can be used to establish an "ELSE": any characters between the colon and the period are included in the string if and only if the IF condition is false. Condition characters (which follow a question mark) may be:

- ?a True if any characters have been included in the prompt so far.
- ?bX True if the byte offset of the specified line is known.
- ?B True if the size of current input file is known.
- ?c True if the text is horizontally shifted (%c is not zero).
- ?dX True if the page number of the specified line is known.
- ?e True if at end-of-file.
- ?f True if there is an input filename (that is, if input is not a pipe).
- ?lX True if the line number of the specified line is known.
- ?L True if the line number of the last line in the file is known.
- ?m True if there is more than one input file.
- ?n True if this is the first prompt in a new input file.
- ?pX True if the percent into the current input file, based on byte offsets, of the specified line is known.
- ?PX True if the percent into the current input file, based on line numbers, of the specified line is known.
- ?s Same as "?B".
- ?x True if there is a next input file (that is, if the current input file is not the last one).

Any characters other than the special ones (question mark, colon, period, percent, and backslash) become literally part of the prompt. Any of the special characters may be included in the prompt literally by preceding it with a backslash.

Some examples:

?f%f:Standard input.

This prompt prints the filename, if known; otherwise the string "Standard input".

?f%f .?lLine %lt:?pt%pt\%:?btByte %bt:-...

This prompt would print the filename, if known. The filename is followed by the line number, if known, otherwise the percent if known, otherwise the byte offset if known. Otherwise, a dash is printed. Notice how each question mark has a matching period, and how the % after the %pt is included literally by escaping it with a backslash.

?n?f%f .?m(%T %i of %m) ..?e(END) ?x- Next\?: %x..%t";

This prints the filename if this is the first prompt in a file, followed by the "file N of N" message if there is more than one input file. Then, if we are at end-of-file, the string "(END)" is printed followed by the name of the next file, if there is one. Finally, any trailing spaces are truncated. This is the default prompt. For reference, here are the defaults for the other two prompts (`-m` and `-M` respectively). Each is broken into two lines here for readability only.

```
?n?f%f .?m(%T %i of %m) ..?e(END) ?x- Next\!: %x.:  
?pB%pB\%:byte %bB?s/%s...%t  
  
?f%f .?n?m(%T %i of %m) ..?lrlines %lt-%lb?L/%L. :  
byte %bB?s/%s..?e(END) ?x- Next\!: %x.:?pB%pB\%..%t
```

And here is the default message produced by the `=` command:

```
?f%f .?m(%T %i of %m) ..?lrlines %lt-%lb?L/%L. .  
byte %bB?s/%s. ?e(END) :?pB%pB\%..%t
```

The prompt expansion features are also used for another purpose: if an environment variable `LESSEDIT` is defined, it is used as the command to be executed when the `v` command is invoked. The `LESSEDIT` string is expanded in the same way as the prompt strings. The default value for `LESSEDIT` is:

```
%E ?lm+%lm. %g
```

Note that this expands to the editor name, followed by a `+` and the line number, followed by the shell-escaped file name. If your editor does not accept the "`+linenumber`" syntax, or has other differences in invocation syntax, the `LESSEDIT` variable can be changed to modify this default.

SECURITY

When the environment variable `LESSSECURE` is set to 1, *less* runs in a "secure" mode. This means these features are disabled:

!	the shell command
	the pipe command
:e	the examine command.
v	the editing command
s -o	log files
-k	use of lesskey files
-t	use of tags files
	metacharacters in filenames, such as *
	filename completion (TAB, ^L)

Less can also be compiled to be permanently in "secure" mode.

COMPATIBILITY WITH MORE

If the environment variable `LESS_IS_MORE` is set to 1, or if the program is invoked via a file link named "more", *less* behaves (mostly) in conformance with the POSIX "more" command specification. In this mode, *less* behaves differently in these ways:

The `-e` option works differently. If the `-e` option is not set, *less* behaves as if the `-e` option were set. If the `-e` option is set, *less* behaves as if the `-E` option were set.

The `-m` option works differently. If the `-m` option is not set, the medium prompt is used, and it is prefixed with the string "--More--". If the `-m` option is set, the short prompt is used.

The `-n` option acts like the `-z` option. The normal behavior of the `-n` option is unavailable in this mode.

The parameter to the `-p` option is taken to be a *less* command rather than a search pattern.

The LESS environment variable is ignored, and the MORE environment variable is used in its place.

ENVIRONMENT VARIABLES

Environment variables may be specified either in the system environment as usual, or in a *lesskey*(1) file. If environment variables are defined in more than one place, variables defined in a local lesskey file take precedence over variables defined in the system environment, which take precedence over variables defined in the system-wide lesskey file.

COLUMNS

Sets the number of columns on the screen. Takes precedence over the number of columns specified by the TERM variable. (But if you have a windowing system which supports TIOCGWINSZ or WIOCGETD, the window system's idea of the screen size takes precedence over the LINES and COLUMNS environment variables.)

EDITOR

The name of the editor (used for the v command).

HOME Name of the user's home directory (used to find a lesskey file on Unix and OS/2 systems).

HOMEDRIVE, HOMEPATH

Concatenation of the HOMEDRIVE and HOMEPATH environment variables is the name of the user's home directory if the HOME variable is not set (only in the Windows version).

INIT Name of the user's init directory (used to find a lesskey file on OS/2 systems).

LANG Language for determining the character set.

LC_CTYPE

Language for determining the character set.

LESS Options which are passed to *less* automatically.

LESSANSIENDCHARS

Characters which may end an ANSI color escape sequence (default "m").

LESSANSIMIDCHARS

Characters which may appear between the ESC character and the end character in an ANSI color escape sequence (default "0123456789:[?!"'#%()^+ "].

LESSBINFMT

Format for displaying non-printable, non-control characters.

LESSCHARDEF

Defines a character set.

LESSCHARSET

Selects a predefined character set.

LESSCLOSE

Command line to invoke the (optional) input-postprocessor.

LESSECHO

Name of the lessecho program (default "lessecho"). The lessecho program is needed to expand metacharacters, such as * and ?, in filenames on Unix systems.

LESSEDIT

Editor prototype string (used for the v command). See discussion under PROMPTS.

LESSGLOBALTAGS

Name of the command used by the -t option to find global tags. Normally should be set to "global" if your system has the *global*(1) command. If not set, global tags are not used.

LESSHISTFILE

Name of the history file used to remember search commands and shell commands between invocations of *less*. If set to "-" or "/dev/null", a history file is not used. The default is "\$XDG_DATA_HOME/.lesshist" or "\$HOME/.lesshist" on Unix systems, "\$HOME/_lesshist" on DOS and Win-

dows systems, or "\$HOME/lessht.ini" or "\$INIT/lessht.ini" on OS/2 systems.

LESSHISTSIZE

The maximum number of commands to save in the history file. The default is 100.

LESSKEYIN

Name of the default *lesskey source* file.

LESSKEY

Name of the default *lesskey binary* file. (Not used if "\$LESSKEYIN" exists.)

LESSKEYIN_SYSTEM

Name of the default system-wide *lesskey source* file.

LESSKEY_SYSTEM

Name of the default system-wide *lesskey binary* file. (Not used if "\$LESSKEYIN_SYSTEM" exists.)

LESSMETACHARS

List of characters which are considered "metacharacters" by the shell.

LESSMETAESCAPE

Prefix which less will add before each metacharacter in a command sent to the shell. If LESSMETAESCAPE is an empty string, commands containing metacharacters will not be passed to the shell.

LESSOPEN

Command line to invoke the (optional) input-preprocessor.

LESSSECURE

Runs less in "secure" mode. See discussion under SECURITY.

LESSSEPARATOR

String to be appended to a directory name in filename completion.

LESSUTFBINFMT

Format for displaying non-printable Unicode code points.

LESS_IS_MORE

Emulate the *more*(1) command.

LINES Sets the number of lines on the screen. Takes precedence over the number of lines specified by the TERM variable. (But if you have a windowing system which supports TIOCGWINSZ or WIOCGETD, the window system's idea of the screen size takes precedence over the LINES and COLUMNS environment variables.)

MORE Options which are passed to *less* automatically when running in *more* compatible mode.

PATH User's search path (used to find a lesskey file on MS-DOS and OS/2 systems).

SHELL

The shell used to execute the ! command, as well as to expand filenames.

TERM The type of terminal on which *less* is being run.

VISUAL

The name of the editor (used for the v command).

NAME

lessecho – expand metacharacters

SYNOPSIS

lessecho [*-ox*] [*-cx*] [*-pn*] [*-dn*] [*-mx*] [*-nn*] [*-ex*] [*-a*] *file ...*

DESCRIPTION

lessecho is a program that simply echos its arguments on standard output. But any metacharacter in the output is preceded by an "escape" character, which by default is a backslash.

OPTIONS

A summary of options is included below.

- ex** Specifies "x", rather than backslash, to be the escape char for metachars. If x is "-", no escape char is used and arguments containing metachars are surrounded by quotes instead.
- ox** Specifies "x", rather than double-quote, to be the open quote character, which is used if the -e- option is specified.
- cx** Specifies "x" to be the close quote character.
- pn** Specifies "n" to be the open quote character, as an integer.
- dn** Specifies "n" to be the close quote character, as an integer.
- mx** Specifies "x" to be a metachar. By default, no characters are considered metachars.
- nn** Specifies "n" to be a metachar, as an integer.
- fn** Specifies "n" to be the escape char for metachars, as an integer.
- a** Specifies that all arguments are to be quoted. The default is that only arguments containing metacharacters are quoted.

NAME

lessfile, *lesspipe* – "input preprocessor" for *less*.

SYNOPSIS

lessfile, lesspipe

DESCRIPTION

This manual page documents briefly the *lessfile*, and *lesspipe* commands. This manual page was written for the Debian GNU/Linux distribution because the input preprocessor scripts are provided by Debian GNU/Linux and are not part of the original program.

lessfile and *lesspipe* are programs that can be used to modify the way the contents of a file are displayed in *less*. What this means is that *less* can automatically open up tar files, uncompress gzipped files, and even display something reasonable for graphics files.

lesspipe will toss the contents/info on STDOUT and *less* will read them as they come across. This means that you do not have to wait for the decoding to finish before less shows you the file. This also means that you will get a 'byte N' instead of an N% as your file position. You can seek to the end and back to get the N% but that means you have to wait for the pipe to finish.

lessfile will toss the contents/info on a file which *less* will then read. After you are done, *lessfile* will then delete the file. This means that the process has to finish before you see it, but you get nice percentages (N%) up front.

USAGE

Just put one of the following two commands in your login script (e.g. `~/.bash_profile`):

```
eval "$(lessfile)"
```

or

```
eval "$(lesspipe)"
```

FILE TYPE RECOGNITION

File types are recognized by their extensions. This is a list of currently supported extensions (grouped by the programs that handle them):

```
*.a  
*.arj  
*.tar.bz2  
*.bz  
*.bz2  
*.deb, *.udeb, *.ddeb  
*.doc  
*.egg  
*.gif, *.jpeg, *.jpg, *.pcd, *.png, *.tga, *.tiff, *.tif  
*.iso, *.raw, *.bin  
*.lha, *.lzh  
*.tar.lz, *.tlz  
*.lz  
*.7z  
*.pdf  
*.rar, *.r[0-9][0-9]  
*.rpm  
*.tar.gz, *.tgz, *.tar.z, *.tar.dz  
*.gz, *.z, *.dz  
*.tar  
*.tar.xz, *.xz  
*.whl  
*.jar, *.war, *.xpi, *.zip
```

```
*.zoo
*.tar.zst, *.tzst
*.zst
```

USER DEFINED FILTERS

It is possible to extend and overwrite the default *lesspipe* and *lessfile* input processor if you have specialized requirements. Create an executable program with the name *.lessfilter* and put it into your home directory. This can be a shell script or a binary program.

It is important that this program returns the correct exit code: return 0 if your filter handles the input, return 1 if the standard *lesspipe/lessfile* filter should handle the input.

Here is an example script:

```
#!/bin/sh

case "$1" in
  *.extension)
    extension-handler "$1"
    ;;
  *)
    # We don't handle this format.
    exit 1
esac

# No further processing by lesspipe necessary
exit 0
```

FILES

~.lessfilter

Executable file that can do user defined processing. See section USER DEFINED FILTERS for more information.

BUGS

Sometimes, less does not display the contents file you want to view but output that is produced by your login scripts (*~/.bashrc* or *~/.bash_profile*). This happens because less uses your current shell to run the *lesspipe* filter. Bash first looks for the variable *\$BASH_ENV* in the environment expands its value and uses the expanded value as the name of a file to read and execute. If this file produces any output less will display this. A way to solve this problem is to put the following lines on the top of your login script that produces output:

```
if [ -z "$PS1" ]; then
  exit
fi
```

This tests whether the prompt variable *\$PS1* is set and if it isn't (which is the case for non-interactive shells) it will exit the script.

NAME

`lesskey` – specify key bindings for `less`

SYNOPSIS (deprecated)

```
lesskey [-o output] [--] [input]
lesskey [--output=output] [--] [input]
lesskey -V
lesskey --version
```

SCOPE

This document describes the format of the `lesskey` source file, which is used by `less` version 582 and later. In previous versions of `less`, a separate program called `lesskey` was used to compile the `lesskey` source file into a format understood by `less`. This compilation step is no longer required and the `lesskey` program is therefore deprecated although the file format remains supported by `less` itself.

FILE FORMAT

The input file consists of one or more *sections*. Each section starts with a line that identifies the type of section. Possible sections are:

#command	Defines new command keys.
#line-edit	Defines new line-editing keys.
#env	Defines environment variables.

Blank lines and lines which start with a pound sign (#) are ignored, except for the special section header lines.

COMMAND SECTION

The command section begins with the line

```
#command
```

If the command section is the first section in the file, this line may be omitted. The command section consists of lines of the form:

```
string <whitespace> action [extra-string] <newline>
```

Whitespace is any sequence of one or more spaces and/or tabs. The *string* is the command key(s) which invoke the action. The *string* may be a single command key, or a sequence of up to 15 keys. The *action* is the name of the less action, from the list below. The characters in the *string* may appear literally, or be prefixed by a caret to indicate a control key. A backslash followed by one to three octal digits may be used to specify a character by its octal value. A backslash followed by certain characters specifies input characters as follows:

\b	BACKSPACE
\e	ESCAPE
\n	NEWLINE
\r	RETURN
\t	TAB
\ku	UP ARROW
\kd	DOWN ARROW
\kr	RIGHT ARROW
\kl	LEFT ARROW

\kU	PAGE UP
\kD	PAGE DOWN
\kh	HOME
\ke	END
\kx	DELETE

A backslash followed by any other character indicates that character is to be taken literally. Characters which must be preceded by backslash include caret, space, tab and the backslash itself.

An action may be followed by an "extra" string. When such a command is entered while running *less*, the action is performed, and then the extra string is parsed, just as if it were typed in to *less*. This feature can be used in certain cases to extend the functionality of a command. For example, see the "{" and ":" commands in the example below. The extra string has a special meaning for the "quit" action: when *less* quits, the first character of the extra string is used as its exit status.

EXAMPLE

The following input file describes the set of default command keys used by *less*:

```
#command
\r      forw-line
\n      forw-line
\ e    forw-line
\ j    forw-line
\kd   forw-line
^E    forw-line
^N    forw-line
\ k    back-line
\ y    back-line
^Y    back-line
^K    back-line
^P    back-line
J     forw-line-force
K     back-line-force
Y     back-line-force
d     forw-scroll
^D   forw-scroll
\ u   back-scroll
^U   back-scroll
\40  forw-screen
f     forw-screen
^F   forw-screen
^V   forw-screen
\kD  forw-screen
b     back-screen
^B   back-screen
\ev  back-screen
\kU  back-screen
z     forw-window
w     back-window
\e\40 forw-screen-force
F     forw-forever
\ef  forw-until-hilite
R     repaint-flush
```

r	repaint
^R	repaint
^L	repaint

q	quit
Q	quit
:q	quit
:Q	quit
ZZ	quit

PRECEDENCE

Commands specified by *lesskey* take precedence over the default commands. A default command key may be disabled by including it in the input file with the action "invalid". Alternatively, a key may be defined to do nothing by using the action "noaction". "noaction" is similar to "invalid", but *less* will give an error beep for an "invalid" command, but not for a "noaction" command. In addition, ALL default commands may be disabled by adding this control line to the input file:

```
#stop
```

This will cause all default commands to be ignored. The #stop line should be the last line in that section of the file.

Be aware that #stop can be dangerous. Since all default commands are disabled, you must provide sufficient commands before the #stop line to enable all necessary actions. For example, failure to provide a "quit" command can lead to frustration.

LINE EDITING SECTION

The line-editing section begins with the line:

```
#line-edit
```

This section specifies new key bindings for the line editing commands, in a manner similar to the way key bindings for ordinary commands are specified in the #command section. The line-editing section consists

of a list of keys and actions, one per line as in the example below.

EXAMPLE

The following input file describes the set of default line-editing keys used by less:

```
#line-edit
\t      forw-complete
\17    back-complete
\e\t   back-complete
^L     expand
^V     literal
^A     literal
\el    right
\kr    right
\eh    left
\kl    left
\eb    word-left
\ekl   word-left
\ew    word-right
\ekr   word-right
\ei    insert
\ex    delete
\kx    delete
\ex    word-delete
\ekx   word-delete
\eb    word-backspace
\eo    home
\kh    home
\es    end
\ke    end
\ek    up
\ku    up
\ej    down
^G    abort
```

LESS ENVIRONMENT VARIABLES

The environment variable section begins with the line

```
#env
```

Following this line is a list of environment variable assignments. Each line consists of an environment variable name, an equals sign (=) and the value to be assigned to the environment variable. White space before and after the equals sign is ignored. Variables assigned in this way are visible only to *less*. If a variable is specified in the system environment and also in a lesskey file, the value in the lesskey file takes precedence. Although the lesskey file can be used to override variables set in the environment, the main purpose of assigning variables in the lesskey file is simply to have all *less* configuration information stored in one file.

EXAMPLE

The following input file sets the *-i* option whenever *less* is run, and specifies the character set to be "latin1":

```
#env
LESS = -i
LESSCHARSET = latin1
```

SEE ALSO

less(1)

WARNINGS

On MS-DOS and OS/2 systems, certain keys send a sequence of characters which start with a NUL character (0). This NUL character should be represented as \340 in a lesskey file.

NAME

lessfile, *lesspipe* – "input preprocessor" for *less*.

SYNOPSIS

lessfile, lesspipe

DESCRIPTION

This manual page documents briefly the *lessfile*, and *lesspipe* commands. This manual page was written for the Debian GNU/Linux distribution because the input preprocessor scripts are provided by Debian GNU/Linux and are not part of the original program.

lessfile and *lesspipe* are programs that can be used to modify the way the contents of a file are displayed in *less*. What this means is that *less* can automatically open up tar files, uncompress gzipped files, and even display something reasonable for graphics files.

lesspipe will toss the contents/info on STDOUT and *less* will read them as they come across. This means that you do not have to wait for the decoding to finish before less shows you the file. This also means that you will get a 'byte N' instead of an N% as your file position. You can seek to the end and back to get the N% but that means you have to wait for the pipe to finish.

lessfile will toss the contents/info on a file which *less* will then read. After you are done, *lessfile* will then delete the file. This means that the process has to finish before you see it, but you get nice percentages (N%) up front.

USAGE

Just put one of the following two commands in your login script (e.g. `~/.bash_profile`):

```
eval "$(lessfile)"
```

or

```
eval "$(lesspipe)"
```

FILE TYPE RECOGNITION

File types are recognized by their extensions. This is a list of currently supported extensions (grouped by the programs that handle them):

```
*.a  
*.arj  
*.tar.bz2  
*.bz  
*.bz2  
*.deb, *.udeb, *.ddeb  
*.doc  
*.egg  
*.gif, *.jpeg, *.jpg, *.pcd, *.png, *.tga, *.tiff, *.tif  
*.iso, *.raw, *.bin  
*.lha, *.lzh  
*.tar.lz, *.tlz  
*.lz  
*.7z  
*.pdf  
*.rar, *.r[0-9][0-9]  
*.rpm  
*.tar.gz, *.tgz, *.tar.z, *.tar.dz  
*.gz, *.z, *.dz  
*.tar  
*.tar.xz, *.xz  
*.whl  
*.jar, *.war, *.xpi, *.zip
```

```
*.zoo
*.tar.zst, *.tzst
*.zst
```

USER DEFINED FILTERS

It is possible to extend and overwrite the default *lesspipe* and *lessfile* input processor if you have specialized requirements. Create an executable program with the name *.lessfilter* and put it into your home directory. This can be a shell script or a binary program.

It is important that this program returns the correct exit code: return 0 if your filter handles the input, return 1 if the standard *lesspipe/lessfile* filter should handle the input.

Here is an example script:

```
#!/bin/sh

case "$1" in
  *.extension)
    extension-handler "$1"
    ;;
  *)
    # We don't handle this format.
    exit 1
esac

# No further processing by lesspipe necessary
exit 0
```

FILES

~.lessfilter

Executable file that can do user defined processing. See section USER DEFINED FILTERS for more information.

BUGS

Sometimes, less does not display the contents file you want to view but output that is produced by your login scripts (*~/.bashrc* or *~/.bash_profile*). This happens because less uses your current shell to run the *lesspipe* filter. Bash first looks for the variable *\$BASH_ENV* in the environment expands its value and uses the expanded value as the name of a file to read and execute. If this file produces any output less will display this. A way to solve this problem is to put the following lines on the top of your login script that produces output:

```
if [ -z "$PS1" ]; then
  exit
fi
```

This tests whether the prompt variable *\$PS1* is set and if it isn't (which is the case for non-interactive shells) it will exit the script.

NAME

plocate – find files by name, quickly

SYNOPSIS

plocate [*OPTION*]... *PATTERN*...

DESCRIPTION

plocate finds all files on the system matching the given pattern (or all of the patterns if multiple are given). It does this by means of an index made by **updatedb(8)** or (less commonly) converted from another index by **plocate-build(8)**.

plocate is largely argument-compatible with **mlocate(1)**, but is significantly faster. In particular, it rarely needs to scan through its entire database, unless the pattern is very short (less than three bytes) or you want to search for a regular expression. It does not try to maintain compatibility with BSD locate, or non-UTF-8 filenames and locales. Most I/O is done asynchronously, but the results are synchronized so that output comes in the same order every time.

When multiple patterns are given, **plocate** will search for files that match *all* of them. This is the main incompatibility with **mlocate(1)**, which searches for files that match one or more patterns, unless the **-A** option is given.

By default, patterns are taken to be substrings to search for. If at least one non-escaped globbing metacharacter (*, ?, or []) is given, that pattern is instead taken to be a glob pattern (which means it needs to start and end in * for a substring match). If **--regexp** is given, patterns are instead taken to be (non-anchored) POSIX basic regular expressions, and if **--regex** is given, patterns are taken to be POSIX extended regular expressions. All of this matches **mlocate(1)** behavior.

Like **mlocate(1)**, **plocate** shows all files visible to the calling user (by virtue of having read and execute permissions on all parent directories), and none that are not, by means of running with the setgid bit set to access the index (which is built as root), but by testing visibility as the calling user.

OPTIONS**-A, --all**

Ignored for compatibility with **mlocate(1)**.

-b, --basename

Match only against the file name portion of the path name, ie., the directory names will be excluded from the match (but still printed). This does not speed up the search, but can suppress uninteresting matches.

-c, --count

Do not print each match. Instead, count them, and print out a total number at the end.

-d, --database DBPATH

Find matches in the given database, instead of **/var/lib/plocate/plocate.db**. This argument can be given multiple times, to search multiple databases. It is also possible to give multiple databases in one argument, separated by :. (Any character, including :, and \, can be escaped by prepending a \.)

-e, --existing

Print only entries that refer to files existing at the time **locate** is run. Note that unlike **mlocate(1)**, symlinks are not followed by default (and indeed, there is no option to change this).

-i, --ignore-case

Do a case-insensitive match as given by the current locale (default is case-sensitive, byte-by-byte match). Note that **plocate** does not support the full range of Unicode case folding rules; in particular, searching for β will not give you matches on ss even in a German locale. Also note that this option will be somewhat slower than a case-sensitive match, since it needs to generate more candidates for searching the index.

-p, --ignore-spaces

Ignore punctuation and spaces when matching patterns.

-l, --limit LIMIT

Stop searching after *LIMIT* matches have been found. If **--count** is given, the number printed out will be at most *LIMIT*.

-N, --literal

Print entry names without quoting. Normally, **plocate** will escape special characters in filenames, so that they are safe for consumption by typical shells (similar to the GNU coreutils *shell-escape-always* quoting style), unless printing to a pipe, but this option will turn off such quoting.

-0, --null

Instead of writing a newline after every match, write a NUL (ASCII 0). This is useful for creating unambiguous output when it is to be processed by other tools (like **xargs(1)**), as filenames are allowed to contain embedded newlines.

-r, --regexp

Patterns are taken to be POSIX basic regular expressions. See **egrep(7)** for more information. Note that this forces a linear scan through the entire database, which is slow.

--regex

Like **--regexp**, but patterns are instead taken to be POSIX *extended* regular expressions.

-w, --wholename

Match against the entire path name. This is the default, so unless **-b** is given first (see above), it will not do anything. This option thus exists only as compatibility with **mlocate(1)**.

--help Print out usage information, then exit successfully.**--version**

Print out version information, then exit successfully.

ENVIRONMENT**LOCATE_PATH**

If given, appended after the list of **--database** paths (whether an explicit is given or the default is used). Colon-delimiting and character escaping follows the same rules as for **--database**.

NAME

ls – list directory contents

SYNOPSIS

ls [*OPTION*]... [*FILE*]...

DESCRIPTION

List information about the **FILEs** (the current directory by default). Sort entries alphabetically if none of **-cftuvSUX** nor **--sort** is specified.

Mandatory arguments to long options are mandatory for short options too.

-a, --all

do not ignore entries starting with `.`

-A, --almost-all

do not list implied `.` and `..`

--author

with **-l**, print the author of each file

-b, --escape

print C-style escapes for nongraphic characters

--block-size=SIZE

with **-l**, scale sizes by **SIZE** when printing them; e.g., '**--block-size=M**'; see **SIZE** format below

-B, --ignore-backups

do not list implied entries ending with `~`

-c with **-lt**: sort by, and show, ctime (time of last modification of file status information); with **-l**: show ctime and sort by name; otherwise: sort by ctime, newest first

-C list entries by columns

--color[=WHEN]

colorize the output; **WHEN** can be 'always' (default if omitted), 'auto', or 'never'; more info below

-d, --directory

list directories themselves, not their contents

-D, --dirend

generate output designed for Emacs' **dirend** mode

-f do not sort, enable **-aU**, disable **-ls --color**

-F, --classify

append indicator (one of `*/=>@|`) to entries

--file-type

likewise, except do not append `*`

--format=WORD

across **-x**, commas **-m**, horizontal **-x**, long **-l**, single-column **-1**, verbose **-l**, vertical **-C**

--full-time

like **-l --time-style=full-iso**

-g like **-l**, but do not list owner

--group-directories-first

group directories before files;

can be augmented with a **--sort** option, but any use of **--sort=none** (**-U**) disables grouping

-G, --no-group
 in a long listing, don't print group names

-h, --human-readable
 with -l and -s, print sizes like 1K 234M 2G etc.

--si likewise, but use powers of 1000 not 1024

-H, --dereference-command-line
 follow symbolic links listed on the command line

--dereference-command-line-symlink-to-dir
 follow each command line symbolic link
 that points to a directory

--hide= PATTERN
 do not list implied entries matching shell PATTERN (overridden by -a or -A)

--hyperlink[= WHEN]
 hyperlink file names; WHEN can be 'always' (default if omitted), 'auto', or 'never'

--indicator-style=WORD
 append indicator with style WORD to entry names: none (default), slash (-p), file-type
 (--file-type), classify (-F)

-i, --inode
 print the index number of each file

-I, --ignore= PATTERN
 do not list implied entries matching shell PATTERN

-k, --kibibytes
 default to 1024-byte blocks for disk usage; used only with -s and per directory totals

-l use a long listing format

-L, --dereference
 when showing file information for a symbolic link, show information for the file the link references rather than for the link itself

-m fill width with a comma separated list of entries

-n, --numeric-uid-gid
 like -l, but list numeric user and group IDs

-N, --literal
 print entry names without quoting

-o like -l, but do not list group information

-p, --indicator-style=slash
 append / indicator to directories

-q, --hide-control-chars
 print ? instead of nongraphic characters

--show-control-chars
 show nongraphic characters as-is (the default, unless program is 'ls' and output is a terminal)

-Q, --quote-name
 enclose entry names in double quotes

--quoting-style=WORD
 use quoting style WORD for entry names: literal, locale, shell, shell-always, shell-escape,
 shell-escape-always, c, escape (overrides QUOTING_STYLE environment variable)

-r, --reverse
 reverse order while sorting

-R, --recursive
 list subdirectories recursively

-s, --size
 print the allocated size of each file, in blocks

-S sort by file size, largest first

--sort=WORD
 sort by WORD instead of name: none (-U), size (-S), time (-t), version (-v), extension (-X)

--time=WORD
 change the default of using modification times; access time (-u): atime, access, use; change time (-c): ctime, status; birth time: birth, creation;
 with -l, WORD determines which time to show; with --sort=time, sort by WORD (newest first)

--time-style=TIME_STYLE
 time/date format with -l; see TIME_STYLE below

-t sort by time, newest first; see --time

-T, --tabsize=COLS
 assume tab stops at each COLS instead of 8

-u with -lt: sort by, and show, access time; with -l: show access time and sort by name; otherwise:
 sort by access time, newest first

-U do not sort; list entries in directory order

-v natural sort of (version) numbers within text

-w, --width=COLS
 set output width to COLS. 0 means no limit

-x list entries by lines instead of by columns

-X sort alphabetically by entry extension

-Z, --context
 print any security context of each file

-1 list one file per line. Avoid '\n' with -q or -b

--help display this help and exit

--version
 output version information and exit

The SIZE argument is an integer and optional unit (example: 10K is 10*1024). Units are K,M,G,T,P,E,Z,Y (powers of 1024) or KB,MB,... (powers of 1000). Binary prefixes can be used, too: KiB=K, MiB=M, and so on.

The TIME_STYLE argument can be full-iso, long-iso, iso, locale, or +FORMAT. FORMAT is interpreted like in date(1). If FORMAT is FORMAT1<newline>FORMAT2, then FORMAT1 applies to non-recent files and FORMAT2 to recent files. TIME_STYLE prefixed with 'posix-' takes effect only outside the POSIX locale. Also the TIME_STYLE environment variable sets the default style to use.

Using color to distinguish file types is disabled both by default and with --color=never. With --color=auto, ls emits color codes only when standard output is connected to a terminal. The LS_COLORS environment variable can change the settings. Use the dircolors command to set it.

Exit status:

0 if OK,

- 1 if minor problems (e.g., cannot access subdirectory),
- 2 if serious trouble (e.g., cannot access command-line argument).

NAME

lsblk – list block devices

SYNOPSIS

lsblk [options] [*device...*]

DESCRIPTION

lsblk lists information about all available or the specified block devices. The **lsblk** command reads the **sysfs** filesystem and **udev db** to gather information. If the udev db is not available or **lsblk** is compiled without udev support, then it tries to read LABELs, UUIDs and filesystem types from the block device. In this case root permissions are necessary.

The command prints all block devices (except RAM disks) in a tree-like format by default. Use **lsblk --help** to get a list of all available columns.

The default output, as well as the default output from options like **--fs** and **--topology**, is subject to change. So whenever possible, you should avoid using default outputs in your scripts. Always explicitly define expected columns by using **--output columns-list** and **--list** in environments where a stable output is required.

Note that **lsblk** might be executed in time when **udev** does not have all information about recently added or modified devices yet. In this case it is recommended to use **udevadm settle** before **lsblk** to synchronize with udev.

The relationship between block devices and filesystems is not always one-to-one. The filesystem may use more block devices, or the same filesystem may be accessible by more paths. This is the reason why **lsblk** provides MOUNTPOINT and MOUNTPOINTS (pl.) columns. The column MOUNTPOINT displays only one mount point (usually the last mounted instance of the filesystem), and the column MOUNTPOINTS displays by multi-line cell all mount points associated with the device.

OPTIONS

-A, --noempty

Don't print empty devices.

-a, --all

Disable all built-in filters and list all empty devices and RAM disk devices too.

-b, --bytes

Print the sizes in bytes rather than in a human-readable format.

By default, the unit, sizes are expressed in, is byte, and unit prefixes are in power of 2^10 (1024).

Abbreviations of symbols are exhibited truncated in order to reach a better readability, by exhibiting alone the first letter of them; examples: "1 KiB" and "1 MiB" are respectively exhibited as "1 K" and "1 M", then omitting on purpose the mention "iB", which is part of these abbreviations.

-D, --discard

Print information about the discarding capabilities (TRIM, UNMAP) for each device.

-d, --nodeps

Do not print holder devices or slaves. For example, **lsblk --nodeps /dev/sda** prints information about the sda device only.

-E, --dedup column

Use *column* as a de-duplication key to de-duplicate output tree. If the key is not available for the device, or the device is a partition and parental whole-disk device provides the same key than the device is always printed.

The usual use case is to de-duplicate output on system multi-path devices, for example by **-E WWN**.

-e, --exclude *list*

Exclude the devices specified by the comma-separated *list* of major device numbers. Note that RAM disks (major=1) are excluded by default if **--all** is not specified. The filter is applied to the top-level devices only. This may be confusing for **--list** output format where hierarchy of the devices is not obvious.

-f, --fs

Output info about filesystems. This option is equivalent to **-o NAME,FSTYPE,FSVER,LABEL,UUID,FSAVAIL,FSUSE%,MOUNTPOINTS**. The authoritative information about filesystems and raids is provided by the **blkid(8)** command.

-I, --include *list*

Include devices specified by the comma-separated *list* of major device numbers. The filter is applied to the top-level devices only. This may be confusing for **--list** output format where hierarchy of the devices is not obvious.

-i, --ascii

Use ASCII characters for tree formatting.

-J, --json

Use JSON output format. It's strongly recommended to use **--output** and also **--tree** if necessary.

-l, --list

Produce output in the form of a list. The output does not provide information about relationships between devices and since version 2.34 every device is printed only once if **--pairs** or **--raw** not specified (the parsable outputs are maintained in backwardly compatible way).

-M, --merge

Group parents of sub-trees to provide more readable output for RAIDs and Multi-path devices. The tree-like output is required.

-m, --perms

Output info about device owner, group and mode. This option is equivalent to **-o NAME,SIZE,OWNER,GROUP,MODE**.

-n, --noheadings

Do not print a header line.

-o, --output *list*

Specify which output columns to print. Use **--help** to get a list of all supported columns. The columns may affect tree-like output. The default is to use tree for the column 'NAME' (see also **--tree**).

The default list of columns may be extended if *list* is specified in the format **+list** (e.g., **lsblk -o +UUID**).

-O, --output-all

Output all available columns.

-P, --pairs

Produce output in the form of key="value" pairs. The output lines are still ordered by dependencies. All potentially unsafe value characters are hex-escaped (`\x<code>`). See also option **--shell**.

-p, --paths

Print full device paths.

-r, --raw

Produce output in raw format. The output lines are still ordered by dependencies. All potentially unsafe characters are hex-escaped (`\x<code>`) in the NAME, KNAME, LABEL, PARTLABEL and MOUNTPOINT columns.

-S, --scsi

Output info about SCSI devices only. All partitions, slaves and holder devices are ignored.

-s, --inverse

Print dependencies in inverse order. If the **--list** output is requested then the lines are still ordered by dependencies.

-T, --tree[=column]

Force tree-like output format. If *column* is specified, then a tree is printed in the column. The default is NAME column.

-t, --topology

Output info about block-device topology. This option is equivalent to

-o

NAME,ALIGNMENT,MIN-IO,OPT-IO,PHY-SEC,LOG-SEC,ROTA,SCHED,RQ-SIZE,RA,WSAME.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

-w, --width number

Specifies output width as a number of characters. The default is the number of the terminal columns, and if not executed on a terminal, then output width is not restricted at all by default. This option also forces **lsblk** to assume that terminal control characters and unsafe characters are not allowed. The expected use-case is for example when **lsblk** is used by the **watch(1)** command.

-x, --sort column

Sort output lines by *column*. This option enables **--list** output format by default. It is possible to use the option **--tree** to force tree-like output and than the tree branches are sorted by the *column*.

-y, --shell

The column name will be modified to contain only characters allowed for shell variable identifiers, for example, MIN_IO and FSUSE_PCT instead of MIN-IO and FSUSE%. This is usable, for example, with **--pairs**. Note that this feature has been automatically enabled for **--pairs** in version 2.37, but due to compatibility issues, now it's necessary to request this behavior by **--shell**.

-z, --zoned

Print the zone related information for each device.

--sysroot directory

Gather data for a Linux instance other than the instance from which the **lsblk** command is issued. The specified directory is the system root of the Linux instance to be inspected. The real device nodes in the target directory can be replaced by text files with udev attributes.

EXIT STATUS

0	success
1	failure
32	none of specified devices found
64	some specified devices found, some not found

ENVIRONMENT

LSBLK_DEBUG=all
enables **lsblk** debug output.

LIBBLKID_DEBUG=all
enables **libblkid** debug output.

LIBMOUNT_DEBUG=all
enables **libmount** debug output.

LIBSMARTCOLS_DEBUG=all
enables **libsmartcols** debug output.

LIBSMARTCOLS_DEBUG_PADDING=on
use visible padding characters.

NOTES

For partitions, some information (e.g., queue attributes) is inherited from the parent device.

The **lsblk** command needs to be able to look up each block device by major:minor numbers, which is done by using `/sys/dev/block`. This sysfs block directory appeared in kernel 2.6.27 (October 2008). In case of problems with a new enough kernel, check that **CONFIG_SYSFS** was enabled at the time of the kernel build.

AVAILABILITY

The **lsblk** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

lscpu – display information about the CPU architecture

SYNOPSIS

lscpu [options]

DESCRIPTION

lscpu gathers CPU architecture information from *sysfs*, */proc/cpuinfo* and any applicable architecture-specific libraries (e.g. **librtas** on Powerpc). The command output can be optimized for parsing or for easy readability by humans. The information includes, for example, the number of CPUs, threads, cores, sockets, and Non-Uniform Memory Access (NUMA) nodes. There is also information about the CPU caches and cache sharing, family, model, bogoMIPS, byte order, and stepping.

The default output formatting on terminal is subject to change and maybe optimized for better readability. The output for non-terminals (e.g., pipes) is never affected by this optimization and it is always in "Field: data\n" format. Use for example "**lscpu | less**" to see the default output without optimizations.

In virtualized environments, the CPU architecture information displayed reflects the configuration of the guest operating system which is typically different from the physical (host) system. On architectures that support retrieving physical topology information, **lscpu** also displays the number of physical sockets, chips, cores in the host system.

Options that result in an output table have a *list* argument. Use this argument to customize the command output. Specify a comma-separated list of column labels to limit the output table to only the specified columns, arranged in the specified order. See **COLUMNS** for a list of valid column labels. The column labels are not case sensitive.

Not all columns are supported on all architectures. If an unsupported column is specified, **lscpu** prints the column but does not provide any data for it.

The cache sizes are reported as summary from all CPUs. The versions before v2.34 reported per-core sizes, but this output was confusing due to complicated CPUs topology and the way how caches are shared between CPUs. For more details about caches see **--cache**. Since version v2.37 **lscpu** follows cache IDs as provided by Linux kernel and it does not always start from zero.

OPTIONS

-a, --all

Include lines for online and offline CPUs in the output (default for **-e**). This option may only be specified together with option **-e** or **-p**.

-B, --bytes

Print the sizes in bytes rather than in a human-readable format.

By default, the unit, sizes are expressed in, is byte, and unit prefixes are in power of 2^{10} (1024). Abbreviations of symbols are exhibited truncated in order to reach a better readability, by exhibiting alone the first letter of them; examples: "1 KiB" and "1 MiB" are respectively exhibited as "1 K" and "1 M", then omitting on purpose the mention "iB", which is part of these abbreviations.

-b, --online

Limit the output to online CPUs (default for **-p**). This option may only be specified together with option **-e** or **-p**.

-C, --caches[=list]

Display details about CPU caches. For details about available information see **--help** output.

If the *list* argument is omitted, all columns for which data is available are included in the command

output.

When specifying the *list* argument, the string of option, equal sign (=), and *list* must not contain any blanks or other whitespace. Examples: **-C=NAME,ONE-SIZE** or **--caches=NAME,ONE-SIZE**.

The default list of columns may be extended if list is specified in the format +list (e.g., **lscpu -C=+ALLOC-POLICY**).

-c, --offline

Limit the output to offline CPUs. This option may only be specified together with option **-e** or **-p**.

-e, --extended[=list]

Display the CPU information in human-readable format.

If the *list* argument is omitted, the default columns are included in the command output. The default output is subject to change.

When specifying the *list* argument, the string of option, equal sign (=), and *list* must not contain any blanks or other whitespace. Examples: **'-e=cpu,node'** or **'--extended=cpu,node'**.

The default list of columns may be extended if list is specified in the format +list (e.g., **lscpu -e=+MHZ**).

-J, --json

Use JSON output format for the default summary or extended output (see **--extended**).

-p, --parse[=list]

Optimize the command output for easy parsing.

If the *list* argument is omitted, the command output is compatible with earlier versions of **lscpu**. In this compatible format, two commas are used to separate CPU cache columns. If no CPU caches are identified the cache column is omitted. If the *list* argument is used, cache columns are separated with a colon (:).

When specifying the *list* argument, the string of option, equal sign (=), and *list* must not contain any blanks or other whitespace. Examples: **'-p=cpu,node'** or **'--parse=cpu,node'**.

The default list of columns may be extended if list is specified in the format +list (e.g., **lscpu -p=+MHZ**).

-s, --sysroot directory

Gather CPU data for a Linux instance other than the instance from which the **lscpu** command is issued. The specified *directory* is the system root of the Linux instance to be inspected.

-x, --hex

Use hexadecimal masks for CPU sets (for example "ff"). The default is to print the sets in list format (for example 0,1). Note that before version 2.30 the mask has been printed with 0x prefix.

-y, --physical

Display physical IDs for all columns with topology elements (core, socket, etc.). Other than logical IDs, which are assigned by **lscpu**, physical IDs are platform-specific values that are provided by the kernel. Physical IDs are not necessarily unique and they might not be arranged sequentially. If the kernel could not retrieve a physical ID for an element **lscpu** prints the dash (-) character.

The CPU logical numbers are not affected by this option.

--output-all

Output all available columns. This option must be combined with either **--extended**, **--parse** or **--caches**.

BUGS

The basic overview of CPU family, model, etc. is always based on the first CPU only.

Sometimes in Xen Dom0 the kernel reports wrong data.

On virtual hardware the number of cores per socket, etc. can be wrong.

The **lscpu** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](#) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

lshw – list hardware

SYNOPSIS

lshw [**-version**]

lshw [**-help**]

lshw [**-X**]

lshw [[**-html**] [**-short**] [**-xml**] [**-json**] [**-businfo**]] [**-dump** *filename*] [**-class** *class...*] [**-disable** *test...*] [**-enable** *test...*] [**-sanitize**] [**-numeric**] [**-quiet**] [**-notime**]

DESCRIPTION

lshw is a small tool to extract detailed information on the hardware configuration of the machine. It can report exact memory configuration, firmware version, mainboard configuration, CPU version and speed, cache configuration, bus speed, etc. on DMI-capable x86 or IA-64 systems and on some PowerPC machines (PowerMac G4 is known to work).

It currently supports DMI (x86 and IA-64 only), OpenFirmware device tree (PowerPC only), PCI/AGP, CPUID (x86), IDE/ATA/ATAPI, PCMCIA (only tested on x86), SCSI and USB.

-version

Displays the version of **lshw** and exits.

-help

Displays the available command line options and quits.

-X

Launch the X11 GUI (if available).

-html

Outputs the device tree as an HTML page.

-xml

Outputs the device tree as an XML tree.

-json

Outputs the device tree as a JSON object (JavaScript Object Notation).

-short

Outputs the device tree showing hardware paths, very much like the output of HP-UX's **ioscan**.

-businfo

Outputs the device list showing bus information, detailing SCSI, USB, IDE and PCI addresses.

-dump *filename*

Display output and dump collected information into a file (SQLite database).

-class *class*

Only show the given class of hardware. *class* can be found using **lshw -short** or **lshw -businfo**.

-C *class*

Alias for **-class** *class*.

-enable *test***-disable** *test*

Enables or disables a test. *test* can be **dmi** (for DMI/SMBIOS extensions), **device-tree** (for OpenFirmware device tree), **spd** (for memory Serial Presence Detect), **memory** (for memory-size guessing heuristics), **cpuinfo** (for kernel-reported CPU detection), **cpuid** (for CPU detection), **pci** (for PCI/AGP access), **isapnp** (for ISA PnP extensions), **pcmcia** (for PCMCIA/PCCARD), **ide** (for IDE/ATAPI), **usb** (for USB devices), **scsi** (for SCSI) or **network** (for network interfaces detection).

-quiet

Don't display status.

-sanitize

Remove potentially sensitive information from output (IP addresses, serial numbers, etc.).

-numeric

Also display numeric IDs (for PCI and USB devices).

-notime

Exclude volatile attributes (timestamps) from output.

BUGS

lshw currently does not detect Firewire(IEEE1394) devices.

Not all architectures supported by GNU/Linux are fully supported (e.g. CPU detection).

"Virtual" SCSI interfaces used for SCSI emulation over IDE are not reported correctly yet.

NOTES

lshw must be run as super user or it will only report partial information.

FILES

/usr/local/share/pci.ids

/usr/share/pci.ids

/etc/pci.ids

/usr/share/hwdata/pci.ids

A list of all known PCI ID's (vendors, devices, classes and subclasses). If compiled with zlib support, **lshw** will look for *pci.ids.gz* first, then for *pci.ids*.

/proc/bus/pci/*

Used to access the configuration of installed PCI buses and devices.

/proc/ide/*

Used to access the configuration of installed IDE buses and devices.

/proc/scsi/*, /dev/sg*

Used to access the configuration of installed SCSI devices.

/dev/cpu/*/cpuid

Used on x86 platforms to access CPU-specific configuration.

/proc/device-tree/*

Used on PowerPC platforms to access OpenFirmware configuration.

/proc/bus/usb/*

Used to access the configuration of installed USB buses and devices.

/sys/* Used on 2.6 kernels to access hardware/driver configuration information.

EXAMPLES

lshw -short

Lists hardware in a compact format.

lshw -class disk -class storage

Lists all disks and storage controllers in the system.

lshw -html -class network

Lists all network interfaces in HTML.

lshw -disable dmi

Don't use DMI to detect hardware.

NAME

lsmod – Show the status of modules in the Linux Kernel

SYNOPSIS

lsmod

DESCRIPTION

lsmod is a trivial program which nicely formats the contents of the /proc/modules, showing what kernel modules are currently loaded.

NAME

lsof – list open files

SYNOPSIS

```
lsof [ -?abChlnNOPRtUvVX ] [ -A A ] [ -c c ] [ +c c ] [ +|-d d ] [ +|-D D ] [ +|-e s ] [ +|-E ] [ +|-f
[cfgGn] ] [ -F [f] ] [ -g [s] ] [ -i [i] ] [ -k k ] [ -K k ] [ +|-L [l] ] [ +|-m m ] [ +|-M ] [ -o [o] ] [ -p s ] [
+|-r [t[m<fmt>]] ] [ -s [p:s] ] [ -S [t] ] [ -T [t] ] [ -u s ] [ +|-w ] [ -x [fl] ] [ -z [z] ] [ -Z [Z] ] [ -- ]
[names]
```

DESCRIPTION

Lsof revision 4.93.2 lists on its standard output file information about files opened by processes for the following UNIX dialects:

Apple Darwin 9 and Mac OS X 10.[567]

FreeBSD 8.[234], 9.0 and 1[012].0 for AMD64-based systems

Linux 2.1.72 and above for x86-based systems

Solaris 9, 10 and 11

(See the **DISTRIBUTION** section of this manual page for information on how to obtain the latest *lsof* revision.)

An open file may be a regular file, a directory, a block special file, a character special file, an executing text reference, a library, a stream or a network file (Internet socket, NFS file or UNIX domain socket.) A specific file or all the files in a file system may be selected by path.

Instead of a formatted display, *lsof* will produce output that can be parsed by other programs. See the **-F** option description, and the **OUTPUT FOR OTHER PROGRAMS** section for more information.

In addition to producing a single output list, *lsof* will run in repeat mode. In repeat mode it will produce output, delay, then repeat the output operation until stopped with an interrupt or quit signal. See the **+|-r [t[m<fmt>]]** option description for more information.

OPTIONS

In the absence of any options, *lsof* lists all open files belonging to all active processes.

If any list request option is specified, other list requests must be specifically requested – e.g., if **-U** is specified for the listing of UNIX socket files, NFS files won't be listed unless **-N** is also specified; or if a user list is specified with the **-u** option, UNIX domain socket files, belonging to users not in the list, won't be listed unless the **-U** option is also specified.

Normally list options that are specifically stated are ORed – i.e., specifying the **-i** option without an address and the **-ufoo** option produces a listing of all network files OR files belonging to processes owned by user “foo”. The exceptions are:

- 1) the ‘^’ (negated) login name or user ID (UID), specified with the **-u** option;
- 2) the ‘^’ (negated) process ID (PID), specified with the **-p** option;
- 3) the ‘^’ (negated) process group ID (PGID), specified with the **-g** option;
- 4) the ‘^’ (negated) command, specified with the **-c** option;
- 5) the (^) negated TCP or UDP protocol state names, specified with the **-s [p:s]** option.

Since they represent exclusions, they are applied without ORing or ANDing and take effect before any other selection criteria are applied.

The **-a** option may be used to AND the selections. For example, specifying **-a**, **-U**, and **-ufoo** produces a listing of only UNIX socket files that belong to processes owned by user “foo”.

Caution: the **-a** option causes all list selection options to be ANDed; it can't be used to cause ANDing of selected pairs of selection options by placing it between them, even though its placement there is acceptable. Wherever **-a** is placed, it causes the ANDing of all selection options.

Items of the same selection set – command names, file descriptors, network addresses, process identifiers, user identifiers, zone names, security contexts – are joined in a single ORed set and applied before the result participates in ANDing. Thus, for example, specifying **-i@aaa.bbb**, **-i@ccc.ddd**, **-a**, and **-u^{ffff}.ggg** will select the listing of files that belong to either login “fff” OR “ggg” AND have network connections to either host aaa.bbb OR ccc.ddd.

Options may be grouped together following a single prefix -- e.g., the option set “**-a -b -C**” may be stated as **-abC**. However, since values are optional following **+|-f**, **-F**, **-g**, **-i**, **+|-L**, **-o**, **+|-r**, **-s**, **-S**, **-T**, **-x** and **-z**. when you have no values for them be careful that the following character isn't ambiguous. For example, **-Fn** might represent the **-F** and **-n** options, or it might represent the **n** field identifier character following the **-F** option. When ambiguity is possible, start a new option with a ‘-’ character – e.g., “**-F -n**”. If the next option is a file name, follow the possibly ambiguous option with “**--**” – e.g., “**-F -- name**”.

Either the ‘+’ or the ‘-’ prefix may be applied to a group of options. Options that don't take on separate meanings for each prefix – e.g., **-i** – may be grouped under either prefix. Thus, for example, “**+M -i**” may be stated as “**+Mi**” and the group means the same as the separate options. Be careful of prefix grouping when one or more options in the group does take on separate meanings under different prefixes – e.g., **+|-M**; “**-iM**” is not the same request as “**-i +M**”. When in doubt, use separate options with appropriate prefixes.

-? -h These two equivalent options select a usage (help) output list. *Lsof* displays a shortened form of this output when it detects an error in the options supplied to it, after it has displayed messages explaining each error. (Escape the ‘?’ character as your shell requires.)

-a causes list selection options to be ANDed, as described above.

-A A is available on systems configured for AFS whose AFS kernel code is implemented via dynamic modules. It allows the *lsof* user to specify A as an alternate name list file where the kernel addresses of the dynamic modules might be found. See the *lsof* FAQ (The **FAQ** section gives its location.) for more information about dynamic modules, their symbols, and how they affect *lsof*.

-b causes *lsof* to avoid kernel functions that might block – *lstat(2)*, *readlink(2)*, and *stat(2)*.

See the **BLOCKS AND TIMEOUTS** and **AVOIDING KERNEL BLOCKS** sections for information on using this option.

-c c selects the listing of files for processes executing the command that begins with the characters of *c*. Multiple commands may be specified, using multiple **-c** options. The *c* are joined in a single ORed set before participating in AND option selection.

If *c* begins with a ‘‘’, then the following characters specify a command name whose processes are to be ignored (excluded.)

If *c* begins and ends with a slash (‘/’), the characters between the slashes are interpreted as a regular expression. Shell meta-characters in the regular expression must be quoted to prevent their interpretation by the shell. The closing slash may be followed by these modifiers:

- b the regular expression is a basic one.
- i ignore the case of letters.
- x the regular expression is an extended one
(default).

See the *lsof* FAQ (The **FAQ** section gives its location.) for more information on basic and extended regular expressions.

The simple command specification is tested first. If that test fails, the command regular expression is applied. If the simple command test succeeds, the command regular expression test isn't made. This may result in “no command found for regex.” messages when *lsof*'s **-V** option is

specified.

+c w defines the maximum number of initial characters of the name, supplied by the UNIX dialect, of the UNIX command associated with a process to be printed in the COMMAND column. (The *lsof* default is nine.)

Note that many UNIX dialects do not supply all command name characters to *lsof* in the files and structures from which *lsof* obtains command name. Often dialects limit the number of characters supplied in those sources. For example, Linux 2.4.27 and Solaris 9 both limit command name length to 16 characters.

If *w* is zero ('0'), all command characters supplied to *lsof* by the UNIX dialect will be printed.

If *w* is less than the length of the column title, "COMMAND", it will be raised to that length.

-C disables the reporting of any path name components from the kernel's name cache. See the **KERNEL NAME CACHE** section for more information.

+d s causes *lsof* to search for all open instances of directory *s* and the files and directories it contains at its top level. **+d** does NOT descend the directory tree, rooted at *s*. The **+D D** option may be used to request a full-descent directory tree search, rooted at directory *D*.

Processing of the **+d** option does not follow symbolic links within *s* unless the **-x** or **-x I** option is also specified. Nor does it search for open files on file system mount points on subdirectories of *s* unless the **-x** or **-x f** option is also specified.

Note: the authority of the user of this option limits it to searching for files that the user has permission to examine with the system *stat*(2) function.

-d s specifies a list of file descriptors (FDs) to exclude from or include in the output listing. The file descriptors are specified in the comma-separated set *s* – e.g., "cwd,1,3", "^6,^2". (There should be no spaces in the set.)

The list is an exclusion list if all entries of the set begin with '^'. It is an inclusion list if no entry begins with '^'. Mixed lists are not permitted.

A file descriptor number range may be in the set as long as neither member is empty, both members are numbers, and the ending member is larger than the starting one – e.g., "0-7" or "3-10". Ranges may be specified for exclusion if they have the '^' prefix – e.g., "^0-7" excludes all file descriptors 0 through 7.

Multiple file descriptor numbers are joined in a single ORed set before participating in AND option selection.

When there are exclusion and inclusion members in the set, *lsof* reports them as errors and exits with a non-zero return code.

See the description of File Descriptor (FD) output values in the **OUTPUT** section for more information on file descriptor names.

+D D causes *lsof* to search for all open instances of directory *D* and all the files and directories it contains to its complete depth.

Processing of the **+D** option does not follow symbolic links within *D* unless the **-x** or **-x I** option is also specified. Nor does it search for open files on file system mount points on subdirectories of *D* unless the **-x** or **-x f** option is also specified.

Note: the authority of the user of this option limits it to searching for files that the user has permission to examine with the system *stat*(2) function.

Further note: *lsof* may process this option slowly and require a large amount of dynamic memory to do it. This is because it must descend the entire directory tree, rooted at *D*, calling *stat*(2) for each file and directory, building a list of all the files it finds, and searching that list for a match with every open file. When directory *D* is large, these steps can take a long time, so use this option prudently.

-D D directs *lsof*'s use of the device cache file. The use of this option is sometimes restricted. See the **DEVICE CACHE FILE** section and the sections that follow it for more information on this option.

-D must be followed by a function letter; the function letter may optionally be followed by a path name. *Lsof* recognizes these function letters:

- ? – report device cache file paths
- b** – build the device cache file
- i** – ignore the device cache file
- r** – read the device cache file
- u** – read and update the device cache file

The **b**, **r**, and **u** functions, accompanied by a path name, are sometimes restricted. When these functions are restricted, they will not appear in the description of the **-D** option that accompanies **-h** or **-?** option output. See the **DEVICE CACHE FILE** section and the sections that follow it for more information on these functions and when they're restricted.

The **?** function reports the read-only and write paths that *lsof* can use for the device cache file, the names of any environment variables whose values *lsof* will examine when forming the device cache file path, and the format for the personal device cache file path. (Escape the "?" character as your shell requires.)

When available, the **b**, **r**, and **u** functions may be followed by the device cache file's path. The standard default is *.lsof_hostname* in the home directory of the real user ID that executes *lsof*, but this could have been changed when *lsof* was configured and compiled. (The output of the **-h** and **-?** options show the current default prefix – e.g., ".*lsof*".) The suffix, *hostname*, is the first component of the host's name returned by *gethostname*(2).

When available, the **b** function directs *lsof* to build a new device cache file at the default or specified path.

The **i** function directs *lsof* to ignore the default device cache file and obtain its information about devices via direct calls to the kernel.

The **r** function directs *lsof* to read the device cache at the default or specified path, but prevents it from creating a new device cache file when none exists or the existing one is improperly structured. The **r** function, when specified without a path name, prevents *lsof* from updating an incorrect or outdated device cache file, or creating a new one in its place. The **r** function is always available when it is specified without a path name argument; it may be restricted by the permissions of the *lsof* process.

When available, the **u** function directs *lsof* to read the device cache file at the default or specified path, if possible, and to rebuild it, if necessary. This is the default device cache file function when no **-D** option has been specified.

+|-e s exempts the file system whose path name is *s* from being subjected to kernel function calls that might block. The **+e** option exempts *stat*(2), *lstat*(2) and most *readlink*(2) kernel function calls. The **-e** option exempts only *stat*(2) and *lstat*(2) kernel function calls. Multiple file systems may be specified with separate **+|-e** specifications and each may have *readlink*(2) calls exempted or not.

This option is currently implemented only for Linux.

CAUTION: this option can easily be mis-applied to other than the file system of interest, because it uses path name rather than the more reliable device and inode numbers. (Device and inode numbers are acquired via the potentially blocking *stat*(2) kernel call and are thus not available, but see the **+|-m m** option as a possible alternative way to supply device numbers.) **Use this option with great care and fully specify the path name of the file system to be exempted.**

When open files on exempted file systems are reported, it may not be possible to obtain all their information. Therefore, some information columns will be blank, the characters “UNKN” preface the values in the TYPE column, and the applicable exemption option is added in parentheses to the end of the NAME column. (Some device number information might be made available via the +|-m m option.)

- +|-E +E specifies that Linux pipe, Linux UNIX socket and Linux pseudoterminal files should be displayed with endpoint information and the files of the endpoints should also be displayed. Note: UNIX socket file endpoint information is only available when the compile flags line of -v output contains HASUXSOCKET, and pseudoterminal endpoint information is only available when the compile flags line contains HASPTYEPT.

Pipe endpoint information is displayed in the NAME column in the form “*PID,cmd,FDmode*”, where *PID* is the endpoint process ID; *cmd* is the endpoint process command; *FD* is the endpoint file’s descriptor; and *mode* is the endpoint file’s access mode.

Pseudoterminal endpoint information is displayed in the NAME column as “->/dev/ptsmin *PID,cmd,FDmode*” or “*PID,cmd,FDmode*”. The first form is for a master device; the second, for a slave device. *min* is a slave device’s minor device number; and *PID*, *cmd*, *FD* and *mode* are the same as with pipe endpoint information. Note: pseudoterminal endpoint information is only available when the compile flags line of -V output contains HASPTYEPT.

UNIX socket file endpoint information is displayed in the NAME column in the form “type=TYPE ->INO=INODE *PID,cmd,FDmode*”, where *TYPE* is the socket type; *INO* is the i-node number of the connected socket; and *PID*, *cmd*, *FD* and *mode* are the same as with pipe endpoint information. Note: UNIX socket file endpoint information is available only when the compile flags line of -v output contains HASUXSOCKET.

Multiple occurrences of this information can appear in a file’s NAME column.

-E specifies that Linux pipe and Linux UNIX socket files should be displayed with endpoint information, but not the files of the endpoints.

+|-f [cfgGn]

f by itself clarifies how path name arguments are to be interpreted. When followed by **c**, **f**, **g**, **G**, or **n** in any combination it specifies that the listing of kernel file structure information is to be enabled (+) or inhibited (-).

Normally a path name argument is taken to be a file system name if it matches a mounted-on directory name reported by *mount*(8), or if it represents a block device, named in the *mount* output and associated with a mounted directory name. When +f is specified, all path name arguments will be taken to be file system names, and *lsof* will complain if any are not. This can be useful, for example, when the file system name (mounted-on device) isn’t a block device. This happens for some CD-ROM file systems.

When -f is specified by itself, all path name arguments will be taken to be simple files. Thus, for example, the “-f -- /” arguments direct *lsof* to search for open files with a ‘/’ path name, not all open files in the ‘/’ (root) file system.

Be careful to make sure +f and -f are properly terminated and aren’t followed by a character (e.g., of the file or file system name) that might be taken as a parameter. For example, use “--” after +f and -f as in these examples.

```
$ lsof +f -- /file/system/name
$ lsof -f -- /file/name
```

The listing of information from kernel file structures, requested with the +f [cfgGn] option form, is normally inhibited, and is not available in whole or part for some dialects – e.g., /proc-based Linux kernels below 2.6.22. When the prefix to f is a plus sign (+), these characters request file structure information:

c	file structure use count (not Linux)
f	file structure address (not Linux)
g	file flag abbreviations (Linux 2.6.22 and up)
G	file flags in hexadecimal (Linux 2.6.22 and up)
n	file structure node address (not Linux)

When the prefix is minus ('-') the same characters disable the listing of the indicated values.

File structure addresses, use counts, flags, and node addresses may be used to detect more readily identical files inherited by child processes and identical files in use by different processes. *Lsof* column output can be sorted by output columns holding the values and listed to identify identical file use, or *lsof* field output can be parsed by an AWK or Perl post-filter script, or by a C program.

-F f specifies a character list, *f*, that selects the fields to be output for processing by another program, and the character that terminates each output field. Each field to be output is specified with a single character in *f*. The field terminator defaults to NL, but may be changed to NUL (000). See the **OUTPUT FOR OTHER PROGRAMS** section for a description of the field identification characters and the field output process.

When the field selection character list is empty, all standard fields are selected (except the raw device field, security context and zone field for compatibility reasons) and the NL field terminator is used.

When the field selection character list contains only a zero ('0'), all fields are selected (except the raw device field for compatibility reasons) and the NUL terminator character is used.

Other combinations of fields and their associated field terminator character must be set with explicit entries in *f*, as described in the **OUTPUT FOR OTHER PROGRAMS** section.

When a field selection character identifies an item *lsof* does not normally list – e.g., PPID, selected with **-R** – specification of the field character – e.g., “**-FR**” – also selects the listing of the item.

When the field selection character list contains the single character ‘?’ , *lsof* will display a help list of the field identification characters. (Escape the ‘?’ character as your shell requires.)

-g [s] excludes or selects the listing of files for the processes whose optional process group IDentification (PGID) numbers are in the comma-separated set *s* – e.g., “123” or “123,^456”. (There should be no spaces in the set.)

PGID numbers that begin with “^” (negation) represent exclusions.

Multiple PGID numbers are joined in a single ORed set before participating in AND option selection. However, PGID exclusions are applied without ORing or ANDing and take effect before other selection criteria are applied.

The **-g** option also enables the output display of PGID numbers. When specified without a PGID set that's all it does.

-i [i] selects the listing of files any of whose Internet address matches the address specified in *i*. If no address is specified, this option selects the listing of all Internet and x.25 (HP-UX) network files.

If **-i4** or **-i6** is specified with no following address, only files of the indicated IP version, IPv4 or IPv6, are displayed. (An IPv6 specification may be used only if the dialects supports IPv6, as indicated by “[46]” and “IPv[46]” in *lsof*'s **-h** or **-?** output.) Sequentially specifying **-i4**, followed by **-i6** is the same as specifying **-i**, and vice-versa. Specifying **-i4**, or **-i6** after **-i** is the same as specifying **-i4** or **-i6** by itself.

Multiple addresses (up to a limit of 100) may be specified with multiple **-i** options. (A port number or service name range is counted as one address.) They are joined in a single ORed set before participating in AND option selection.

An Internet address is specified in the form (Items in square brackets are optional.):

[46][*protocol*][@*hostname* | *hostaddr*][:*service* | *port*]

where:

46 specifies the IP version, IPv4 or IPv6
 that applies to the following address.
 '6' may be specified only if the UNIX
 dialect supports IPv6. If neither '4' nor
 '6' is specified, the following address
 applies to all IP versions.

protocol is a protocol name – **TCP, UDP**

hostname is an Internet host name. Unless a
 specific IP version is specified, open
 network files associated with host names
 of all versions will be selected.

hostaddr is a numeric Internet IPv4 address in
 dot form; or an IPv6 numeric address in
 colon form, enclosed in brackets, if the
 UNIX dialect supports IPv6. When an IP
 version is selected, only its numeric
 addresses may be specified.

service is an /etc/services name – e.g., **smtp** –
 or a list of them.

port is a port number, or a list of them.

IPv6 options may be used only if the UNIX dialect supports IPv6. To see if the dialect supports IPv6, run *lsof* and specify the **-h** or **-?** (help) option. If the displayed description of the **-i** option contains “[46]” and “IPv[46]”, IPv6 is supported.

IPv4 host names and addresses may not be specified if network file selection is limited to IPv6 with **-i 6**. IPv6 host names and addresses may not be specified if network file selection is limited to IPv4 with **-i 4**. When an open IPv4 network file’s address is mapped in an IPv6 address, the open file’s type will be IPv6, not IPv4, and its display will be selected by '6', not '4'.

At least one address component – **4, 6, protocol, hostname, hostaddr, or service** – must be supplied. The ‘@’ character, leading the host specification, is always required; as is the ‘:’, leading the port specification. Specify either *hostname* or *hostaddr*. Specify either *service* name list or *port* number list. If a *service* name list is specified, the *protocol* may also need to be specified if the TCP, UDP and UDPLITE port numbers for the service name are different. Use any case – lower or upper – for *protocol*.

Service names and *port* numbers may be combined in a list whose entries are separated by commas and whose numeric range entries are separated by minus signs. There may be no embedded spaces, and all service names must belong to the specified *protocol*. Since service names may contain embedded minus signs, the starting entry of a range can’t be a service name; it can be a port number, however.

Here are some sample addresses:

```
-i6 - IPv6 only
TCP:25 - TCP and port 25
@1.2.3.4 - Internet IPv4 host address 1.2.3.4
@[3ffe:1ebc::1]:1234 - Internet IPv6 host address
  3ffe:1ebc::1, port 1234
UDP:who - UDP who service port
TCP@lsof.itap:513 - TCP, port 513 and host name lsof.itap
tcp@foo:1-10,smtp,99 - TCP, ports 1 through 10,
  service name smtp, port 99, host name foo
```

`tcp@bar:1-smtp` – TCP, ports 1 through *smtp*, host bar
`:time` – either TCP, UDP or UDPLITE time service port

-K k selects the listing of tasks (threads) of processes, on dialects where task (thread) reporting is supported. (If help output – i.e., the output of the **-h** or **-?** options – shows this option, then task (thread) reporting is supported by the dialect.)

If **-K** is followed by a value, *k*, it must be “*i*”. That causes *lsof* to ignore tasks, particularly in the default, list-everything case when no other options are specified.

When **-K** and **-a** are both specified on Linux, and the tasks of a main process are selected by other options, the main process will also be listed as though it were a task, but without a task ID. (See the description of the TID column in the **OUTPUT** section.)

Where the FreeBSD version supports threads, all threads will be listed with their IDs.

In general threads and tasks inherit the files of the caller, but may close some and open others, so *lsof* always reports all the open files of threads and tasks.

-k k specifies a kernel name list file, *k*, in place of `/vmunix`, `/mach`, etc. **-k** is not available under AIX on the IBM RISC/System 6000.

-l inhibits the conversion of user ID numbers to login names. It is also useful when login name lookup is working improperly or slowly.

+|-L [l] enables (+) or disables (-) the listing of file link counts, where they are available – e.g., they aren't available for sockets, or most FIFOs and pipes.

When **+L** is specified without a following number, all link counts will be listed. When **-L** is specified (the default), no link counts will be listed.

When **+L** is followed by a number, only files having a link count less than that number will be listed. (No number may follow **-L**.) A specification of the form “**+L1**” will select open files that have been unlinked. A specification of the form “**+aL1 <file_system>**” will select un-linked open files on the specified file system.

For other link count comparisons, use field output (**-F**) and a post-processing script or program.

+|-m m specifies an alternate kernel memory file or activates mount table supplement processing.

The option form **-m m** specifies a kernel memory file, *m*, in place of `/dev/kmem` or `/dev/mem` – e.g., a crash dump file.

The option form **+m** requests that a mount supplement file be written to the standard output file. All other options are silently ignored.

There will be a line in the mount supplement file for each mounted file system, containing the mounted file system directory, followed by a single space, followed by the device number in hexadecimal "0x" format – e.g.,

/ 0x801

Lsof can use the mount supplement file to get device numbers for file systems when it can't get them via `stat(2)` or `lstat(2)`.

The option form **+m m** identifies *m* as a mount supplement file.

Note: the **+m** and **+m m** options are not available for all supported dialects. Check the output of *lsof*'s **-h** or **-?** options to see if the **+m** and **+m m** options are available.

+|-M Enables (+) or disables (-) the reporting of portmapper registrations for local TCP, UDP and UDPLITE ports, where port mapping is supported. (See the last paragraph of this option description for information about where portmapper registration reporting is supported.)

The default reporting mode is set by the *lsof* builder with the HASPMAPENABLED #define in the dialect's machine.h header file; *lsof* is distributed with the HASPMAPENABLED #define deactivated, so portmapper reporting is disabled by default and must be requested with **+M**.

Specifying *lsof*'s **-h** or **-?** option will report the default mode. Disabling portmapper registration when it is already disabled or enabling it when already enabled is acceptable. When portmapper registration reporting is enabled, *lsof* displays the portmapper registration (if any) for local TCP, UDP or UDPLITE ports in square brackets immediately following the port numbers or service names – e.g., “:1234[name]” or “:name[100083]”. The registration information may be a name or number, depending on what the registering program supplied to the portmapper when it registered the port.

When portmapper registration reporting is enabled, *lsof* may run a little more slowly or even become blocked when access to the portmapper becomes congested or stopped. Reverse the reporting mode to determine if portmapper registration reporting is slowing or blocking *lsof*.

For purposes of portmapper registration reporting *lsof* considers a TCP, UDP or UDPLITE port local if: it is found in the local part of its containing kernel structure; or if it is located in the foreign part of its containing kernel structure and the local and foreign Internet addresses are the same; or if it is located in the foreign part of its containing kernel structure and the foreign Internet address is INADDR_LOOPBACK (127.0.0.1). This rule may make *lsof* ignore some foreign ports on machines with multiple interfaces when the foreign Internet address is on a different interface from the local one.

See the *lsof* FAQ (The **FAQ** section gives its location.) for further discussion of portmapper registration reporting issues.

Portmapper registration reporting is supported only on dialects that have RPC header files. (Some Linux distributions with GlibC 2.14 do not have them.) When portmapper registration reporting is supported, the **-h** or **-?** help output will show the **+|-M** option.

- n** inhibits the conversion of network numbers to host names for network files. Inhibiting conversion may make *lsof* run faster. It is also useful when host name lookup is not working properly.
 - N** selects the listing of NFS files.
 - o** directs *lsof* to display file offset at all times. It causes the SIZE/OFF output column title to be changed to OFFSET. Note: on some UNIX dialects *lsof* can't obtain accurate or consistent file offset information from its kernel data sources, sometimes just for particular kinds of files (e.g., socket files.) Consult the *lsof* FAQ (The **FAQ** section gives its location.) for more information.
- The **-o** and **-s** options are mutually exclusive; they can't both be specified. When neither is specified, *lsof* displays whatever value – size or offset – is appropriate and available for the type of the file.
- o o** defines the number of decimal digits (*o*) to be printed after the “0t” for a file offset before the form is switched to “0x...”. A value of zero (unlimited) directs *lsof* to use the “0t” form for all offset output.

This option does NOT direct *lsof* to display offset at all times; specify **-o** (without a trailing number) to do that. **-o o** only specifies the number of digits after ‘‘0t’’ in either mixed size and offset or offset-only output. Thus, for example, to direct *lsof* to display offset at all times with a decimal digit count of 10, use:

```
-o -o 10
or
-oo10
```

The default number of digits allowed after “0t” is normally 8, but may have been changed by the *lsof* builder. Consult the description of the **-o o** option in the output of the **-h** or **-?** option to determine the default that is in effect.

- O** directs *lsof* to bypass the strategy it uses to avoid being blocked by some kernel operations – i.e., doing them in forked child processes. See the **BLOCKS AND TIMEOUTS** and **AVOIDING KERNEL BLOCKS** sections for more information on kernel operations that may block *lsof*.

While use of this option will reduce *lsof* startup overhead, it may also cause *lsof* to hang when the kernel doesn't respond to a function. Use this option cautiously.

-p s excludes or selects the listing of files for the processes whose optional process IDentification (PID) numbers are in the comma-separated set *s* – e.g., “123” or “123,^456”. (There should be no spaces in the set.)

PID numbers that begin with ‘^’ (negation) represent exclusions.

Multiple process ID numbers are joined in a single ORed set before participating in AND option selection. However, PID exclusions are applied without ORing or ANDing and take effect before other selection criteria are applied.

-P inhibits the conversion of port numbers to port names for network files. Inhibiting the conversion may make *lsof* run a little faster. It is also useful when port name lookup is not working properly.

+|-r [t[m<fmt>]]

puts *lsof* in repeat mode. There *lsof* lists open files as selected by other options, delays *t* seconds (default fifteen), then repeats the listing, delaying and listing repetitively until stopped by a condition defined by the prefix to the option.

If the prefix is a ‘-’, repeat mode is endless. *Lsof* must be terminated with an interrupt or quit signal.

If the prefix is ‘+’, repeat mode will end the first cycle no open files are listed – and of course when *lsof* is stopped with an interrupt or quit signal. When repeat mode ends because no files are listed, the process exit code will be zero if any open files were ever listed; one, if none were ever listed.

Lsof marks the end of each listing: if field output is in progress (the **-F** option has been specified), the default marker is ‘m’; otherwise the default marker is “=====”. The marker is followed by a NL character.

The optional “m<fmt>” argument specifies a format for the marker line. The <fmt> characters following ‘m’ are interpreted as a format specification to the *strftime(3)* function, when both it and the *localtime(3)* function are available in the dialect’s C library. Consult the *strftime(3)* documentation for what may appear in its format specification. Note that when field output is requested with the **-F** option, <fmt> cannot contain the NL format, “%n”. Note also that when <fmt> contains spaces or other characters that affect the shell’s interpretation of arguments, <fmt> must be quoted appropriately.

Repeat mode reduces *lsof* startup overhead, so it is more efficient to use this mode than to call *lsof* repetitively from a shell script, for example.

To use repeat mode most efficiently, accompany **+|-r** with specification of other *lsof* selection options, so the amount of kernel memory access *lsof* does will be kept to a minimum. Options that filter at the process level – e.g., **-c**, **-g**, **-p**, **-u** – are the most efficient selectors.

Repeat mode is useful when coupled with field output (see the **-F**, option description) and a supervising *awk* or *Perl* script, or a C program.

-R directs *lsof* to list the Parent Process IDentification number in the PPID column.

-s [p:s] *s* alone directs *lsof* to display file size at all times. It causes the SIZE/OFF output column title to be changed to SIZE. If the file does not have a size, nothing is displayed.

The optional **-s p:s** form is available only for selected dialects, and only when the **-h** or **-?** help output lists it.

When the optional form is available, the *s* may be followed by a protocol name (*p*), either TCP or UDP, a colon (‘:’) and a comma-separated protocol state name list, the option causes open TCP and UDP files to be excluded if their state name(s) are in the list (*s*) preceded by a ‘^’; or included if their name(s) are not preceded by a ‘^’.

Dialects that support this option may support only one protocol. When an unsupported protocol is specified, a message will be displayed indicating state names for the protocol are unavailable.

When an inclusion list is defined, only network files with state names in the list will be present in the *lsof* output. Thus, specifying one state name means that only network files with that lone state name will be listed.

Case is unimportant in the protocol or state names, but there may be no spaces and the colon (‘:’) separating the protocol name (*p*) and the state name list (*s*) is required.

If only TCP and UDP files are to be listed, as controlled by the specified exclusions and inclusions, the **-i** option must be specified, too. If only a single protocol's files are to be listed, add its name as an argument to the **-i** option.

For example, to list only network files with TCP state LISTEN, use:

```
-iTCP -sTCP:LISTEN
```

Or, for example, to list network files with all UDP states except Idle, use:

```
-iUDP -sUDP:^Idle
```

State names vary with UNIX dialects, so it's not possible to provide a complete list. Some common TCP state names are: CLOSED, IDLE, BOUND, LISTEN, ESTABLISHED, SYN_SENT, SYN_RCDV, ESTABLISHED, CLOSE_WAIT, FIN_WAIT1, CLOSING, LAST_ACK, FIN_WAIT_2, and TIME_WAIT. Two common UDP state names are Unbound and Idle.

See the *lsof* FAQ (The **FAQ** section gives its location.) for more information on how to use protocol state exclusion and inclusion, including examples.

The **-o** (without a following decimal digit count) and **-s** option (without a following protocol and state name list) are mutually exclusive; they can't both be specified. When neither is specified, *lsof* displays whatever value – size or offset – is appropriate and available for the type of file.

Since some types of files don't have true sizes – sockets, FIFOs, pipes, etc. – *lsof* displays for their sizes the content amounts in their associated kernel buffers, if possible.

-S [t] specifies an optional time-out seconds value for kernel functions – *lstat(2)*, *readlink(2)*, and *stat(2)* – that might otherwise deadlock. The minimum for *t* is two; the default, fifteen; when no value is specified, the default is used.

See the **BLOCKS AND TIMEOUTS** section for more information.

-T [t] controls the reporting of some TCP/TPI information, also reported by *netstat(1)*, following the network addresses. In normal output the information appears in parentheses, each item except TCP or TPI state name identified by a keyword, followed by ‘=’, separated from others by a single space:

```
<TCP or TPI state name>
QR=<read queue length>
QS=<send queue length>
SO=<socket options and values>
SS=<socket states>
TF=<TCP flags and values>
WR=<window read length>
WW=<window write length>
```

Not all values are reported for all UNIX dialects. Items values (when available) are reported after the item name and ‘=’.

When the field output mode is in effect (See **OUTPUT FOR OTHER PROGRAMS.**) each item appears as a field with a ‘T’ leading character.

-T with no following key characters disables TCP/TPI information reporting.

-T with following characters selects the reporting of specific TCP/TPI information:

- f** selects reporting of socket options, states and values, and TCP flags and values.
- q** selects queue length reporting.
- s** selects connection state reporting.
- w** selects window size reporting.

Not all selections are enabled for some UNIX dialects. State may be selected for all dialects and is reported by default. The **-h** or **-?** help output for the **-T** option will show what selections may be used with the UNIX dialect.

When **-T** is used to select information – i.e., it is followed by one or more selection characters – the displaying of state is disabled by default, and it must be explicitly selected again in the characters following **-T**. (In effect, then, the default is equivalent to **-Ts**.) For example, if queue lengths and state are desired, use **-Tqs**.

Socket options, socket states, some socket values, TCP flags and one TCP value may be reported (when available in the UNIX dialect) in the form of the names that commonly appear after `SO_`, `so_`, `SS_`, `TCP_` and `TF_` in the dialect's header files – most often `<sys/socket.h>`, `<sys/socketvar.h>` and `<netinet/tcp_var.h>`. Consult those header files for the meaning of the flags, options, states and values.

“`SO=`” precedes socket options and values; “`SS=`”, socket states; and “`TF=`”, TCP flags and values.

If a flag or option has a value, the value will follow an ‘=’ and the name -- e.g., “`SO=LINGER=5`”, “`SO=QLIM=5`”, “`TF=MSS=512`”. The following seven values may be reported:

Name Reported	Description (Common Symbol)
KEEPALIVE	keep alive time (SO_KEEPALIVE)
LINGER	linger time (SO_LINGER)
MSS	maximum segment size (TCP_MAXSEG)
PQLEN	partial listen queue connections
QLEN	established listen queue connections
QLIM	established listen queue limit
RCVBUF	receive buffer length (SO_RCVBUF)
SNDBUF	send buffer length (SO_SNDBUF)

Details on what socket options and values, socket states, and TCP flags and values may be displayed for particular UNIX dialects may be found in the answer to the “Why doesn't lsof report socket options, socket states, and TCP flags and values for my dialect?” and “Why doesn't lsof report the partial listen queue connection count for my dialect?” questions in the *lsof FAQ* (The **FAQ** section gives its location.)

-t specifies that *lsof* should produce terse output with process identifiers only and no header – e.g., so that the output may be piped to *kill(1)*. **-t** selects the **-w** option.

-u s selects the listing of files for the user whose login names or user ID numbers are in the comma-separated set *s* – e.g., “abe”, or “548,root”. (There should be no spaces in the set.)

Multiple login names or user ID numbers are joined in a single ORed set before participating in AND option selection.

If a login name or user ID is preceded by a ‘^’, it becomes a negation – i.e., files of processes owned by the login name or user ID will never be listed. A negated login name or user ID

selection is neither ANDed nor ORed with other selections; it is applied before all other selections and absolutely excludes the listing of the files of the process. For example, to direct *lsof* to exclude the listing of files belonging to root processes, specify “*–u^root*” or “*–u^0*”.

- U*** selects the listing of UNIX domain socket files.
- v*** selects the listing of *lsof* version information, including: revision number; when the *lsof* binary was constructed; who constructed the binary and where; the name of the compiler used to construct the *lsof* binary; the version number of the compiler when readily available; the compiler and loader flags used to construct the *lsof* binary; and system information, typically the output of *uname*'s ***–a*** option.
- V*** directs *lsof* to indicate the items it was asked to list and failed to find – command names, file names, Internet addresses or files, login names, NFS files, PIDs, PGIDs, and UIDs.

When other options are ANDed to search options, or compile-time options restrict the listing of some files, *lsof* may not report that it failed to find a search item when an ANDed option or compile-time option prevents the listing of the open file containing the located search item.

For example, “*lsof –V –iTCP@foobar –a –d 999*” may not report a failure to locate open files at “TCP@foobar” and may not list any, if none have a file descriptor number of 999. A similar situation arises when HASSECURITY and HASNOSOCKSECURITY are defined at compile time and they prevent the listing of open files.

- +|–w*** Enables (+) or disables (–) the suppression of warning messages.
The ***lsof*** builder may choose to have warning messages disabled or enabled by default. The default warning message state is indicated in the output of the ***–h*** or ***–?*** option. Disabling warning messages when they are already disabled or enabling them when already enabled is acceptable.
The ***–t*** option selects the ***–w*** option.
- x [fl]*** may accompany the ***+d*** and ***+D*** options to direct their processing to cross over symbolic links and/or file system mount points encountered when scanning the directory (***+d***) or directory tree (***+D***).
If ***–x*** is specified by itself without a following parameter, cross-over processing of both symbolic links and file system mount points is enabled. Note that when ***–x*** is specified without a parameter, the next argument must begin with ‘–’ or ‘+’.
The optional ‘f’ parameter enables file system mount point cross-over processing; ‘l’, symbolic link cross-over processing.
The ***–x*** option may not be supplied without also supplying a ***+d*** or ***+D*** option.
- X*** This is a dialect-specific option.

AIX:

This IBM AIX RISC/System 6000 option requests the reporting of executed text file and shared library references.

WARNING: because this option uses the kernel readx() function, its use on a busy AIX system might cause an application process to hang so completely that it can neither be killed nor stopped. I have never seen this happen or had a report of its happening, but I think there is a remote possibility it could happen.

By default use of readx() is disabled. On AIX 5L and above *lsof* may need setuid-root permission to perform the actions this option requests.

The *lsof* builder may specify that the ***–X*** option be restricted to processes whose real UID is root. If that has been done, the ***–X*** option will not appear in the ***–h*** or ***–?*** help output unless the real UID of the *lsof* process is root. The default *lsof* distribution allows any UID to specify ***–X***, so by default it will appear in the help output.

When AIX readx() use is disabled, *lsof* may not be able to report information for all text and loader file references, but it may also avoid exacerbating an AIX kernel directory search kernel error, known as the Stale Segment ID bug.

The readx() function, used by *lsof* or any other program to access some sections of kernel virtual memory, can trigger the Stale Segment ID bug. It can cause the kernel's dir_search() function to believe erroneously that part of an in-memory copy of a file system directory has been zeroed. Another application process, distinct from *lsof*, asking the kernel to search the directory – e.g., by using *open(2)* – can cause dir_search() to loop forever, thus hanging the application process.

Consult the *lsof* FAQ (The **FAQ** section gives its location.) and the *00README* file of the *lsof* distribution for a more complete description of the Stale Segment ID bug, its APAR, and methods for defining readx() use when compiling *lsof*.

Linux:

This Linux option requests that *lsof* skip the reporting of information on all open TCP, UDP and UDPLITE IPv4 and IPv6 files.

This Linux option is most useful when the system has an extremely large number of open TCP, UDP and UDPLITE files, the processing of whose information in the */proc/net/tcp** and */proc/net/udp** files would take *lsof* a long time, and whose reporting is not of interest.

Use this option with care and only when you are sure that the information you want *lsof* to display isn't associated with open TCP, UDP or UDPLITE socket files.

Solaris 10 and above:

This Solaris 10 and above option requests the reporting of cached paths for files that have been deleted – i.e., removed with *rm(1)* or *unlink(2)*.

The cached path is followed by the string “(deleted)” to indicate that the path by which the file was opened has been deleted.

Because intervening changes made to the path – i.e., renames with *mv(1)* or *rename(2)* – are not recorded in the cached path, what *lsof* reports is only the path by which the file was opened, not its possibly different final path.

-z [z] specifies how Solaris 10 and higher zone information is to be handled.

Without a following argument – e.g., NO *z* – the option specifies that zone names are to be listed in the ZONE output column.

The **-z** option may be followed by a zone name, **z**. That causes *lsof* to list only open files for processes in that zone. Multiple **-z z** option and argument pairs may be specified to form a list of named zones. Any open file of any process in any of the zones will be listed, subject to other conditions specified by other options and arguments.

-Z [Z] specifies how SELinux security contexts are to be handled. It and 'Z' field output character support are inhibited when SELinux is disabled in the running Linux kernel. See **OUTPUT FOR OTHER PROGRAMS** for more information on the 'Z' field output character.

Without a following argument – e.g., NO *Z* – the option specifies that security contexts are to be listed in the SECURITY-CONTEXT output column.

The **-Z** option may be followed by a wildcard security context name, **Z**. That causes *lsof* to list only open files for processes in that security context. Multiple **-Z Z** option and argument pairs may be specified to form a list of security contexts. Any open file of any process in any of the security contexts will be listed, subject to other conditions specified by other options and arguments. Note that *Z* can be *A:B:C* or **:B:C* or *A:B:** or **:*:C* to match against the *A:B:C* context.

-- The double minus sign option is a marker that signals the end of the keyed options. It may be used, for example, when the first file name begins with a minus sign. It may also be used when

the absence of a value for the last keyed option must be signified by the presence of a minus sign in the following option and before the start of the file names.

names These are path names of specific files to list. Symbolic links are resolved before use. The first name may be separated from the preceding options with the “**--**” option.

If a *name* is the mounted-on directory of a file system or the device of the file system, *lsof* will list all the files open on the file system. To be considered a file system, the *name* must match a mounted-on directory name in *mount(8)* output, or match the name of a block device associated with a mounted-on directory name. The **+|-f** option may be used to force *lsof* to consider a *name* a file system identifier (**+f**) or a simple file (**-f**).

If *name* is a path to a directory that is not the mounted-on directory name of a file system, it is treated just as a regular file is treated – i.e., its listing is restricted to processes that have it open as a file or as a process-specific directory, such as the root or current working directory. To request that *lsof* look for open files inside a directory name, use the **+d s** and **+D D** options.

If a *name* is the base name of a family of multiplexed files – e.g., AIX’s */dev/pt[cs]* – *lsof* will list all the associated multiplexed files on the device that are open – e.g., */dev/pt[cs]/1*, */dev/pt[cs]/2*, etc.

If a *name* is a UNIX domain socket name, *lsof* will usually search for it by the characters of the name alone – exactly as it is specified and is recorded in the kernel socket structure. (See the next paragraph for an exception to that rule for Linux.) Specifying a relative path – e.g., *./file* – in place of the file’s absolute path – e.g., */tmp/file* – won’t work because *lsof* must match the characters you specify with what it finds in the kernel UNIX domain socket structures.

If a *name* is a Linux UNIX domain socket name, in one case *lsof* is able to search for it by its device and inode number, allowing *name* to be a relative path. The case requires that the absolute path -- i.e., one beginning with a slash (‘/’) be used by the process that created the socket, and hence be stored in the */proc/net/unix* file; and it requires that *lsof* be able to obtain the device and node numbers of both the absolute path in */proc/net/unix* and *name* via successful *stat(2)* system calls. When those conditions are met, *lsof* will be able to search for the UNIX domain socket when some path to it is specified in *name*. Thus, for example, if the path is */dev/log*, and an *lsof* search is initiated when the working directory is */dev*, then *name* could be *.log*.

If a *name* is none of the above, *lsof* will list any open files whose device and inode match that of the specified path *name*.

If you have also specified the **-b** option, the only *names* you may safely specify are file systems for which your mount table supplies alternate device numbers. See the **AVOIDING KERNEL BLOCKS** and **ALTERNATE DEVICE NUMBERS** sections for more information.

Multiple file names are joined in a single ORed set before participating in AND option selection.

AFS

lsof supports the recognition of AFS files for these dialects (and AFS versions):

- AIX 4.1.4 (AFS 3.4a)
- HP-UX 9.0.5 (AFS 3.4a)
- Linux 1.2.13 (AFS 3.3)
- Solaris 2.[56] (AFS 3.4a)

It may recognize AFS files on other versions of these dialects, but has not been tested there. Depending on how AFS is implemented, *lsof* may recognize AFS files in other dialects, or may have difficulties recognizing AFS files in the supported dialects.

lsof may have trouble identifying all aspects of AFS files in supported dialects when AFS kernel support is implemented via dynamic modules whose addresses do not appear in the kernel’s variable name list. In that case, *lsof* may have to guess at the identity of AFS files, and might not be able to obtain volume

information from the kernel that is needed for calculating AFS volume node numbers. When *lsof* can't compute volume node numbers, it reports blank in the NODE column.

The **-A** option is available in some dialect implementations of *lsof* for specifying the name list file where dynamic module kernel addresses may be found. When this option is available, it will be listed in the *lsof* help output, presented in response to the **-h** or **-?**

See the *lsof* FAQ (The **FAQ** section gives its location.) for more information about dynamic modules, their symbols, and how they affect *lsof* options.

Because AFS path lookups don't seem to participate in the kernel's name cache operations, *lsof* can't identify path name components for AFS files.

SECURITY

Lsof has three features that may cause security concerns. First, its default compilation mode allows anyone to list all open files with it. Second, by default it creates a user-readable and user-writable device cache file in the home directory of the real user ID that executes *lsof*. (The list-all-open-files and device cache features may be disabled when *lsof* is compiled.) Third, its **-k** and **-m** options name alternate kernel name list or memory files.

Restricting the listing of all open files is controlled by the compile-time HASSECURITY and HASNOSOCKSECURITY options. When HASSECURITY is defined, *lsof* will allow only the root user to list all open files. The non-root user may list only open files of processes with the same user IDentification number as the real user ID number of the *lsof* process (the one that its user logged on with).

However, if HASSECURITY and HASNOSOCKSECURITY are both defined, anyone may list open socket files, provided they are selected with the **-i** option.

When HASSECURITY is not defined, anyone may list all open files.

Help output, presented in response to the **-h** or **-?** option, gives the status of the HASSECURITY and HASNOSOCKSECURITY definitions.

See the **Security** section of the *00README* file of the *lsof* distribution for information on building *lsof* with the HASSECURITY and HASNOSOCKSECURITY options enabled.

Creation and use of a user-readable and user-writable device cache file is controlled by the compile-time HASDCACHE option. See the **DEVICE CACHE FILE** section and the sections that follow it for details on how its path is formed. For security considerations it is important to note that in the default *lsof* distribution, if the real user ID under which *lsof* is executed is root, the device cache file will be written in root's home directory – e.g., */* or */root*. When HASDCACHE is not defined, *lsof* does not write or attempt to read a device cache file.

When HASDCACHE is defined, the *lsof* help output, presented in response to the **-h**, **-D?**, or **-?** options, will provide device cache file handling information. When HASDCACHE is not defined, the **-h** or **-?** output will have no **-D** option description.

Before you decide to disable the device cache file feature – enabling it improves the performance of *lsof* by reducing the startup overhead of examining all the nodes in */dev* (or */devices*) – read the discussion of it in the *00DCACHE* file of the *lsof* distribution and the *lsof* FAQ (The **FAQ** section gives its location.)

WHEN IN DOUBT, YOU CAN TEMPORARILY DISABLE THE USE OF THE DEVICE CACHE FILE WITH THE **-Di OPTION.**

When *lsof* user declares alternate kernel name list or memory files with the **-k** and **-m** options, *lsof* checks the user's authority to read them with *access(2)*. This is intended to prevent whatever special power *lsof*'s modes might confer on it from letting it read files not normally accessible via the authority of the real user ID.

OUTPUT

This section describes the information *lsof* lists for each open file. See the **OUTPUT FOR OTHER PROGRAMS** section for additional information on output that can be processed by another program.

Lsof only outputs printable (declared so by *isprint(3)*) 8 bit characters. Non-printable characters are

printed in one of three forms: the C “\[bfrnt]” form; the control character “`” form (e.g., “^@”); or hexa-decimal leading “\x” form (e.g., “\xab”). Space is non-printable in the COMMAND column (“\x20”) and printable elsewhere.

For some dialects – if HASSETLOCALE is defined in the dialect’s machine.h header file – *lsof* will print the extended 8 bit characters of a language locale. The *lsof* process must be supplied a language locale environment variable (e.g., LANG) whose value represents a known language locale in which the extended characters are considered printable by *isprint(3)*. Otherwise *lsof* considers the extended characters non-printable and prints them according to its rules for non-printable characters, stated above. Consult your dialect’s *setlocale(3)* man page for the names of other environment variables that may be used in place of LANG – e.g., LC_ALL, LC_CTYPE, etc.

Lsof’s language locale support for a dialect also covers wide characters – e.g., UTF-8 – when HASSETLOCALE and HASWIDECHAR are defined in the dialect’s machine.h header file, and when a suitable language locale has been defined in the appropriate environment variable for the *lsof* process. Wide characters are printable under those conditions if *iswprint(3)* reports them to be. If HASSETLOCALE, HASWIDECHAR and a suitable language locale aren’t defined, or if *iswprint(3)* reports wide characters that aren’t printable, *lsof* considers the wide characters non-printable and prints each of their 8 bits according to its rules for non-printable characters, stated above.

Consult the answers to the "Language locale support" questions in the *lsof* FAQ (The **FAQ** section gives its location.) for more information.

Lsof dynamically sizes the output columns each time it runs, guaranteeing that each column is a minimum size. It also guarantees that each column is separated from its predecessor by at least one space.

COMMAND contains the first nine characters of the name of the UNIX command associated with the process. If a non-zero *w* value is specified to the **+c w** option, the column contains the first *w* characters of the name of the UNIX command associated with the process up to the limit of characters supplied to *lsof* by the UNIX dialect. (See the description of the **+c w** command or the *lsof* FAQ for more information. The **FAQ** section gives its location.)

If *w* is less than the length of the column title, “COMMAND”, it will be raised to that length.

If a zero *w* value is specified to the **+c w** option, the column contains all the characters of the name of the UNIX command associated with the process.

All command name characters maintained by the kernel in its structures are displayed in field output when the command name descriptor (‘c’) is specified. See the **OUTPUT FOR OTHER COMMANDS** section for information on selecting field output and the associated command name descriptor.

PID is the Process IDentification number of the process.

TID is the task (thread) IDentification number, if task (thread) reporting is supported by the dialect and a task (thread) is being listed. (If help output – i.e., the output of the **-h** or **-?** options – shows this option, then task (thread) reporting is supported by the dialect.)

A blank TID column in Linux indicates a process – i.e., a non-task.

TASKCMD is the task command name. Generally this will be the same as the process named in the COMMAND column, but some task implementations (e.g., Linux) permit a task to change its command name.

The TASKCMD column width is subject to the same size limitation as the COMMAND column.

ZONE is the Solaris 10 and higher zone name. This column must be selected with the **-z** option.

SECURITY-CONTEXT

is the SELinux security context. This column must be selected with the **-Z** option. Note that the **-Z** option is inhibited when SELinux is disabled in the running Linux kernel.

PPID

is the Parent Process IDentification number of the process. It is only displayed when the **-R** option has been specified.

PGID

is the process group IDentification number associated with the process. It is only displayed when the **-g** option has been specified.

USER

is the user ID number or login name of the user to whom the process belongs, usually the same as reported by *ps*(1). However, on Linux USER is the user ID number or login that owns the directory in /proc where *lsof* finds information about the process. Usually that is the same value reported by *ps*(1), but may differ when the process has changed its effective user ID. (See the **-I** option description for information on when a user ID number or login name is displayed.)

FD

is the File Descriptor number of the file or:

cwd	current working directory;
Lnn	library references (AIX);
err	FD information error (see NAME column);
jld	jail directory (FreeBSD);
ltx	shared library text (code and data);
Mxx	hex memory-mapped type number xx.
m86	DOS Merge mapped file;
mem	memory-mapped file;
mmap	memory-mapped device;
pd	parent directory;
rtd	root directory;
tr	kernel trace file (OpenBSD);
txt	program text (code and data);
v86	VP/ix mapped file;

FD is followed by one of these characters, describing the mode under which the file is open:

- r** for read access;
- w** for write access;
- u** for read and write access;
- space if mode unknown and no lock character follows;
- '-' if mode unknown and lock character follows.

The mode character is followed by one of these lock characters, describing the type of lock applied to the file:

- N** for a Solaris NFS lock of unknown type;
- r** for read lock on part of the file;
- R** for a read lock on the entire file;
- w** for a write lock on part of the file;
- W** for a write lock on the entire file;
- u** for a read and write lock of any length;
- U** for a lock of unknown type;
- x** for an SCO OpenServer Xenix lock on part of the file;
- X** for an SCO OpenServer Xenix lock on the entire file;
- space if there is no lock.

	See the LOCKS section for more information on the lock information character.
TYPE	The FD column contents constitutes a single field for parsing in post-processing scripts. is the type of the node associated with the file – e.g., GDIR, GREG, VDIR, VREG, etc. or “IPv4” for an IPv4 socket; or “IPv6” for an open IPv6 network file – even if its address is IPv4, mapped in an IPv6 address; or “ax25” for a Linux AX.25 socket; or “inet” for an Internet domain socket; or “lla” for a HP-UX link level access file; or “rte” for an AF_ROUTE socket; or “sock” for a socket of unknown domain; or “unix” for a UNIX domain socket; or “x.25” for an HP-UX x.25 socket; or “BLK” for a block special file; or “CHR” for a character special file; or “DEL” for a Linux map file that has been deleted; or “DIR” for a directory; or “DOOR” for a VDOOR file; or “FIFO” for a FIFO special file; or “KQUEUE” for a BSD style kernel event queue file; or “LINK” for a symbolic link file; or “MPB” for a multiplexed block file; or “MPC” for a multiplexed character file; or “NOFD” for a Linux /proc/<PID>/fd directory that can't be opened -- the directory path appears in the NAME column, followed by an error message; or “PAS” for a /proc/as file; or “PAXV” for a /proc/auxv file; or “PCRE” for a /proc/cred file; or “PCTL” for a /proc control file; or “PCUR” for the current /proc process; or “PCWD” for a /proc current working directory; or “PDIR” for a /proc directory; or “PETY” for a /proc executable type (<i>etype</i>); or “PFD” for a /proc file descriptor; or “PFDR” for a /proc file descriptor directory; or “PFIL” for an executable /proc file; or “PFPR” for a /proc FP register set; or “PGD” for a /proc/pagedata file; or “PGID” for a /proc group notifier file;

or “PIPE” for pipes;
or “PLC” for a */proc/lwpctl* file;
or “PLDR” for a */proc/lpw* directory;
or “PLDT” for a */proc/ldt* file;
or “PLPI” for a */proc/lpsinfo* file;
or “PLST” for a */proc/lstatus* file;
or “PLU” for a */proc/lusage* file;
or “PLWG” for a */proc/gwindows* file;
or “PLWI” for a */proc/lwpsinfo* file;
or “PLWS” for a */proc/lwpstatus* file;
or “PLWU” for a */proc/lwpusage* file;
or “PLWX” for a */proc/xregs* file;
or “PMAP” for a */proc* map file (*map*);
or “PMEM” for a */proc* memory image file;
or “PNTF” for a */proc* process notifier file;
or “POBJ” for a */proc/object* file;
or “PODR” for a */proc/object* directory;
or “POLP” for an old format */proc* light weight process file;
or “POPF” for an old format */proc* PID file;
or “POPG” for an old format */proc* page data file;
or “PORT” for a SYSV named pipe;
or “PREG” for a */proc* register file;
or “PRMP” for a */proc/rmap* file;
or “PRTD” for a */proc* root directory;
or “PSGA” for a */proc/sigact* file;
or “PSIN” for a */proc/psinfo* file;
or “PSTA” for a */proc* status file;
or “PSXSEM” for a POSIX semaphore file;
or “PSXSHM” for a POSIX shared memory file;
or “PTS” for a */dev/pts* file;
or “PUSG” for a */proc/usage* file;
or “PW” for a */proc/watch* file;
or “PXMP” for a */proc/xmap* file;
or “REG” for a regular file;
or “SMT” for a shared memory transport file;
or “STSO” for a stream socket;
or “UNNM” for an unnamed type file;
or “XNAM” for an OpenServer Xenix special file of unknown type;

	or “XSEM” for an OpenServer Xenix semaphore file;
	or “XSD” for an OpenServer Xenix shared data file;
	or the four type number octets if the corresponding name isn't known.
FILE-ADDR	contains the kernel file structure address when f has been specified to +f ;
FCT	contains the file reference count from the kernel file structure when c has been specified to +f ;
FILE-FLAG	when g or G has been specified to +f , this field contains the contents of the f_flag[s] member of the kernel file structure and the kernel's per-process open file flags (if available); ‘G’ causes them to be displayed in hexadecimal; ‘g’, as short-hand names; two lists may be displayed with entries separated by commas, the lists separated by a semi-colon (‘;’); the first list may contain short-hand names for f_flag[s] values from the following table:
AIO	asynchronous I/O (e.g., FAIO)
AP	append
ASYN	asynchronous I/O (e.g., FASYNC)
BAS	block, test, and set in use
BKIU	block if in use
BL	use block offsets
BSK	block seek
CA	copy avoid
CIO	concurrent I/O
CLON	clone
CLRD	CL read
CR	create
DF	defer
DFI	defer IND
DFLU	data flush
DIR	direct
DLY	delay
DOCL	do clone
DSYN	data-only integrity
DTY	must be a directory
EVO	event only
EX	open for exec
EXCL	exclusive open
FSYN	synchronous writes
GCDF	defer during unp_gc() (AIX)
GCMK	mark during unp_gc() (AIX)
GTTY	accessed via /dev/tty
HUP	HUP in progress
KERN	kernel
KIOC	kernel-issued ioctl
LCK	has lock
LG	large file
MBLK	stream message block
MK	mark
MNT	mount
MSYN	multiplex synchronization
NATM	don't update atime
NB	non-blocking I/O
NBDR	no BDRM check
NBIO	SYSV non-blocking I/O

NBF	n-buffering in effect
NC	no cache
ND	no delay
NDSY	no data synchronization
NET	network
NFLK	don't follow links
NMFS	NM file system
NOTO	disable background stop
NSH	no share
NTTY	no controlling TTY
OLRM	OLR mirror
PAIO	POSIX asynchronous I/O
PP	POSIX pipe
R	read
RC	file and record locking cache
REV	revoked
RSH	shared read
RSYN	read synchronization
RW	read and write access
SL	shared lock
SNAP	cooked snapshot
SOCK	socket
SQSH	Sequent shared set on open
SQSV	Sequent SVM set on open
SQR	Sequent set repair on open
SQS1	Sequent full shared open
SQS2	Sequent partial shared open
STPI	stop I/O
SWR	synchronous read
SYN	file integrity while writing
TCPM	avoid TCP collision
TR	truncate
W	write
WKUP	parallel I/O synchronization
WTG	parallel I/O synchronization
VH	vhangup pending
VTXT	virtual text
XL	exclusive lock

this list of names was derived from F* #define's in dialect header files <fcntl.h>, <linux</fs.h>, <sys/fcntl.c>, <sys/fcntlcom.h>, and <sys/file.h>; see the lsof.h header file for a list showing the correspondence between the above short-hand names and the header file definitions;

the second list (after the semicolon) may contain short-hand names for kernel per-process open file flags from this table:

ALLC	allocated
BR	the file has been read
BHUP	activity stopped by SIGHUP
BW	the file has been written
CLSG	closing
CX	close-on-exec (see fcntl(F_SETFD))
LCK	lock was applied
MP	memory-mapped
OPIP	open pending – in progress

	RSVW	reserved wait
	SHMT	UF_FSHMAT set (AIX)
	USE	in use (multi-threaded)
NODE-ID	(or INODE-ADDR for some dialects)	contains a unique identifier for the file node (usually the kernel vnode or inode address, but also occasionally a concatenation of device and node number) when n has been specified to +f;
DEVICE		contains the device numbers, separated by commas, for a character special, block special, regular, directory or NFS file; or "memory" for a memory file system node under Tru64 UNIX; or the address of the private data area of a Solaris socket stream; or a kernel reference address that identifies the file (The kernel reference address may be used for FIFO's, for example.); or the base address or device name of a Linux AX.25 socket device. Usually only the lower thirty two bits of Tru64 UNIX kernel addresses are displayed.
SIZE, SIZE/OFF, or OFFSET		is the size of the file or the file offset in bytes. A value is displayed in this column only if it is available. <i>Lsof</i> displays whatever value – size or offset – is appropriate for the type of the file and the version of <i>Lsof</i> . On some UNIX dialects <i>Lsof</i> can't obtain accurate or consistent file offset information from its kernel data sources, sometimes just for particular kinds of files (e.g., socket files.) In other cases, files don't have true sizes – e.g., sockets, FIFOs, pipes – so <i>Lsof</i> displays for their sizes the content amounts it finds in their kernel buffer descriptors (e.g., socket buffer size counts or TCP/IP window sizes.) Consult the <i>Lsof</i> FAQ (The FAQ section gives its location.) for more information. The file size is displayed in decimal; the offset is normally displayed in decimal with a leading "0t" if it contains 8 digits or less; in hexadecimal with a leading "0x" if it is longer than 8 digits. (Consult the -o o option description for information on when 8 might default to some other value.) Thus the leading "0t" and "0x" identify an offset when the column may contain both a size and an offset (i.e., its title is SIZE/OFF). If the -o option is specified, <i>Lsof</i> always displays the file offset (or nothing if no offset is available) and labels the column OFFSET. The offset always begins with "0t" or "0x" as described above. The <i>Lsof</i> user can control the switch from "0t" to "0x" with the -o o option. Consult its description for more information. If the -s option is specified, <i>Lsof</i> always displays the file size (or nothing if no size is available) and labels the column SIZE. The -o and -s options are mutually exclusive; they can't both be specified. For files that don't have a fixed size – e.g., don't reside on a disk device – <i>Lsof</i> will display appropriate information about the current size or position of the file if it is available in the kernel structures that define the file.
NLINK		contains the file link count when +L has been specified;
NODE		is the node number of a local file; or the inode number of an NFS file in the server host; or the Internet protocol type – e.g, "TCP";

	<p>or “STR” for a stream;</p> <p>or “CCITT” for an HP–UX x.25 socket;</p> <p>or the IRQ or inode number of a Linux AX.25 socket device.</p>
NAME	<p>is the name of the mount point and file system on which the file resides;</p> <p>or the name of a file specified in the <i>names</i> option (after any symbolic links have been resolved);</p> <p>or the name of a character special or block special device;</p> <p>or the local and remote Internet addresses of a network file; the local host name or IP number is followed by a colon (‘:’), the port, “->”, and the two-part remote address; IP addresses may be reported as numbers or names, depending on the + –M, –n, and –P options; colon-separated IPv6 numbers are enclosed in square brackets; IPv4 IN-ADDR_ANY and IPv6 IN6_IS_ADDR_UNSPECIFIED addresses, and zero port numbers are represented by an asterisk (*); a UDP destination address may be followed by the amount of time elapsed since the last packet was sent to the destination; TCP, UDP and UDPLITE remote addresses may be followed by TCP/TPI information in parentheses – state (e.g., “(ESTABLISHED)”, “(Unbound)”), queue sizes, and window sizes (not all dialects) – in a fashion similar to what <i>netstat</i>(1) reports; see the –T option description or the description of the TCP/TPI field in OUTPUT FOR OTHER PROGRAMS for more information on state, queue size, and window size;</p> <p>or the address or name of a UNIX domain socket, possibly including a stream clone device name, a file system object’s path name, local and foreign kernel addresses, socket pair information, and a bound vnode address;</p> <p>or the local and remote mount point names of an NFS file;</p> <p>or “STR”, followed by the stream name;</p> <p>or a stream character device name, followed by “->” and the stream name or a list of stream module names, separated by “->”;</p> <p>or “STR:” followed by the SCO OpenServer stream device and module names, separated by “->”;</p> <p>or system directory name, “—”, and as many components of the path name as <i>lsof</i> can find in the kernel’s name cache for selected dialects (See the KERNEL NAME CACHE section for more information.);</p> <p>or “PIPE->”, followed by a Solaris kernel pipe destination address;</p> <p>or “COMMON:”, followed by the vnode device information structure’s device name, for a Solaris common vnode;</p> <p>or the address family, followed by a slash (/), followed by fourteen comma-separated bytes of a non-Internet raw socket address;</p> <p>or the HP–UX x.25 local address, followed by the virtual connection number (if any), followed by the remote address (if any);</p> <p>or “(dead)” for disassociated Tru64 UNIX files – typically terminal files that have been flagged with the TIOCNNOTTY ioctl and closed by daemons;</p> <p>or “rd=<offset>” and “wr=<offset>” for the values of the read and write offsets of a FIFO;</p> <p>or “clone n:/dev/event” for SCO OpenServer file clones of the /dev/event device, where n is the minor device number of the file;</p> <p>or “(socketpair: n)” for a Solaris 2.6, 8, 9 or 10 UNIX domain socket, created by the <i>socketpair</i>(3N) network function;</p>

or “no PCB” for socket files that do not have a protocol block associated with them, optionally followed by “, CANTSENDMORE” if sending on the socket has been disabled, or “, CANTRCVMORE” if receiving on the socket has been disabled (e.g., by the *shutdown(2)* function);

or the local and remote addresses of a Linux IPX socket file in the form <net>:[<node>:]<port>, followed in parentheses by the transmit and receive queue sizes, and the connection state;

or “dgram” or “stream” for the type UnixWare 7.1.1 and above in-kernel UNIX domain sockets, followed by a colon (‘:’) and the local path name when available, followed by “->” and the remote path name or kernel socket address in hexadecimal when available;

or the association value, association index, endpoint value, local address, local port, remote address and remote port for Linux SCTP sockets;

or “protocol:” followed by the Linux socket’s protocol attribute.

For dialects that support a “namefs” file system, allowing one file to be attached to another with *fattach(3C)*, *lsof* will add “(FA:<address1><direction><address2>)” to the NAME column. <address1> and <address2> are hexadecimal vnode addresses. <direction> will be “<–” if <address2> has been fattach’ed to this vnode whose address is <address1>; and “->” if <address1>, the vnode address of this vnode, has been fattach’ed to <address2>. <address1> may be omitted if it already appears in the DEVICE column.

Lsof may add two parenthetical notes to the NAME column for open Solaris 10 files: “(?)” if *lsof* considers the path name of questionable accuracy; and “(deleted)” if the **-X** option has been specified and *lsof* detects the open file’s path name has been deleted. Consult the *lsof* FAQ (The **FAQ** section gives its location.) for more information on these NAME column additions.

LOCKS

Lsof can’t adequately report the wide variety of UNIX dialect file locks in a single character. What it reports in a single character is a compromise between the information it finds in the kernel and the limitations of the reporting format.

Moreover, when a process holds several byte level locks on a file, *lsof* only reports the status of the first lock it encounters. If it is a byte level lock, then the lock character will be reported in lower case – i.e., ‘r’, ‘w’, or ‘x’ – rather than the upper case equivalent reported for a full file lock.

Generally *lsof* can only report on locks held by local processes on local files. When a local process sets a lock on a remotely mounted (e.g., NFS) file, the remote server host usually records the lock state. One exception is Solaris – at some patch levels of 2.3, and in all versions above 2.4, the Solaris kernel records information on remote locks in local structures.

Lsof has trouble reporting locks for some UNIX dialects. Consult the **BUGS** section of this manual page or the *lsof* FAQ (The **FAQ** section gives its location.) for more information.

OUTPUT FOR OTHER PROGRAMS

When the **-F** option is specified, *lsof* produces output that is suitable for processing by another program – e.g, an *awk* or *Perl* script, or a C program.

Each unit of information is output in a field that is identified with a leading character and terminated by a NL (012) (or a NUL (000) if the 0 (zero) field identifier character is specified.) The data of the field follows immediately after the field identification character and extends to the field terminator.

It is possible to think of field output as process and file sets. A process set begins with a field whose identifier is ‘p’ (for process IDentifier (PID)). It extends to the beginning of the next PID field or the beginning of the first file set of the process, whichever comes first. Included in the process set are fields that identify the command, the process group IDentification (PGID) number, the task (thread) ID (TID), and the user ID (UID) number or login name.

A file set begins with a field whose identifier is ‘f’ (for file descriptor). It is followed by lines that describe the file’s access mode, lock state, type, device, size, offset, inode, protocol, name and stream module names. It extends to the beginning of the next file or process set, whichever comes first.

When the NUL (000) field terminator has been selected with the 0 (zero) field identifier character, *lsof* ends each process and file set with a NL (012) character.

Lsof always produces one field, the PID ('p') field. All other fields may be declared optionally in the field identifier character list that follows the **-F** option. When a field selection character identifies an item *lsof* does not normally list – e.g., PPID, selected with **-R** – specification of the field character – e.g., “**-FR**” – also selects the listing of the item.

It is entirely possible to select a set of fields that cannot easily be parsed – e.g., if the field descriptor field is not selected, it may be difficult to identify file sets. To help you avoid this difficulty, *lsof* supports the **-F0** option; it selects the output of all fields with NL terminators (the **-F0** option pair selects the output of all fields with NUL terminators). For compatibility reasons neither **-F** nor **-F0** select the raw device field.

These are the fields that *lsof* will produce. The single character listed first is the field identifier.

a	file access mode
c	process command name (all characters from proc or user structure)
C	file structure share count
d	file's device character code
D	file's major/minor device number (0x<hexadecimal>)
f	file descriptor (always selected)
F	file structure address (0x<hexadecimal>)
G	file flaGs (0x<hexadecimal>; names if +fg follows)
g	process group ID
i	file's inode number
K	tasK ID
k	link count
l	file's lock status
L	process login name
m	marker between repeated output
M	the task comMand name
n	file name, comment, Internet address
N	node identifier (0x<hexadecimal>)
o	file's offset (decimal)
p	process ID (always selected)
P	protocol name
r	raw device number (0x<hexadecimal>)
R	parent process ID
s	file's size (decimal)
S	file's stream identification
t	file's type
T	TCP/TPI information, identified by prefixes (the '=' is part of the prefix): QR=<read queue size> QS=<send queue size> SO=<socket options and values> (not all dialects) SS=<socket states> (not all dialects) ST=<connection state> TF=<TCP flags and values> (not all dialects) WR=<window read size> (not all dialects) WW=<window write size> (not all dialects) (TCP/TPI information isn't reported for all supported UNIX dialects. The -h or -? help output for the -T option will show what TCP/TPI reporting can be requested.)
u	process user ID

z	Solaris 10 and higher zone name
Z	SELinux security context (inhibited when SELinux is disabled)
0	use NUL field terminator character in place of NL
1–9	dialect-specific field identifiers (The output of -F? identifies the information to be found in dialect-specific fields.)

You can get on-line help information on these characters and their descriptions by specifying the **-F?** option pair. (Escape the “?” character as your shell requires.) Additional information on field content can be found in the **OUTPUT** section.

As an example, “**-F pcfn**” will select the process ID ('p'), command name ('c'), file descriptor ('f') and file name ('n') fields with an NL field terminator character; “**-F pcfn0**” selects the same output with a NUL (000) field terminator character.

Lsof doesn't produce all fields for every process or file set, only those that are available. Some fields are mutually exclusive: file device characters and file major/minor device numbers; file inode number and protocol name; file name and stream identification; file size and offset. One or the other member of these mutually exclusive sets will appear in field output, but not both.

Normally *lsof* ends each field with a NL (012) character. The 0 (zero) field identifier character may be specified to change the field terminator character to a NUL (000). A NUL terminator may be easier to process with *xargs (1)*, for example, or with programs whose quoting mechanisms may not easily cope with the range of characters in the field output. When the NUL field terminator is in use, *lsof* ends each process and file set with a NL (012).

Three aids to producing programs that can process *lsof* field output are included in the *lsof* distribution. The first is a C header file, *lsof_fields.h*, that contains symbols for the field identification characters, indexes for storing them in a table, and explanation strings that may be compiled into programs. *Lsof* uses this header file.

The second aid is a set of sample scripts that process field output, written in *awk*, *Perl* 4, and *Perl* 5. They're located in the *scripts* subdirectory of the *lsof* distribution.

The third aid is the C library used for the *lsof* test suite. The test suite is written in C and uses field output to validate the correct operation of *lsof*. The library can be found in *thetests/L Tlib.c* file of the *lsof* distribution. The library uses the first aid, *thelsof_fields.h* header file.

BLOCKS AND TIMEOUTS

Lsof can be blocked by some kernel functions that it uses – *lstat(2)*, *readlink(2)*, and *stat(2)*. These functions are stalled in the kernel, for example, when the hosts where mounted NFS file systems reside become inaccessible.

Lsof attempts to break these blocks with timers and child processes, but the techniques are not wholly reliable. When *lsof* does manage to break a block, it will report the break with an error message. The messages may be suppressed with the **-t** and **-w** options.

The default timeout value may be displayed with the **-h** or **-?** option, and it may be changed with the **-S [t]** option. The minimum for *t* is two seconds, but you should avoid small values, since slow system responsiveness can cause short timeouts to expire unexpectedly and perhaps stop *lsof* before it can produce any output.

When *lsof* has to break a block during its access of mounted file system information, it normally continues, although with less information available to display about open files.

Lsof can also be directed to avoid the protection of timers and child processes when using the kernel functions that might block by specifying the **-O** option. While this will allow *lsof* to start up with less overhead, it exposes *lsof* completely to the kernel situations that might block it. Use this option cautiously.

AVOIDING KERNEL BLOCKS

You can use the **-b** option to tell *lsof* to avoid using kernel functions that would block. Some cautions apply.

First, using this option usually requires that your system supply alternate device numbers in place of the device numbers that *lsof* would normally obtain with the *lstat(2)* and *stat(2)* kernel functions. See the **ALTERNATE DEVICE NUMBERS** section for more information on alternate device numbers.

Second, you can't specify *names* for *lsof* to locate unless they're file system names. This is because *lsof* needs to know the device and inode numbers of files listed with *names* in the *lsof* options, and the **-b** option prevents *lsof* from obtaining them. Moreover, since *lsof* only has device numbers for the file systems that have alternates, its ability to locate files on file systems depends completely on the availability and accuracy of the alternates. If no alternates are available, or if they're incorrect, *lsof* won't be able to locate files on the named file systems.

Third, if the names of your file system directories that *lsof* obtains from your system's mount table are symbolic links, *lsof* won't be able to resolve the links. This is because the **-b** option causes *lsof* to avoid the kernel *readlink(2)* function it uses to resolve symbolic links.

Finally, using the **-b** option causes *lsof* to issue warning messages when it needs to use the kernel functions that the **-b** option directs it to avoid. You can suppress these messages by specifying the **-w** option, but if you do, you won't see the alternate device numbers reported in the warning messages.

ALTERNATE DEVICE NUMBERS

On some dialects, when *lsof* has to break a block because it can't get information about a mounted file system via the *lstat(2)* and *stat(2)* kernel functions, or because you specified the **-b** option, *lsof* can obtain some of the information it needs – the device number and possibly the file system type – from the system mount table. When that is possible, *lsof* will report the device number it obtained. (You can suppress the report by specifying the **-w** option.)

You can assist this process if your mount table is supported with an */etc/mtab* or */etc/mnttab* file that contains an options field by adding a “*dev=xxxx*” field for mount points that do not have one in their options strings. Note: you must be able to edit the file – i.e., some mount tables like recent Solaris */etc/mnttab* or Linux */proc/mounts* are read-only and can't be modified.

You may also be able to supply device numbers using the **+m** and **+m m** options, provided they are supported by your dialect. Check the output of *lsof*'s **-h** or **-?** options to see if the **+m** and **+m m** options are available.

The “*xxxx*” portion of the field is the hexadecimal value of the file system's device number. (Consult the *st_dev* field of the output of the *lstat(2)* and *stat(2)* functions for the appropriate values for your file systems.) Here's an example from a Sun Solaris 2.6 */etc/mnttab* for a file system remotely mounted via NFS:

```
nfs ignore,noquota,dev=2a40001
```

There's an advantage to having “*dev=xxxx*” entries in your mount table file, especially for file systems that are mounted from remote NFS servers. When a remote server crashes and you want to identify its users by running *lsof* on one of its clients, *lsof* probably won't be able to get output from the *lstat(2)* and *stat(2)* functions for the file system. If it can obtain the file system's device number from the mount table, it will be able to display the files open on the crashed NFS server.

Some dialects that do not use an ASCII */etc/mtab* or */etc/mnttab* file for the mount table may still provide an alternative device number in their internal mount tables. This includes AIX, Apple Darwin, FreeBSD, NetBSD, OpenBSD, and Tru64 UNIX. *Lsof* knows how to obtain the alternative device number for these dialects and uses it when its attempt to *lstat(2)* or *stat(2)* the file system is blocked.

If you're not sure your dialect supplies alternate device numbers for file systems from its mount table, use this *lsof* incantation to see if it reports any alternate device numbers:

```
lsof -b
```

Look for standard error file warning messages that begin “assuming “*dev=xxxx*” from ...”.

KERNEL NAME CACHE

Lsof is able to examine the kernel's name cache or use other kernel facilities (e.g., the ADVFS 4.x *tag_to_path()* function under Tru64 UNIX) on some dialects for most file system types, excluding AFS, and extract recently used path name components from it. (AFS file system path lookups don't use the kernel's

name cache; some Solaris VxFS file system operations apparently don't use it, either.)

lsof reports the complete paths it finds in the NAME column. If *lsof* can't report all components in a path, it reports in the NAME column the file system name, followed by a space, two '-' characters, another space, and the name components it has located, separated by the '/' character.

When *lsof* is run in repeat mode – i.e., with the **-r** option specified – the extent to which it can report path name components for the same file may vary from cycle to cycle. That's because other running processes can cause the kernel to remove entries from its name cache and replace them with others.

Lsof's use of the kernel name cache to identify the paths of files can lead it to report incorrect components under some circumstances. This can happen when the kernel name cache uses device and node number as a key (e.g., SCO OpenServer) and a key on a rapidly changing file system is reused. If the UNIX dialect's kernel doesn't purge the name cache entry for a file when it is unlinked, *lsof* may find a reference to the wrong entry in the cache. The *lsof* FAQ (The **FAQ** section gives its location.) has more information on this situation.

Lsof can report path name components for these dialects:

- FreeBSD
- HP-UX
- Linux
- NetBSD
- NEXTSTEP
- OpenBSD
- OPENSTEP
- SCO OpenServer
- SCO|Caldera UnixWare
- Solaris
- Tru64 UNIX

Lsof can't report path name components for these dialects:

- AIX

If you want to know why *lsof* can't report path name components for some dialects, see the *lsof* FAQ (The **FAQ** section gives its location.)

DEVICE CACHE FILE

Examining all members of the */dev* (or */devices*) node tree with *stat(2)* functions can be time consuming. What's more, the information that *lsof* needs – device number, inode number, and path – rarely changes.

Consequently, *lsof* normally maintains an ASCII text file of cached */dev* (or */devices*) information (exception: the */proc*-based Linux *lsof* where it's not needed.) The local system administrator who builds *lsof* can control the way the device cache file path is formed, selecting from these options:

- Path from the **-D** option;
- Path from an environment variable;
- System-wide path;
- Personal path (the default);
- Personal path, modified by an environment variable.

Consult the output of the **-h**, **-D?**, or **-?** help options for the current state of device cache support. The help output lists the default read-mode device cache file path that is in effect for the current invocation of *lsof*. The **-D?** option output lists the read-only and write device cache file paths, the names of any applicable environment variables, and the personal device cache path format.

Lsof can detect that the current device cache file has been accidentally or maliciously modified by integrity checks, including the computation and verification of a sixteen bit Cyclic Redundancy Check (CRC) sum on the file's contents. When *lsof* senses something wrong with the file, it issues a warning and attempts to remove the current cache file and create a new copy, but only to a path that the process can legitimately write.

The path from which a *lsof* process may attempt to read a device cache file may not be the same as the path to which it can legitimately write. Thus when *lsof* senses that it needs to update the device cache file, it may choose a different path for writing it from the path from which it read an incorrect or outdated version.

If available, the **-Dr** option will inhibit the writing of a new device cache file. (It's always available when specified without a path name argument.)

When a new device is added to the system, the device cache file may need to be recreated. Since *lsof* compares the mtime of the device cache file with the mtime and ctime of the */dev* (or */devices*) directory, it usually detects that a new device has been added; in that case *lsof* issues a warning message and attempts to rebuild the device cache file.

Whenever *lsof* writes a device cache file, it sets its ownership to the real UID of the executing process, and its permission modes to 0600, this restricting its reading and writing to the file's owner.

LSOF PERMISSIONS THAT AFFECT DEVICE CACHE FILE ACCESS

Two permissions of the *lsof* executable affect its ability to access device cache files. The permissions are set by the local system administrator when *lsof* is installed.

The first and rarer permission is setuid-root. It comes into effect when *lsof* is executed; its effective UID is then root, while its real (i.e., that of the logged-on user) UID is not. The *lsof* distribution recommends that versions for these dialects run setuid-root.

HP-UX 11.11 and 11.23
Linux

The second and more common permission is setgid. It comes into effect when the effective group IDentification number (GID) of the *lsof* process is set to one that can access kernel memory devices – e.g., “kmem”, “sys”, or “system”.

An *lsof* process that has setgid permission usually surrenders the permission after it has accessed the kernel memory devices. When it does that, *lsof* can allow more liberal device cache path formations. The *lsof* distribution recommends that versions for these dialects run setgid and be allowed to surrender setgid permission.

AIX 5.[12] and 5.3-ML1
Apple Darwin 7.x Power Macintosh systems
FreeBSD 4.x, 4.1x, 5.x and [6789].x for x86-based systems
FreeBSD 5.x, [6789].x and 1[012].8 for Alpha, AMD64 and Sparc64
based systems
HP-UX 11.00
NetBSD 1.[456], 2.x and 3.x for Alpha, x86, and SPARC-based
systems
NEXTSTEP 3.[13] for NEXTSTEP architectures
OpenBSD 2.[89] and 3.[0–9] for x86-based systems
OPENSTEP 4.x
SCO OpenServer Release 5.0.6 for x86-based systems
SCO|Caldera UnixWare 7.1.4 for x86-based systems
Solaris 2.6, 8, 9 and 10
Tru64 UNIX 5.1

(Note: *lsof* for AIX 5L and above needs setuid-root permission if its **-X** option is used.)

lsof for these dialects does not support a device cache, so the permissions given to the executable don't apply to the device cache file.

Linux

DEVICE CACHE FILE PATH FROM THE **-D OPTION**

The **-D** option provides limited means for specifying the device cache file path. Its **? function** will report the read-only and write device cache file paths that *lsof* will use.

When the **-D b, r, and u** functions are available, you can use them to request that the cache file be built in a

specific location (**b**[*path*]); read but not rebuilt (**r**[*path*]); or read and rebuilt (**u**[*path*]). The **b**, **r**, and **u** functions are restricted under some conditions. They are restricted when the *lsof* process is setuid–root. The path specified with the **r** function is always read–only, even when it is available.

The **b**, **r**, and **u** functions are also restricted when the *lsof* process runs setgid and *lsof* doesn't surrender the setgid permission. (See the **LSOF PERMISSIONS THAT AFFECT DEVICE CACHE FILE ACCESS** section for a list of implementations that normally don't surrender their setgid permission.)

A further **-D** function, **i** (for ignore), is always available.

When available, the **b** function tells *lsof* to read device information from the kernel with the *stat*(2) function and build a device cache file at the indicated path.

When available, the **r** function tells *lsof* to read the device cache file, but not update it. When a path argument accompanies **-Dr**, it names the device cache file path. The **r** function is always available when it is specified without a path name argument. If *lsof* is not running setuid–root and surrenders its setgid permission, a path name argument may accompany the **r** function.

When available, the **u** function tells *lsof* to attempt to read and use the device cache file. If it can't read the file, or if it finds the contents of the file incorrect or outdated, it will read information from the kernel, and attempt to write an updated version of the device cache file, but only to a path it considers legitimate for the *lsof* process effective and real UIDs.

DEVICE CACHE PATH FROM AN ENVIRONMENT VARIABLE

lsof's second choice for the device cache file is the contents of the LSOFDEVCACHE environment variable. It avoids this choice if the *lsof* process is setuid–root, or the real UID of the process is root.

A further restriction applies to a device cache file path taken from the LSOFDEVCACHE environment variable: *lsof* will not write a device cache file to the path if the *lsof* process doesn't surrender its setgid permission. (See the **LSOF PERMISSIONS THAT AFFECT DEVICE CACHE FILE ACCESS** section for information on implementations that don't surrender their setgid permission.)

The local system administrator can disable the use of the LSOFDEVCACHE environment variable or change its name when building *lsof*. Consult the output of **-D?** for the environment variable's name.

SYSTEM-WIDE DEVICE CACHE PATH

The local system administrator may choose to have a system–wide device cache file when building *lsof*. That file will generally be constructed by a special system administration procedure when the system is booted or when the contents of */dev* or */devices* changes. If defined, it is *lsof*'s third device cache file path choice.

You can tell that a system–wide device cache file is in effect for your local installation by examining the *lsof* help option output – i.e., the output from the **-h** or **-?** option.

lsof will never write to the system–wide device cache file path by default. It must be explicitly named with a **-D** function in a root–owned procedure. Once the file has been written, the procedure must change its permission modes to 0644 (owner–read and owner–write, group–read, and other–read).

PERSONAL DEVICE CACHE PATH (DEFAULT)

The default device cache file path of the *lsof* distribution is one recorded in the home directory of the real UID that executes *lsof*. Added to the home directory is a second path component of the form *lsof_hostname*.

This is *lsof*'s fourth device cache file path choice, and is usually the default. If a system–wide device cache file path was defined when *lsof* was built, this fourth choice will be applied when *lsof* can't find the system–wide device cache file. This is the **only** time *lsof* uses two paths when reading the device cache file.

The *hostname* part of the second component is the base name of the executing host, as returned by *gethostname*(2). The base name is defined to be the characters preceding the first ‘.’ in the *gethostname*(2) output, or all the *gethostname*(2) output if it contains no ‘.’.

The device cache file belongs to the user ID and is readable and writable by the user ID alone – i.e., its modes are 0600. Each distinct real user ID on a given host that executes *lsof* has a distinct device cache

file. The *hostname* part of the path distinguishes device cache files in an NFS-mounted home directory into which device cache files are written from several different hosts.

The personal device cache file path formed by this method represents a device cache file that *lsof* will attempt to read, and will attempt to write should it not exist or should its contents be incorrect or outdated.

The **-Dr** option without a path name argument will inhibit the writing of a new device cache file.

The **-D?** option will list the format specification for constructing the personal device cache file. The conversions used in the format specification are described in the *00DCACHE* file of the *lsof* distribution.

MODIFIED PERSONAL DEVICE CACHE PATH

If this option is defined by the local system administrator when *lsof* is built, the LSOPERSDCPATH environment variable contents may be used to add a component of the personal device cache file path.

The LSOPERSDCPATH variable contents are inserted in the path at the place marked by the local system administrator with the “%p” conversion in the HASPERSDC format specification of the dialect’s *machine.h* header file. (It’s placed right after the home directory in the default *lsof* distribution.)

Thus, for example, if LSOPERSDCPATH contains “LSOF”, the home directory is “/Homes/abe”, the host name is “lsof.itap.purdue.edu”, and the HASPERSDC format is the default (“%h/%p.lsof_%L”), the modified personal device cache file path is:

```
/Homes/abe/LSOF/.lsof_vic
```

The LSOPERSDCPATH environment variable is ignored when the *lsof* process is setuid-root or when the real UID of the process is root.

lsof will not write to a modified personal device cache file path if the *lsof* process doesn’t surrender setgid permission. (See the **LSOF PERMISSIONS THAT AFFECT DEVICE CACHE FILE ACCESS** section for a list of implementations that normally don’t surrender their setgid permission.)

If, for example, you want to create a sub-directory of personal device cache file paths by using the LSOPERSDCPATH environment variable to name it, and *lsof* doesn’t surrender its setgid permission, you will have to allow *lsof* to create device cache files at the standard personal path and move them to your subdirectory with shell commands.

The local system administrator may: disable this option when *lsof* is built; change the name of the environment variable from LSOPERSDCPATH to something else; change the HASPERSDC format to include the personal path component in another place; or exclude the personal path component entirely. Consult the output of the **-D?** option for the environment variable’s name and the HASPERSDC format specification.

DIAGNOSTICS

Errors are identified with messages on the standard error file.

lsof returns a one (1) if any error was detected, including the failure to locate command names, file names, Internet addresses or files, login names, NFS files, PIDs, PGIDs, or UIDs it was asked to list. If the **-V** option is specified, *lsof* will indicate the search items it failed to list.

It returns a zero (0) if no errors were detected and if it was able to list some information about all the specified search arguments.

When *lsof* cannot open access to */dev* (or */devices*) or one of its subdirectories, or get information on a file in them with *stat(2)*, it issues a warning message and continues. That *lsof* will issue warning messages about inaccessible files in */dev* (or */devices*) is indicated in its help output – requested with the **-h** or **>B -?** options – with the message:

Inaccessible /dev warnings are enabled.

The warning message may be suppressed with the **-w** option. It may also have been suppressed by the system administrator when *lsof* was compiled by the setting of the **WARNDEVACCESS** definition. In this case, the output from the help options will include the message:

Inaccessible /dev warnings are disabled.

Inaccessible device warning messages usually disappear after *lsof* has created a working device cache file.

EXAMPLES

For a more extensive set of examples, documented more fully, see the *00QUICKSTART* file of the *lsof* distribution.

To list all open files, use:

```
lsof
```

To list all open Internet, x.25 (HP-UX), and UNIX domain files, use:

```
lsof -i -U
```

To list all open IPv4 network files in use by the process whose PID is 1234, use:

```
lsof -i 4 -a -p 1234
```

Presuming the UNIX dialect supports IPv6, to list only open IPv6 network files, use:

```
lsof -i 6
```

To list all files using any protocol on ports 513, 514, or 515 of host wonderland.cc.purdue.edu, use:

```
lsof -i @wonderland.cc.purdue.edu:513-515
```

To list all files using any protocol on any port of mace.cc.purdue.edu (cc.purdue.edu is the default domain), use:

```
lsof -i @mace
```

To list all open files for login name “abe”, or user ID 1234, or process 456, or process 123, or process 789, use:

```
lsof -p 456,123,789 -u 1234,abe
```

To list all open files on device /dev/hd4, use:

```
lsof /dev/hd4
```

To find the process that has /u/abe/foo open, use:

```
lsof /u/abe/foo
```

To send a SIGHUP to the processes that have /u/abe/bar open, use:

```
kill -HUP `lsof -t /u/abe/bar`
```

To find any open file, including an open UNIX domain socket file, with the name /dev/log, use:

```
lsof /dev/log
```

To find processes with open files on the NFS file system named /nfs/mount/point whose server is inaccessible, and presuming your mount table supplies the device number for /nfs/mount/point, use:

```
lsof -b /nfs/mount/point
```

To do the preceding search with warning messages suppressed, use:

```
lsof -bw /nfs/mount/point
```

To ignore the device cache file, use:

```
lsof -Di
```

To obtain PID and command name field output for each process, file descriptor, file device number, and file inode number for each file of each process, use:

```
lsof -FpcfDi
```

To list the files at descriptors 1 and 3 of every process running the *lsof* command for login ID “abe” every 10 seconds, use:

```
lsof -c lsof -a -d 1 -d 3 -u abe -r10
```

To list the current working directory of processes running a command that is exactly four characters long and has an 'o' or 'O' in character three, use this regular expression form of the **-c** option:

```
lsof -c ^..o./i -a -d cwd
```

To find an IP version 4 socket file by its associated numeric dot-form address, use:

```
lsof -i@128.210.15.17
```

To find an IP version 6 socket file (when the UNIX dialect supports IPv6) by its associated numeric colon-form address, use:

```
lsof -i@[0:1:2:3:4:5:6:7]
```

To find an IP version 6 socket file (when the UNIX dialect supports IPv6) by an associated numeric colon-form address that has a run of zeroes in it – e.g., the loop-back address – use:

```
lsof -i@[::1]
```

To obtain a repeat mode marker line that contains the current time, use:

```
lsof -rm====%T=====
```

To add spaces to the previous marker line, use:

```
lsof -r "m==== %T ====="
```

BUGS

Since *lsof* reads kernel memory in its search for open files, rapid changes in kernel memory may produce unpredictable results.

When a file has multiple record locks, the lock status character (following the file descriptor) is derived from a test of the first lock structure, not from any combination of the individual record locks that might be described by multiple lock structures.

Lsof can't search for files with restrictive access permissions by *name* unless it is installed with root set-UID permission. Otherwise it is limited to searching for files to which its user or its set-GID group (if any) has access permission.

The display of the destination address of a raw socket (e.g., for *ping*) depends on the UNIX operating system. Some dialects store the destination address in the raw socket's protocol control block, some do not.

Lsof can't always represent Solaris device numbers in the same way that *ls(1)* does. For example, the major and minor device numbers that the *lstat(2)* and *stat(2)* functions report for the directory on which CD-ROM files are mounted (typically */cdrom*) are not the same as the ones that it reports for the device on which CD-ROM files are mounted (typically */dev/sr0*). (*Lsof* reports the directory numbers.)

The support for */proc* file systems is available only for BSD and Tru64 UNIX dialects, Linux, and dialects derived from SYSV R4 – e.g., FreeBSD, NetBSD, OpenBSD, Solaris, UnixWare.

Some */proc* file items – device number, inode number, and file size – are unavailable in some dialects. Searching for files in a */proc* file system may require that the full path name be specified.

No text (**txt**) file descriptors are displayed for Linux processes. All entries for files other than the current working directory, the root directory, and numerical file descriptors are labeled **mem** descriptors.

Lsof can't search for Tru64 UNIX named pipes by name, because their kernel implementation of *Istat(2)* returns an improper device number for a named pipe.

Lsof can't report fully or correctly on HP-UX 9.01, 10.20, and 11.00 locks because of insufficient access to kernel data or errors in the kernel data. See the *lsof* FAQ (The **FAQ** section gives its location.) for details.

The AIX SMT file type is a fabrication. It's made up for file structures whose type (15) isn't defined in the AIX */usr/include/sys/file.h* header file. One way to create such file structures is to run X clients with the DISPLAY variable set to “:0.0”.

The `+|-f[cfn]` option is not supported under /proc-based Linux *lsof*, because it doesn't read kernel structures from kernel memory.

ENVIRONMENT

lsof may access these environment variables.

LANG	defines a language locale. See <i>setlocale(3)</i> for the names of other variables that can be used in place of LANG – e.g., LC_ALL, LC_TYPE, etc.
LSOFDEVCACHE	defines the path to a device cache file. See the DEVICE CACHE PATH FROM AN ENVIRONMENT VARIABLE section for more information.
LSOFPERSDCPATH	defines the middle component of a modified personal device cache file path. See the MODIFIED PERSONAL DEVICE CACHE PATH section for more information.

FAQ

Frequently-asked questions and their answers (an FAQ) are available in the *00FAQ* file of the *lsof* distribution.

That file is also available via anonymous ftp from *lsof.itap.purdue.edu* at *pub/tools/unix/lsofFAQ*. The URL is:

<ftp://lsof.itap.purdue.edu/pub/tools/unix/lsof/FAQ>

FILES

<i>/dev/kmem</i>	kernel virtual memory device
<i>/dev/mem</i>	physical memory device
<i>/dev/swap</i>	system paging device
<i>.lsof_hostname</i>	<i>lsof</i> 's device cache file (The suffix, <i>hostname</i> , is the first component of the host's name returned by <i>gethostname(2)</i> .)

AUTHORS

lsof was written by Victor A. Abell <abe@purdue.edu> of Purdue University. Many others have contributed to *lsof*. They're listed in the *00CREDITS* file of the *lsof* distribution.

DISTRIBUTION

The latest distribution of *lsof* is available via anonymous ftp from the host *lsof.itap.purdue.edu*. You'll find the *lsof* distribution in the *pub/tools/unix/lsof* directory.

You can also use this URL:

<ftp://lsof.itap.purdue.edu/pub/tools/unix/lsof>

lsof is also mirrored elsewhere. When you access *lsof.itap.purdue.edu* and change to its *pub/tools/unix/lsof* directory, you'll be given a list of some mirror sites. The *pub/tools/unix/lsof* directory also contains a more complete list in its *mirrors* file. Use mirrors with caution – not all mirrors always have the latest *lsof* revision.

Some pre-compiled *lsof* executables are available on *lsof.itap.purdue.edu*, but their use is discouraged – it's better that you build your own from the sources. If you feel you must use a pre-compiled executable, please read the cautions that appear in the *README* files of the *pub/tools/unix/lsof/binaries* subdirectories and in the *00** files of the distribution.

More information on the *lsof* distribution can be found in its *README.lsof_<version>* file. If you intend to get the *lsof* distribution and build it, please read *README.lsof_<version>* and the other *00** files of the distribution before sending questions to the author.

SEE ALSO

Not all the following manual pages may exist in every UNIX dialect to which *lsof* has been ported.

NAME

lspci – list all PCI devices

SYNOPSIS

lspci [options]

DESCRIPTION

lspci is a utility for displaying information about PCI buses in the system and devices connected to them.

By default, it shows a brief list of devices. Use the options described below to request either a more verbose output or output intended for parsing by other programs.

If you are going to report bugs in PCI device drivers or in *lspci* itself, please include output of "lspci -vvx" or even better "lspci -vvvxx" (however, see below for possible caveats).

Some parts of the output, especially in the highly verbose modes, are probably intelligible only to experienced PCI hackers. For exact definitions of the fields, please consult either the PCI specifications or the **header.h** and **/usr/include/linux/pci.h** include files.

Access to some parts of the PCI configuration space is restricted to root on many operating systems, so the features of *lspci* available to normal users are limited. However, *lspci* tries its best to display as much as available and mark all other information with <access denied> text.

OPTIONS

Basic display modes

- m Dump PCI device data in a backward-compatible machine readable form. See below for details.
- mm Dump PCI device data in a machine readable form for easy parsing by scripts. See below for details.
- t Show a tree-like diagram containing all buses, bridges, devices and connections between them.

Display options

- v Be verbose and display detailed information about all devices.
- vv Be very verbose and display more details. This level includes everything deemed useful.
- vvv Be even more verbose and display everything we are able to parse, even if it doesn't look interesting at all (e.g., undefined memory regions).
- k Show kernel drivers handling each device and also kernel modules capable of handling it. Turned on by default when -v is given in the normal mode of output. (Currently works only on Linux with kernel 2.6 or newer.)
- x Show hexadecimal dump of the standard part of the configuration space (the first 64 bytes or 128 bytes for CardBus bridges).
- xxx Show hexadecimal dump of the whole PCI configuration space. It is available only to root as several PCI devices **crash** when you try to read some parts of the config space (this behavior probably doesn't violate the PCI standard, but it's at least very stupid). However, such devices are rare, so you needn't worry much.
- xxxx Show hexadecimal dump of the extended (4096-byte) PCI configuration space available on PCI-X 2.0 and PCI Express buses.
- b Bus-centric view. Show all IRQ numbers and addresses as seen by the cards on the PCI bus instead of as seen by the kernel.
- D Always show PCI domain numbers. By default, *lspci* suppresses them on machines which have only domain 0.

- P** Identify PCI devices by path through each bridge, instead of by bus number.
- PP** Identify PCI devices by path through each bridge, showing the bus number as well as the device number.

Options to control resolving ID's to names

- n** Show PCI vendor and device codes as numbers instead of looking them up in the PCI ID list.
- nn** Show PCI vendor and device codes as both numbers and names.
- q** Use DNS to query the central PCI ID database if a device is not found in the local **pci.ids** file. If the DNS query succeeds, the result is cached in **~/.pcids-cache** and it is recognized in subsequent runs even if **-q** is not given any more. Please use this switch inside automated scripts only with caution to avoid overloading the database servers.
- qq** Same as **-q**, but the local cache is reset.
- Q** Query the central database even for entries which are recognized locally. Use this if you suspect that the displayed entry is wrong.

Options for selection of devices

-s [[[<domain>]:]<bus>]:]<device>][.[<func>]]

Show only devices in the specified domain (in case your machine has several host bridges, they can either share a common bus number space or each of them can address a PCI domain of its own; domains are numbered from 0 to ffff), bus (0 to ff), device (0 to 1f) and function (0 to 7). Each component of the device address can be omitted or set to "*", both meaning "any value". All numbers are hexadecimal. E.g., "0:" means all devices on bus 0, "0" means all functions of device 0 on any bus, "0.3" selects third function of device 0 on all buses and ".4" shows only the fourth function of each device.

-d [<vendor>]:[<device>][:<class>]

Show only devices with specified vendor, device and class ID. The ID's are given in hexadecimal and may be omitted or given as "*", both meaning "any value".

Other options

-i <file>

Use **<file>** as the PCI ID list instead of /usr/share/misc/pci.ids.

-p <file>

Use **<file>** as the map of PCI ID's handled by kernel modules. By default, lspci uses /lib/modules/kernel_version/modules.pcimap. Applies only to Linux systems with recent enough module tools.

-M

Invoke bus mapping mode which performs a thorough scan of all PCI devices, including those behind misconfigured bridges, etc. This option gives meaningful results only with a direct hardware access mode, which usually requires root privileges. Please note that the bus mapper only scans PCI domain 0.

--version

Shows *lspci* version. This option should be used stand-alone.

PCI access options

The PCI utilities use the PCI library to talk to PCI devices (see **pcilib(7)** for details). You can use the following options to influence its behavior:

-A <method>

The library supports a variety of methods to access the PCI hardware. By default, it uses the first access method available, but you can use this option to override this decision. See **-A help** for a list of available methods and their descriptions.

-O <param>=<value>

The behavior of the library is controlled by several named parameters. This option allows one to set the value of any of the parameters. Use **-O help** for a list of known parameters and their default values.

-H1 Use direct hardware access via Intel configuration mechanism 1. (This is a shorthand for **-A intel-conf1**.)

-H2 Use direct hardware access via Intel configuration mechanism 2. (This is a shorthand for **-A intel-conf2**.)

-F <file>

Instead of accessing real hardware, read the list of devices and values of their configuration registers from the given file produced by an earlier run of lspci -x. This is very useful for analysis of user-supplied bug reports, because you can display the hardware configuration in any way you want without disturbing the user with requests for more dumps.

-G Increase debug level of the library.

MACHINE READABLE OUTPUT

If you intend to process the output of lspci automatically, please use one of the machine-readable output formats (**-m**, **-vm**, **-vmm**) described in this section. All other formats are likely to change between versions of lspci.

All numbers are always printed in hexadecimal. If you want to process numeric ID's instead of names, please add the **-n** switch.

Simple format (-m)

In the simple format, each device is described on a single line, which is formatted as parameters suitable for passing to a shell script, i.e., values separated by whitespaces, quoted and escaped if necessary. Some of the arguments are positional: slot, class, vendor name, device name, subsystem vendor name and subsystem name (the last two are empty if the device has no subsystem); the remaining arguments are option-like:

-rev Revision number.

-p *progif*

Programming interface.

The relative order of positional arguments and options is undefined. New options can be added in future versions, but they will always have a single argument not separated from the option by any spaces, so they can be easily ignored if not recognized.

Verbose format (-vmm)

The verbose output is a sequence of records separated by blank lines. Each record describes a single device by a sequence of lines, each line containing a single ‘tag: value’ pair. The *tag* and the *value* are separated by a single tab character. Neither the records nor the lines within a record are in any particular order. Tags are case-sensitive.

The following tags are defined:

Slot The name of the slot where the device resides (*[domain:]bus:device.function*). This tag is always the first in a record.

Class Name of the class.

Vendor

Name of the vendor.

Device Name of the device.

SVendor

Name of the subsystem vendor (optional).

SDevice

Name of the subsystem (optional).

PhySlot

The physical slot where the device resides (optional, Linux only).

Rev Revision number (optional).

ProgIf Programming interface (optional).

Driver Kernel driver currently handling the device (optional, Linux only).

Module

Kernel module reporting that it is capable of handling the device (optional, Linux only). Multiple lines with this tag can occur.

NUMANode

NUMA node this device is connected to (optional, Linux only).

IOMMUGroup

IOMMU group that this device is part of (optional, Linux only).

New tags can be added in future versions, so you should silently ignore any tags you don't recognize.

Backward-compatible verbose format (-vm)

In this mode, lspci tries to be perfectly compatible with its old versions. It's almost the same as the regular verbose format, but the **Device** tag is used for both the slot and the device name, so it occurs twice in a single record. Please avoid using this format in any new code.

FILES

/usr/share/misc/pci.ids

A list of all known PCI ID's (vendors, devices, classes and subclasses). Maintained at <https://pci-ids.ucw.cz/>, use the **update-pciids** utility to download the most recent version.

/usr/share/misc/pci.ids.gz

If lspci is compiled with support for compression, this file is tried before pci.ids.

~/.pciids-cache

All ID's found in the DNS query mode are cached in this file.

BUGS

Sometimes, lspci is not able to decode the configuration registers completely. This usually happens when not enough documentation was available to the authors. In such cases, it at least prints the <?> mark to signal that there is potentially something more to say. If you know the details, patches will be of course welcome.

Access to the extended configuration space is currently supported only by the **linux_sysfs** back-end.

AUTHOR

The PCI Utilities are maintained by Martin Mares <mj@ucw.cz>.

NAME

stat, fstat, lstat, fstatat – get file status

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/stat.h>
int stat(const char *restrict pathname,
         struct stat *restrict statbuf);
int fstat(int fd, struct stat *statbuf);
int lstat(const char *restrict pathname,
          struct stat *restrict statbuf);

#include <fcntl.h>      /* Definition of AT_* constants */
#include <sys/stat.h>

int fstatat(int dirfd, const char *restrict pathname,
            struct stat *restrict statbuf, int flags);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
lstat():
/* Since glibc 2.20 */ __DEFAULT_SOURCE
|| __XOPEN_SOURCE >= 500
|| /* Since glibc 2.10: */ __POSIX_C_SOURCE >= 200112L
|| /* glibc 2.19 and earlier */ __BSD_SOURCE

fstatat():
Since glibc 2.10:
__POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
__ATFILE_SOURCE
```

DESCRIPTION

These functions return information about a file, in the buffer pointed to by *statbuf*. No permissions are required on the file itself, but—in the case of **stat()**, **fstat()**, and **lstat()**—execute (search) permission is required on all of the directories in *pathname* that lead to the file.

stat() and **fstat()** retrieve information about the file pointed to by *pathname*; the differences for **fstatat()** are described below.

lstat() is identical to **stat()**, except that if *pathname* is a symbolic link, then it returns information about the link itself, not the file that the link refers to.

fstat() is identical to **stat()**, except that the file about which information is to be retrieved is specified by the file descriptor *fd*.

The stat structure

All of these system calls return a *stat* structure (see **stat(3type)**).

Note: for performance and simplicity reasons, different fields in the *stat* structure may contain state information from different moments during the execution of the system call. For example, if *st_mode* or *st_uid* is changed by another process by calling **chmod(2)** or **chown(2)**, **stat()** might return the old *st_mode* together with the new *st_uid*, or the old *st_uid* together with the new *st_mode*.

fstatat()

The **fstatat()** system call is a more general interface for accessing file information which can still provide exactly the behavior of each of **stat()**, **lstat()**, and **fstat()**.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **stat()** and **lstat()** for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like **stat()** and **lstat()**).

If *pathname* is absolute, then *dirfd* is ignored.

flags can either be 0, or include one or more of the following flags ORed:

AT_EMPTY_PATH (since Linux 2.6.39)

If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the **open(2)** **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory, and the behavior of **fstatat()** is similar to that of **fstat()**. If *dirfd* is **AT_FDCWD**, the call operates on the current working directory. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_NO_AUTOMOUNT (since Linux 2.6.38)

Don't automount the terminal ("basename") component of *pathname*. Since Linux 3.1 this flag is ignored. Since Linux 4.11 this flag is implied.

AT_SYMLINK_NOFOLLOW

If *pathname* is a symbolic link, do not dereference it: instead return information about the link itself, like **lstat()**. (By default, **fstatat()** dereferences symbolic links, like **stat()**.)

See **openat(2)** for an explanation of the need for **fstatat()**.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES

Search permission is denied for one of the directories in the path prefix of *pathname*. (See also **path_resolution(7)**.)

EBADF

fd is not a valid open file descriptor.

EBADF

(**fstatat()**) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT

Bad address.

EINVAL

(**fstatat()**) Invalid flag specified in *flags*.

ELOOP

Too many symbolic links encountered while traversing the path.

ENAMETOOLONG

pathname is too long.

ENOENT

A component of *pathname* does not exist or is a dangling symbolic link.

ENOENT

pathname is an empty string and **AT_EMPTY_PATH** was not specified in *flags*.

ENOMEM

Out of memory (i.e., kernel memory).

ENOTDIR

A component of the path prefix of *pathname* is not a directory.

ENOTDIR

(**fstatat()**) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EOVERFLOW

pathname or *fd* refers to a file whose size, inode number, or number of blocks cannot be represented in, respectively, the types *off_t*, *ino_t*, or *blkcnt_t*. This error can occur when, for example, an application compiled on a 32-bit platform without *-D_FILE_OFFSET_BITS=64* calls **stat()** on a file whose size exceeds $(1 << 31) - 1$ bytes.

VERSIONS

fstatat() was added in Linux 2.6.16; library support was added in glibc 2.4.

STANDARDS

stat(), **fstat()**, **lstat()**: SVr4, 4.3BSD, POSIX.1-2001, POSIX.1-2008.

fstatat(): POSIX.1-2008.

According to POSIX.1-2001, **lstat()** on a symbolic link need return valid information only in the *st_size* field and the file type of the *st_mode* field of the *stat* structure. POSIX.1-2008 tightens the specification, requiring **lstat()** to return valid information in all fields except the mode bits in *st_mode*.

Use of the *st_blocks* and *st_blksize* fields may be less portable. (They were introduced in BSD. The interpretation differs between systems, and possibly on a single system when NFS mounts are involved.)

NOTES**C library/kernel differences**

Over time, increases in the size of the *stat* structure have led to three successive versions of **stat()**: *sys_stat()* (slot *__NR_oldstat*), *sys_newstat()* (slot *__NR_stat*), and *sys_stat64()* (slot *__NR_stat64*) on 32-bit platforms such as i386. The first two versions were already present in Linux 1.0 (albeit with different names); the last was added in Linux 2.4. Similar remarks apply for **fstat()** and **lstat()**.

The kernel-internal versions of the *stat* structure dealt with by the different versions are, respectively:

__old_kernel_stat

The original structure, with rather narrow fields, and no padding.

stat Larger *st_ino* field and padding added to various parts of the structure to allow for future expansion.

stat64 Even larger *st_ino* field, larger *st_uid* and *st_gid* fields to accommodate the Linux-2.4 expansion of UIDs and GIDs to 32 bits, and various other enlarged fields and further padding in the structure. (Various padding bytes were eventually consumed in Linux 2.6, with the advent of 32-bit device IDs and nanosecond components for the timestamp fields.)

The glibc **stat()** wrapper function hides these details from applications, invoking the most recent version of the system call provided by the kernel, and repacking the returned information if required for old binaries.

On modern 64-bit systems, life is simpler: there is a single **stat()** system call and the kernel deals with a *stat* structure that contains fields of a sufficient size.

The underlying system call employed by the glibc **fstatat()** wrapper function is actually called **fstatat64()** or, on some architectures, **newfstatat()**.

EXAMPLES

The following program calls **lstat()** and displays selected fields in the returned *stat* structure.

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/stat.h>
#include <sys/sysmacros.h>
#include <time.h>

int
main(int argc, char *argv[ ])
{
```

```

    struct stat sb;

    if (argc != 2) {
        fprintf(stderr, "Usage: %s <pathname>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    if (lstat(argv[1], &sb) == -1) {
        perror("lstat");
        exit(EXIT_FAILURE);
    }

    printf("ID of containing device: [%x,%x]\n",
           major(sb.st_dev),
           minor(sb.st_dev));

    printf("File type:                 ");

    switch (sb.st_mode & S_IFMT) {
    case S_IFBLK:   printf("block device\n");          break;
    case S_IFCHR:   printf("character device\n");       break;
    case S_IFDIR:   printf("directory\n");              break;
    case S_IFIFO:   printf("FIFO/pipe\n");              break;
    case S_IFLNK:   printf("symlink\n");                break;
    case S_IFREG:   printf("regular file\n");            break;
    case S_IFSOCK:  printf("socket\n");                 break;
    default:        printf("unknown?\n");               break;
    }

    printf("I-node number:             %ju\n", (uintmax_t) sb.st_ino);

    printf("Mode:                      %jo (octal)\n",
           (uintmax_t) sb.st_mode);

    printf("Link count:                %ju\n", (uintmax_t) sb.st_nlink);
    printf("Ownership:                 UID=%ju     GID=%ju\n",
           (uintmax_t) sb.st_uid, (uintmax_t) sb.st_gid);

    printf("Preferred I/O block size: %jd bytes\n",
           (intmax_t) sb.st_blksize);
    printf("File size:                  %jd bytes\n",
           (intmax_t) sb.st_size);
    printf("Blocks allocated:          %jd\n",
           (intmax_t) sb.st_blocks);

    printf("Last status change:        %s", ctime(&sb.st_ctime));
    printf("Last file access:          %s", ctime(&sb.st_atime));
    printf("Last file modification:   %s", ctime(&sb.st_mtime));

    exit(EXIT_SUCCESS);
}

```

DESCRIPTION

lvchange changes LV attributes in the VG, changes LV activation in the kernel, and includes other utilities for LV maintenance.

USAGE

Change a general LV attribute.

For options listed in parentheses, any one is required, after which the others are optional.

lvchange

```
( -C|--contiguous y|n,
-p|--permission rw|r,
-r|--readahead auto|none|Number,
-k|--setactivationskip y|n,
-Z|--zero y|n,
-M|--persistent n,
--addtag Tag,
--deltag Tag,
--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit,
--compression y|n,
--deduplication y|n,
--detachprofile,
--metadataprofile String,
--profile String,
--errorwhenfull y|n,

--cachemode writethrough|writeback|passthrough,
--cachepolicy String,
--cachesettings String,
--[raid]minrecoverystart Size[k|UNIT],
--[raid]maxrecoverystart Size[k|UNIT],
--[raid]writebehind Number,
--[raid]writemostly PV[:t|n|y] )
```

VG|LV|Tag|Select ...

```
[ -a|--activate y|n|ay ]
[ --poll y|n ]
[ --monitor y|n ]
[ COMMON_OPTIONS ]
```

Resyncronize a mirror or raid LV.

Use to reset 'R' attribute on a not initially synchronized LV.

```
lvchange --resync VG|LV_mIRROR_RAID|Tag|Select ...
[ -a|--activate y|n|ay ]
[ COMMON_OPTIONS ]
```

Resynchronize or check a raid LV.

```
lvchange --syncaction check|repair VG|LV_raid|Tag|Select ...
[ COMMON_OPTIONS ]
```

Reconstruct data on specific PVs of a raid LV.

```
lvchange --rebuild PV VG|LV_raid|Tag|Select ...
[ COMMON_OPTIONS ]
```

Activate or deactivate an LV.

```
lvchange -a|--activate y|n|ay VG|LV|Tag|Select ...
[ -P|--partial ]
[ -K|--ignoreactivationskip ]
[ --activationmode partial|degraded|complete ]
[ --poll y|n ]
[ --monitor y|n ]
[ --ignorelockingfailure ]
[ --sysinit ]
[ --readonly ]
[ COMMON_OPTIONS ]
```

Reactivate an LV using the latest metadata.

```
lvchange --refresh VG|LV|Tag|Select ...
[ -P|--partial ]
[ --activationmode partial|degraded|complete ]
[ --poll y|n ]
[ --monitor y|n ]
[ COMMON_OPTIONS ]
```

Start or stop monitoring an LV from dmeventd.

```
lvchange --monitor y|n VG|LV|Tag|Select ...
[ COMMON_OPTIONS ]
```

Start or stop processing an LV conversion.

```
lvchange --poll y|n VG|LV|Tag|Select ...
[ --monitor y|n ]
[ COMMON_OPTIONS ]
```

Make the minor device number persistent for an LV.

```
lvchange -M|--persistent y --minor Number LV
[ -j|--major Number ]
[ -a|--activate y|n|ay ]
[ --poll y|n ]
[ --monitor y|n ]
[ COMMON_OPTIONS ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ -f|--force ]
[ -S|--select String ]
[ --ignoremonitoring ]
[ --noudevsync ]
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-a|--activate y|n|ay

Change the active state of LVs. An active LV can be used through a block device, allowing data on the LV to be accessed. **y** makes LVs active, or available. **n** makes LVs inactive, or unavailable. The block device for the LV is added or removed from the system using device-mapper in the kernel. A symbolic link /dev/VGName/LVName pointing to the device node is also added/removed. All software and scripts should access the device through the symbolic link and present this as the name of the device. The location and name of the underlying device node may depend on the distribution, configuration (e.g. udev), or release version. **ay** specifies autoactivation, in which case an LV is activated only if it matches an item in lvm.conf activation/auto_activation_volume_list. If the list is not set, all LVs are considered to match, and if the list is set but empty, no LVs match. Autoactivation should be used during system boot to make it possible to select which LVs should be automatically activated by the system. See **lvmlockd(8)** for more information about activation options **ey** and **sy** for shared VGs.

--activationmode partial|degraded|complete

Determines if LV activation is allowed when PVs are missing, e.g. because of a device failure. **complete** only allows LVs with no missing PVs to be activated, and is the most restrictive mode. **degraded** allows RAID LVs with missing PVs to be activated. (This does not include the "mirror" type, see "raid1" instead.) **partial** allows any LV with missing PVs to be activated, and should only be used for recovery or repair. For default, see lvm.conf/activation_mode. See **lvmraid(7)** for more information.

--addtag Tag

Adds a tag to a PV, VG or LV. This option can be repeated to add multiple tags at once. See **lvm(8)** for information about tags.

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the

same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--cachemode writethrough|writeback|passthrough

Specifies when writes to a cache LV should be considered complete. **writeback** considers a write complete as soon as it is stored in the cache pool. **writethrough** considers a write complete only when it has been stored in both the cache pool and on the origin LV. While writethrough may be slower for writes, it is more resilient if something should happen to a device associated with the cache pool LV. With **passthrough**, all reads are served from the origin LV (all reads miss the cache) and all writes are forwarded to the origin LV; additionally, write hits cause cache block invalidates. See **lvmcache(7)** for more information.

--cachepolicy String

Specifies the cache policy for a cache LV. See **lvmcache(7)** for more information.

--cachesettings String

Specifies tunable values for a cache LV in "Key = Value" form. Repeat this option to specify multiple values. (The default values should usually be adequate.) The special string value **default** switches settings back to their default kernel values and removes them from the list of settings stored in LVM metadata. See **lvmcache(7)** for more information.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--compression y|n

Controls whether compression is enabled or disable for VDO volume. See **lvmvdo(7)** for more information about VDO usage.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-C|--contiguous y|n

Sets or resets the contiguous allocation policy for LVs. Default is no contiguous allocation based on a next free principle. It is only possible to change a non-contiguous allocation policy to contiguous if all of the allocated physical extents in the LV are already contiguous.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--deduplication y|n

Controls whether deduplication is enabled or disable for VDO volume. See **lvmvdo(7)** for more information about VDO usage.

--deltag Tag

Deletes a tag from a PV, VG or LV. This option can be repeated to delete multiple tags at once. See **lvm(8)** for information about tags.

--detachprofile

Detaches a metadata profile from a VG or LV. See **lvm.conf(5)** for more information about profiles.

--discards passdown|nopassdown|ignore

Specifies how the device-mapper thin pool layer in the kernel should handle discards. **ignore** causes the thin pool to ignore discards. **nopassdown** causes the thin pool to process discards itself to allow reuse of unneeded extents in the thin pool. **passdown** causes the thin pool to process discards itself (like nopassdown) and pass the discards to the underlying device. See **lvmthin(7)** for more information.

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--errorwhenfull y|n

Specifies thin pool behavior when data space is exhausted. When yes, device-mapper will immediately return an error when a thin pool is full and an I/O request requires space. When no, device-mapper will queue these I/O requests for a period of time to allow the thin pool to be extended. Errors are returned if no space is available after the timeout. (Also see dm-thin-pool kernel module option no_space_timeout.) See **lvmthin(7)** for more information.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

-K|--ignoreactivationskip

Ignore the "activation skip" LV flag during activation to allow LVs with the flag set to be activated.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--ignoremonitoring

Do not interact with dmeventd unless --monitor is specified. Do not use this if dmeventd is already monitoring a device.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-j|--major Number

Sets the major number of an LV block device.

--[raid]maxrecoveryrate Size[k|UNIT]

Sets the maximum recovery rate for a RAID LV. The rate value is an amount of data per second for each device in the array. Setting the rate to 0 means it will be unbounded. See **lvmraid(7)** for more information.

--metadataprofile String

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--minor Number

Sets the minor number of an LV block device.

--[raid]minrecoveryrate Size[k|UNIT]

Sets the minimum recovery rate for a RAID LV. The rate value is an amount of data per second for each device in the array. Setting the rate to 0 means it will be unbounded. See **lvmraid(7)** for more information.

--monitor y|n

Start (yes) or stop (no) monitoring an LV with dmeventd. dmeventd monitors kernel events for an LV, and performs automated maintenance for the LV in response to specific events. See **dmeventd(8)** for more information.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

-P|--partial

Commands will do their best to activate LVs with missing PV extents. Missing extents may be replaced with error or zero segments according to the lvm.conf missing_stripe_filler setting. Metadata may not be changed with this option.

-p|--permission rw|r

Set access permission to read only **r** or read and write **rw**.

-M|--persistent y|n

When yes, makes the specified minor number persistent.

--poll y|n

When yes, start the background transformation of an LV. An incomplete transformation, e.g. pv-move or lvconvert interrupted by reboot or crash, can be restarted from the last checkpoint with --poll y. When no, background transformation of an LV will not occur, and the transformation will not complete. It may not be appropriate to immediately poll an LV after activation, in which case --poll n can be used to defer polling until a later --poll y command.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

-r|--readahead auto|none|Number

Sets read ahead sector count of an LV. **auto** is the default which allows the kernel to choose a suitable value automatically. **none** is equivalent to zero.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--rebuild PV

Selects a PV to rebuild in a raid LV. Multiple PVs can be rebuilt by repeating this option. Use this option in place of --resync or --syncaction repair when the PVs with corrupted data are known, and their data should be reconstructed rather than reconstructing default (rotating) data. See **lvm-raid(7)** for more information.

--refresh

If the LV is active, reload its metadata. This is not necessary in normal operation, but may be useful if something has gone wrong, or if some form of manual LV sharing is being used.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--resync

Initiates mirror synchronization. Synchronization generally happens automatically, but this option forces it to run. Also see --rebuild to synchronize a specific PV. During synchronization, data is

read from the primary mirror device and copied to the others. This can take considerable time, during which the LV is without a complete redundant copy of the data. See **lvmraid(7)** for more information.

-S|—select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by **--select help** and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See **--options help** for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

-k|—setactivationskip y|n

Persistently sets (yes) or clears (no) the "activation skip" flag on an LV. An LV with this flag set is not activated unless the **--ignoreactivationskip** option is used by the activation command. This flag is set by default on new thin snapshot LVs. The flag is not applied to deactivation. The current value of the flag is indicated in the lvs lv_attr bits.

--[raid]syncaction check|repair

Initiate different types of RAID synchronization. This causes the RAID LV to read all data and parity blocks in the array and check for discrepancies (mismatches between mirrors or incorrect parity values). **check** will count but not correct discrepancies. **repair** will correct discrepancies. See lvs for reporting discrepancies found or repaired.

--sysinit

Indicates that vgchange/lvchange is being invoked from early system initialisation scripts (e.g. rc.sysinit or an initrd), before writable filesystems are available. As such, some functionality needs to be disabled and this option acts as a shortcut which selects an appropriate set of options. Currently, this is equivalent to using **--ignorelockingfailure**, **--ignoremonitoring**, **--poll n**, and setting env var **LVM_SUPPRESS_LOCKING_FAILURE_MESSAGES**. vgchange/lvchange skip autoactivation, and defer to pvscan autoactivation.

-t|—test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|—verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

--[raid]writebehind Number

The maximum number of outstanding writes that are allowed to devices in a RAID1 LV that is marked write-mostly. Once this value is exceeded, writes become synchronous (i.e. all writes to the constituent devices must complete before the array signals the write has completed). Setting the value to zero clears the preference and allows the system to choose the value arbitrarily.

--[raid]writemostly PV[:t|n|y]

Mark a device in a RAID1 LV as write-mostly. All reads to these drives will be avoided unless absolutely necessary. This keeps the number of I/Os to the drive to a minimum. The default behavior is to set the write-mostly attribute for the specified PV. It is also possible to remove the write-mostly flag by adding the suffix **:n** at the end of the PV name, or to toggle the value with the suffix **:t**. Repeat this option to change the attribute on multiple PVs.

-y|—yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme

caution. (For automatic no, see `-qq`.)

-Z|--zero y|n

Set zeroing mode for thin pool. Note: already provisioned blocks from pool in non-zero mode are not cleared in unwritten parts when setting `--zero y`.

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV. LV followed by `_<type>` indicates that an LV of the given type is required. (raid represents raid<N> type)

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

Select

Select indicates that a required positional parameter can be omitted if the `--select` option is used. No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control `--units`, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Change LV permission to read-only:

lvchange -pr vg00/lvol1

-Z|--zero y|n
```

DESCRIPTION

lvconvert changes the LV type and includes utilities for LV data maintenance. The LV type controls data layout and redundancy. The LV type is also called the segment type or segtype.

To display the current LV type, run the command:

```
lvs -o name,segtype LV
```

In some cases, an LV is a single device mapper (dm) layer above physical devices. In other cases, hidden LVs (dm devices) are layered between the visible LV and physical devices. LVs in the middle layers are called sub LVs. A command run on a visible LV sometimes operates on a sub LV rather than the specified LV. In other cases, a sub LV must be specified directly on the command line.

Sub LVs can be displayed with the command:

```
lvs -a
```

The **linear** type is equivalent to the **striped** type when one stripe exists. In that case, the types can sometimes be used interchangably.

In most cases, the **mirror** type is deprecated and the **raid1** type should be used. They are both implementations of mirroring.

Striped raid types are **raid0/raid0_meta**, **raid5** (an alias for **raid5_ls**), **raid6** (an alias for **raid6_zr**) and **raid10** (an alias for **raid10_near**).

As opposed to mirroring, **raid5** and **raid6** stripe data and calculate parity blocks. The parity blocks can be used for data block recovery in case devices fail. A maximum number of one device in a **raid5** LV may fail, and two in case of **raid6**. Striped raid types typically rotate the parity and data blocks for performance reasons, thus avoiding contention on a single device. Specific arrangements of parity and data blocks (layouts) can be used to optimize I/O performance, or to convert between raid levels. See **lvmraid(7)** for more information.

Layouts of **raid5** rotating parity blocks can be: left-asymmetric (**raid5_la**), left-symmetric (**raid5_ls** with

alias raid5), right-asymmetric (raid5_ra), right-symmetric (raid5_rs) and raid5_n, which doesn't rotate parity blocks. Layouts of raid6 are: zero-restart (raid6_zr with alias raid6), next-restart (raid6_nr), and next-continue (raid6_nc).

Layouts including _n allow for conversion between raid levels (raid5_n to raid6 or raid5_n to striped/raid0/raid0_meta). Additionally, special raid6 layouts for raid level conversions between raid5 and raid6 are: raid6_ls_6, raid6_rs_6, raid6_la_6 and raid6_ra_6. Those correspond to their raid5 counterparts (e.g. raid5_rs can be directly converted to raid6_rs_6 and vice-versa).

raid10 (an alias for raid10_near) is currently limited to one data copy and even number of sub LVs. This is a mirror group layout, thus a single sub LV may fail per mirror group without data loss.

Striped raid types support converting the layout, their stripesize and their number of stripes.

The striped raid types combined with raid1 allow for conversion from linear-> striped/raid0/raid0_meta and vice-versa by e.g. linear <-> raid1 <-> raid5_n (then adding stripes) <-> striped/raid0/raid0_meta.

USAGE

Convert LV to linear.

```
lvconvert --type linear LV
[ COMMON_OPTIONS ]
[ PV ... ]
```

Convert LV to striped.

```
lvconvert --type striped LV
[ -I|--stripesize Size[k|UNIT] ]
[ -R|--regionsize Size[m|UNIT] ]
[ -i|--interval Number ]
[ --stripes Number ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Convert LV to type mirror (also see type raid1),

```
lvconvert --type mirror LV
[ -m|--mirrors [+|-]Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ -R|--regionsize Size[m|UNIT] ]
[ -i|--interval Number ]
[ --stripes Number ]
[ --mirrorlog core|disk ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Convert LV to raid or change raid layout
(a specific raid level must be used, e.g. raid1).

```
lvconvert --type raid LV
[ -m|--mirrors [+|-]Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ -R|--regionsize Size[m|UNIT] ]
[ -i|--interval Number ]
```

```
[ --stripes Number ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Convert LV to raid1 or mirror, or change number of mirror images.

```
lvconvert -m|--mirrors [+|-]Number LV
[ -R|--regionsize Size[m|UNIT] ]
[ -i|--interval Number ]
[ --mirrorlog core|disk ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Convert raid LV to change number of stripe images.

```
lvconvert --stripes Number LV_raid
[ -i|--interval Number ]
[ -R|--regionsize Size[m|UNIT] ]
[ -I|--stripesize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Convert raid LV to change the stripe size.

```
lvconvert -I|--stripesize Size[k|UNIT] LV_raid
[ -i|--interval Number ]
[ -R|--regionsize Size[m|UNIT] ]
[ COMMON_OPTIONS ]
```

Split images from a raid1 or mirror LV and use them to create a new LV.

```
lvconvert --splitmirrors Number -n|--name LV_new LV_cache_mirror_raid1
[ COMMON_OPTIONS ]
[ PV ... ]
```

Split images from a raid1 LV and track changes to origin for later merge.

```
lvconvert --splitmirrors Number --trackchanges LV_cache_raid1
[ COMMON_OPTIONS ]
[ PV ... ]
```

Merge LV images that were split from a raid1 LV.

```
lvconvert --mergemirrors VG|LV_linear_raid|Tag ...
[ COMMON_OPTIONS ]
```

Convert LV to a thin LV, using the original LV as an external origin.

```
lvconvert --type thin --thinpool LV LV_linear_striped_thin_cache_raid
[ -T|--thin ]
[ -r|--readahead auto|none|Number ]
[ -c|--chunksize Size[k|UNIT] ]
```

```
[ -Z|--zero y|n ]
[ --originname LV_new ]
[ --poolmetadata LV ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --metadaprofile String ]
[ COMMON_OPTIONS ]
```

Attach a cache pool to an LV, converts the LV to type cache.

```
lvconvert --type cache --cachepool LV LV_linear_stripped_thinpool_vdo_vdopool_vdopooldata_raid
[ -H|--cache ]
[ -Z|--zero y|n ]
[ -r|--readahead auto|none|Number ]
[ -c|--chunksize Size[k|UNIT] ]
[ --cachemetadataformat auto|1|2 ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --poolmetadata LV ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --metadaprofile String ]
[ COMMON_OPTIONS ]
```

Attach a writecache to an LV, converts the LV to type writecache.

```
lvconvert --type writecache --cachevol LV LV_linear_stripped_raid
[ --cachesettings String ]
[ COMMON_OPTIONS ]
```

Attach a cache to an LV, converts the LV to type cache.

```
lvconvert --type cache --cachevol LV LV_linear_stripped_thinpool_raid
[ -H|--cache ]
[ -Z|--zero y|n ]
[ -c|--chunksize Size[k|UNIT] ]
[ --cachemetadataformat auto|1|2 ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --poolmetadatasize Size[m|UNIT] ]
[ COMMON_OPTIONS ]
```

Add a writecache to an LV, using a specified cache device.

```
lvconvert --type writecache --cachedevice PV LV_linear_stripped_raid
[ --cachesize Size[m|UNIT] ]
[ --cachesettings String ]
[ COMMON_OPTIONS ]
```

Add a cache to an LV, using a specified cache device.

```
lvconvert --type cache --cachedevice PV LV_linear_striped_thinpool_raid
[ -c|--chunksize Size[k|UNIT] ]
[ --cachesize Size[m|UNIT] ]
[ --cachesettings String ]
[ COMMON_OPTIONS ]
```

Convert LV to type thin-pool.

```
lvconvert --type thin-pool LV_linear_striped_cache_raid
[ -I|--stripesize Size[k|UNIT] ]
[ -r|--readahead auto|none|Number ]
[ -c|--chunksize Size[k|UNIT] ]
[ -Z|--zero y|n ]

Common options for command:

- [**-b|--background**]
- [**-f|--force**]
- [**--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit**]
- [**--noudevsync**]

Common options for lvm:

- [**-d|--debug**]
- [**-h|--help**]
- [**-q|--quiet**]
- [**-t|--test**]
- [**-v|--verbose**]
- [**-y|--yes**]
- [**--commandprofile String**]
- [**--config String**]
- [**--driverloaded y|n**]
- [**--lockopt String**]
- [**--longhelp**]
- [**--nolocking**]
- [**--profile String**]
- [**--version**]

OPTIONS

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-b|--background

If the operation requires polling, this option causes the command to return before the operation is complete, and polling is done in the background.

-H|--cache

Specifies the command is handling a cache LV or cache pool. See **--type cache** and **--type cache-pool**. See **lvmcache(7)** for more information about LVM caching.

--cachedevice PV

The name of a device to use for a cache.

--cachemetadataformat auto|1|2

Specifies the cache metadata format used by cache target.

--cachemode writethrough|writeback|passthrough

Specifies when writes to a cache LV should be considered complete. **writeback** considers a write complete as soon as it is stored in the cache pool. **writethrough** considers a write complete only when it has been stored in both the cache pool and on the origin LV. While writethrough may be slower for writes, it is more resilient if something should happen to a device associated with the cache pool LV. With **passthrough**, all reads are served from the origin LV (all reads miss the cache) and all writes are forwarded to the origin LV; additionally, write hits cause cache block invalidates. See **lvmcache(7)** for more information.

--cachepolicy String

Specifies the cache policy for a cache LV. See **lvmcache(7)** for more information.

--cachepool *LV*

The name of a cache pool.

--cachesettings *String*

Specifies tunable values for a cache LV in "Key = Value" form. Repeat this option to specify multiple values. (The default values should usually be adequate.) The special string value **default** switches settings back to their default kernel values and removes them from the list of settings stored in LVM metadata. See **lvmcache(7)** for more information.

--cachesize *Size[m|UNIT]*

The size of cache to use.

--cachevol *LV*

The name of a cache volume.

-c|--chunksizes *Size[k|UNIT]*

The size of chunks in a snapshot, cache pool or thin pool. For snapshots, the value must be a power of 2 between 4KiB and 512KiB and the default value is 4. For a cache pool the value must be between 32KiB and 1GiB and the default value is 64. For a thin pool the value must be between 64KiB and 1GiB and the default value starts with 64 and scales up to fit the pool metadata size within 128MiB, if the pool metadata size is not specified. The value must be a multiple of 64KiB. See **lvmthin(7)** and **lvmcache(7)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--compression *y|n*

Controls whether compression is enabled or disable for VDO volume. See **lvmvdo(7)** for more information about VDO usage.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--deduplication *y|n*

Controls whether deduplication is enabled or disable for VDO volume. See **lvmvdo(7)** for more information about VDO usage.

--discards *passdown|nopassdown|ignore*

Specifies how the device-mapper thin pool layer in the kernel should handle discards. **ignore** causes the thin pool to ignore discards. **nopassdown** causes the thin pool to process discards itself to allow reuse of unneeded extents in the thin pool. **passdown** causes the thin pool to process discards itself (like nopassdown) and pass the discards to the underlying device. See **lvmthin(7)** for more information.

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

-i|--interval *Number*

Report progress at regular intervals.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--merge

An alias for --mergethin, --mergemirrors, or --mergesnapshot, depending on the type of LV.

--mergemirrors

Merge LV images that were split from a raid1 LV. See --splitmirrors with --trackchanges.

--mergesnapshot

Merge COW snapshot LV into its origin. When merging a snapshot, if both the origin and snapshot LVs are not open, the merge will start immediately. Otherwise, the merge will start the first time either the origin or snapshot LV are activated and both are closed. Merging a snapshot into an origin that cannot be closed, for example a root filesystem, is deferred until the next time the origin volume is activated. When merging starts, the resulting LV will have the origin's name, minor number and UUID. While the merge is in progress, reads or writes to the origin appear as being directed to the snapshot being merged. When the merge finishes, the merged snapshot is removed. Multiple snapshots may be specified on the command line or a @tag may be used to specify multiple snapshots be merged to their respective origin.

--mergethin

Merge thin LV into its origin LV. The origin thin LV takes the content of the thin snapshot, and the thin snapshot LV is removed. See **lvmthin(7)** for more information.

--metadataprofile *String*

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--mirrorlog *core|disk*

Specifies the type of mirror log for LVs with the "mirror" type (does not apply to the "raid1" type.) **disk** is a persistent log and requires a small amount of storage space, usually on a separate device from the data being mirrored. **core** is not persistent; the log is kept only in memory. In this case, the mirror must be synchronized (by copying LV data from the first device to others) each time the LV is activated, e.g. after reboot. **mirrored** is a persistent log that is itself mirrored, but should be avoided. Instead, use the raid1 type for log redundancy.

-m|--mirrors [+|-]Number

Specifies the number of mirror images in addition to the original LV image, e.g. --mirrors 1 means there are two images of the data, the original and one mirror image. Optional positional PV args on the command line can specify the devices the images should be placed on. There are two mirroring implementations: "raid1" and "mirror". These are the names of the corresponding LV types, or "segment types". Use the --type option to specify which to use (raid1 is default, and mirror is legacy) Use lvm.conf global/mirror_segtpe_default and global/raid10_segtpe_default to configure the default types. The plus prefix + can be used, in which case the number is added to the current number of images, or the minus prefix - can be used, in which case the number is subtracted from the current number of images. See **lvmraid(7)** for more information.

-n|--name *String*

Specifies the name of a new LV. When unspecified, a default name of "lvol#" is generated, where # is a number generated by LVM.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--originname *LV*

Specifies the name to use for the external origin LV when converting an LV to a thin LV. The LV being converted becomes a read-only external origin with this name.

--poolmetadata *LV*

The name of a an LV to use for storing pool metadata.

--poolmetadatasize *Size[m|UNIT]*

Specifies the size of the new pool metadata LV.

--poolmetadataspare *y|n*

Enable or disable the automatic creation and management of a spare pool metadata LV in the VG. A spare metadata LV is reserved space that can be used when repairing a pool.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--raidintegrity *y|n*

Enable or disable data integrity checksums for raid images.

--raidintegrityblocksize *Number*

The block size to use for dm-integrity on raid images. The integrity block size should usually match the device logical block size, or the file system block size. It may be less than the file system block size, but not less than the device logical block size. Possible values: 512, 1024, 2048, 4096.

--raidintegritymode *String*

Use a journal (default) or bitmap for keeping integrity checksums consistent in case of a crash. The bitmap areas are recalculated after a crash, so corruption in those areas would not be detected. A journal does not have this problem. The journal mode doubles writes to storage, but can improve performance for scattered writes packed into a single journal write. bitmap mode can in theory achieve full write throughput of the device, but would not benefit from the potential scattered write optimization.

-r|--readahead *auto|none|Number*

Sets read ahead sector count of an LV. **auto** is the default which allows the kernel to choose a suitable value automatically. **none** is equivalent to zero.

-R|--regionsize *Size[m|UNIT]*

Size of each raid or mirror synchronization region. lvm.conf activation/raid_region_size can be used to configure a default.

--repair

Replace failed PVs in a raid or mirror LV, or run a repair utility on a thin pool. See **lvmraid(7)** and **lvmthin(7)** for more information.

--replace *PV*

Replace a specific PV in a raid LV with another PV. The new PV to use can be optionally specified after the LV. Multiple PVs can be replaced by repeating this option. See **lvmraid(7)** for more information.

-s|--snapshot

Combine a former COW snapshot LV with a former origin LV to reverse a previous --splitsnapshot command.

--splitcache

Separates a cache pool from a cache LV, and keeps the unused cache pool LV. Before the separation, the cache is flushed. Also see --uncache.

--splitmirrors *Number*

Splits the specified number of images from a raid1 or mirror LV and uses them to create a new LV. If --trackchanges is also specified, changes to the raid1 LV are tracked while the split LV remains detached. If --name is specified, then the images are permanently split from the original LV and changes are not tracked.

--splitsnapshot

Separates a COW snapshot from its origin LV. The LV that is split off contains the chunks that differ from the origin LV along with metadata describing them. This LV can be wiped and then destroyed with lvremove.

--startpoll

Start polling an LV to continue processing a conversion.

--stripes *Number*

Specifies the number of stripes in a striped LV. This is the number of PVs (devices) that a striped LV is spread across. Data that appears sequential in the LV is spread across multiple devices in units of the stripe size (see --stripesize). This does not apply to existing allocated space, only newly allocated space can be striped.

-I|--stripesize *Size[k|UNIT]*

The amount of data that is written to one device before moving to the next in a striped LV.

--swapmetadata

Extracts the metadata LV from a pool and replaces it with another specified LV. The extracted LV is preserved and given the name of the LV that replaced it. Use for repair only. When the metadata LV is swapped out of the pool, it can be activated directly and used with thin provisioning tools: **cache_dump(8)**, **cache_repair(8)**, **cache_restore(8)**, **thin_dump(8)**, **thin_repair(8)**, **thin_restore(8)**.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-T|--thin

Specifies the command is handling a thin LV or thin pool. See --type thin, --type thin-pool, and --virtualsize. See **lvmthin(7)** for more information about LVM thin provisioning.

--thinpool *LV*

The name of a thin pool LV.

--trackchanges

Can be used with --splitmirrors on a raid1 LV. This causes changes to the original raid1 LV to be tracked while the split images remain detached. This is a temporary state that allows the read-only detached image to be merged efficiently back into the raid1 LV later. Only the regions with changed data are resynchronized during merge. While a raid1 LV is tracking changes, operations on it are limited to merging the split image (see --mergemirrors) or permanently splitting the image (see --splitmirrors with --name).

--type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool

The LV type, also known as "segment type" or "segtype". See usage descriptions for the specific ways to use these types. For more information about redundancy and performance (**raid<N>**, **mirror**, **striped**, **linear**) see **lvmraid(7)**. For thin provisioning (**thin**, **thin-pool**) see **lvmthin(7)**. For performance caching (**cache**, **cache-pool**) see **lvmcache(7)**. For copy-on-write snapshots (**snapshot**) see usage definitions. For VDO (**vdo**) see **lvmvdo(7)**. Several commands omit an explicit type option because the type is inferred from other options or shortcuts (e.g. --stripes, --mirrors, --snapshot, --virtualsize, --thin, --cache, --vdo). Use inferred types with care because it can lead to unexpected results.

--uncache

Separates a cache pool from a cache LV, and deletes the unused cache pool LV. Before the separation, the cache is flushed. Also see **--splitcache**.

--usepolicies

Perform an operation according to the policy configured in lvm.conf or a profile.

--vdopool LV

The name of a VDO pool LV. See **lvmvdo(7)** for more information about VDO usage.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-V|--virtualsize Size[m|UNIT]

The virtual size of a new thin LV. See **lvmthin(7)** for more information about LVM thin provisioning. Using virtual size (-V) and actual size (-L) together creates a sparse LV. lvm.conf global/sparse_sectype_default determines the default segment type used to create a sparse LV. Anything written to a sparse LV will be returned when reading from it. Reading from other areas of the LV will return blocks of zeros. When using a snapshot to create a sparse LV, a hidden virtual device is created using the zero target, and the LV has the suffix _vorigin. Snapshots are less efficient than thin provisioning when creating large sparse LVs (GiB).

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

-Z|--zero y|n

For snapshots, this controls zeroing of the first 4KiB of data in the snapshot. If the LV is read-only, the snapshot will not be zeroed. For thin pools, this controls zeroing of provisioned blocks. Provisioning of large zeroed chunks negatively impacts performance.

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV. LV followed by _<type> indicates that an LV of the given type is required. (raid represents raid<N> type)

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is

TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

ADVANCED USAGE

Alternate command forms, advanced command usage, and listing of all valid syntax for completeness.

Change the region size of an LV.

```
lvconvert -R|--regionsize Size[m|UNIT] LV_raid
[COMMON_OPTIONS]
```

Change the type of mirror log used by a mirror LV.

```
lvconvert --mirrorlog core|disk LV_mirror
[COMMON_OPTIONS]
[PV ...]
```

Convert LV to a thin LV, using the original LV as an external origin (infers --type thin).

```
lvconvert -T|--thin --thinpool LV LV_linear_striped_thin_cache_raid
[-r|--readahead auto|none|Number]
[-c|--chunksize Size[k|UNIT]]
[-Z|--zero y|n]
[--type thin]
[--originname LV_new]
[--poolmetadata LV]
[--poolmetadatasize Size[m|UNIT]]
[--poolmetadataspare y|n]
[--metadataprofile String]
[COMMON_OPTIONS]
```

Attach a cache pool to an LV (infers --type cache).

```
lvconvert -H|--cache --cachepool LV LV_linear_striped_thinpool_vdo_vdopool_vdopooldata_raid
[-Z|--zero y|n]
[-r|--readahead auto|none|Number]
[-c|--chunksize Size[k|UNIT]]
[--type cache]
[--cachemetadataformat auto|1|2]
[--cachemode writethrough|writeback|passthrough]
[--cachepolicy String]
[--cachesettings String]
[--poolmetadata LV]
[--poolmetadatasize Size[m|UNIT]]
[--poolmetadataspare y|n]
[--metadataprofile String]
[COMMON_OPTIONS]
```

Attach a cache to an LV, converts the LV to type cache.

```
lvconvert -H|--cache --cachevol LV LV_linear_stripped_thinpool_raid
[ -Z|--zero y|n ]
[ -c|--chunksize Size[k|UNIT] ]
[ --cachemetadataformat auto|1|2 ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --poolmetadatasize Size[m|UNIT] ]
[ COMMON_OPTIONS ]
```

Convert LV to type vdopool.

```
lvconvert --vdopool LV_linear_stripped_cache_raid
[ -n|--name LV_new ]
[ -V|--virtualsize Size[m|UNIT] ]
[ --type vdo-pool ]
[ --compression y|n ]
[ --deduplication y|n ]
[ COMMON_OPTIONS ]
```

Detach and delete a cache from an LV.

```
lvconvert --uncache LV_thinpool_cache_vdopool_writecache
[ --cachesettings String ]
[ COMMON_OPTIONS ]
```

Swap metadata LV in a thin pool or cache pool (for repair only).

```
lvconvert --swapmetadata --poolmetadata LV LV_thinpool_cachepool
[ -c|--chunksize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
```

Merge LV that was split from a mirror (variant, use **--mergemirrors**).

Merge thin LV into its origin LV (variant, use **--mergethin**).

Merge COW snapshot LV into its origin (variant, use **--mergesnapshot**).

```
lvconvert --merge VG|LV_linear_striped_snapshot_thin_raid|Tag ...
[ -i|--interval Number ]
[ COMMON_OPTIONS ]
```

Separate a COW snapshot from its origin LV.

```
lvconvert --splitsnapshot LV_snapshot
[ COMMON_OPTIONS ]
```

Combine a former COW snapshot (second arg) with a former origin LV (first arg) to reverse a splitsnapshot command.

```
lvconvert -s|--snapshot LV LV_linear_striped
[ -c|--chunksize Size[k|UNIT] ]
[ -Z|--zero y|n ]
[ --type snapshot ]
```

[COMMON_OPTIONS]

Poll LV to continue conversion (also see **--startpoll**)
or waits till conversion/mirror syncing is finished

lvconvert *LV_mirror_raid*
[COMMON_OPTIONS]

NOTES

This previous command syntax would perform two different operations:

lvconvert --thinpool *LV1* **--poolmetadata** *LV2*

If *LV1* was not a thin pool, the command would convert *LV1* to a thin pool, optionally using a specified LV for metadata. But, if *LV1* was already a thin pool, the command would swap the current metadata LV with *LV2* (for repair purposes.)

In the same way, this previous command syntax would perform two different operations:

lvconvert --cachepool *LV1* **--poolmetadata** *LV2*

If *LV1* was not a cache pool, the command would convert *LV1* to a cache pool, optionally using a specified LV for metadata. But, if *LV1* was already a cache pool, the command would swap the current metadata LV with *LV2* (for repair purposes.)

EXAMPLES

Convert a linear LV to a two-way mirror LV.

lvconvert --type mirror --mirrors 1 *vg/lvol1*

Convert a linear LV to a two-way RAID1 LV.

lvconvert --type raid1 --mirrors 1 *vg/lvol1*

Convert a mirror LV to use an in-memory log.

lvconvert --mirrorlog core *vg/lvol1*

Convert a mirror LV to use a disk log.

lvconvert --mirrorlog disk *vg/lvol1*

Convert a mirror or raid1 LV to a linear LV.

lvconvert --type linear *vg/lvol1*

Convert a mirror LV to a raid1 LV with the same number of images.

lvconvert --type raid1 *vg/lvol1*

Convert a linear LV to a two-way mirror LV, allocating new extents from specific PV ranges.

lvconvert --mirrors 1 *vg/lvol1 /dev/sda:0-15 /dev/sdb:0-15*

Convert a mirror LV to a linear LV, freeing physical extents from a specific PV.

lvconvert --type linear *vg/lvol1 /dev/sda*

Split one image from a mirror or raid1 LV, making it a new LV.

lvconvert --splitmirrors 1 --name *lv_split* *vg/lvol1*

Split one image from a raid1 LV, and track changes made to the raid1 LV while the split image remains detached.

lvconvert --splitmirrors 1 --trackchanges *vg/lvol1*

Merge an image (that was previously created with --splitmirrors and --trackchanges) back into the original raid1 LV.

lvconvert --mergemirrors vg/lvol1_rimage_1

Replace PV /dev/sdb1 with PV /dev/sdf1 in a raid1/4/5/6/10 LV.

lvconvert --replace /dev/sdb1 vg/lvol1 /dev/sdf1

Replace 3 PVs /dev/sd[b-d]1 with PVs /dev/sd[f-h]1 in a raid1 LV.

**lvconvert --replace /dev/sdb1 --replace /dev/sdc1 --replace /dev/sdd1
vg/lvol1 /dev/sd[fgh]1**

Replace the maximum of 2 PVs /dev/sd[bc]1 with PVs /dev/sd[gh]1 in a raid6 LV.

lvconvert --replace /dev/sdb1 --replace /dev/sdc1 vg/lvol1 /dev/sd[gh]1

Convert an LV into a thin LV in the specified thin pool. The existing LV is used as an external read-only origin for the new thin LV.

lvconvert --type thin --thinpool vg/tpool1 vg/lvol1

Convert an LV into a thin LV in the specified thin pool. The existing LV is used as an external read-only origin for the new thin LV, and is renamed "external".

**lvconvert --type thin --thinpool vg/tpool1
--originname external vg/lvol1**

Convert an LV to a cache pool LV using another specified LV for cache pool metadata.

lvconvert --type cache-pool --poolmetadata vg/poolmeta1 vg/lvol1

Convert an LV to a cache LV using the specified cache pool and chunk size.

lvconvert --type cache --cachepool vg/cpool1 -c 128 vg/lvol1

Detach and keep the cache pool from a cache LV.

lvconvert --splitcache vg/lvol1

Detach and remove the cache pool from a cache LV.

lvconvert --uncache vg/lvol1

```

DESCRIPTION

lvcreate creates a new LV in a VG. For standard LVs, this requires allocating logical extents from the VG's free physical extents. If there is not enough free space, the VG can be extended with other PVs (**vgextend**(8)), or existing LVs can be reduced or removed (**lvremove**(8), **lvreduce**(8).)

To control which PVs a new LV will use, specify one or more PVs as position args at the end of the command line. **lvcreate** will allocate physical extents only from the specified PVs.

lvcreate can also create snapshots of existing LVs, e.g. for backup purposes. The data in a new snapshot LV represents the content of the original LV from the time the snapshot was created.

RAID LVs can be created by specifying an LV type when creating the LV (see **lvmraid**(7)). Different RAID levels require different numbers of unique PVs be available in the VG for allocation.

Thin pools (for thin provisioning) and cache pools (for caching) are represented by special LVs with types `thin-pool` and `cache-pool` (see **lvmthin**(7) and **lvmcache**(7)). The pool LVs are not usable as standard block devices, but the LV names act as references to the pools.

Thin LVs are thinly provisioned from a thin pool, and are created with a virtual size rather than a physical size. A cache LV is the combination of a standard LV with a cache pool, used to cache active portions of the LV to improve performance.

VDO LVs are also provisioned volumes from a VDO pool, and are created with a virtual size rather than a physical size (see **lvmvdo**(7)).

Usage notes

In the usage section below, `--size Size` can be replaced with `--extents Number`. See descriptions in the options section.

In the usage section below, `--name` is omitted from the required options, even though it is typically used. When the name is not specified, a new LV name is generated with the "lvol" prefix and a unique numeric suffix.

In the usage section below, when creating a pool and the name is omitted the new LV pool name is generated with the "vpool" for vdo-pools for prefix and a unique numeric suffix.

Pool name can be specified together with VG name i.e.: vg00/mythinpool.

USAGE

Create a linear LV.

```
lvcreate -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ --type linear ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a striped LV (infers --type striped).

```
lvcreate -i|--stripes Number -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -I|--stripesize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a raid1 or mirror LV (infers --type raid1|mirror).

```
lvcreate -m|--mirrors Number -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -R|--regionsize Size[m|UNIT] ]
[ --mirrorlog core|disk ]
[ --[raid]minrecoveryrate Size[k|UNIT] ]
[ --[raid]maxrecoveryrate Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a raid LV (a specific raid level must be used, e.g. raid1).

```
lvcreate --type raid -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -m|--mirrors Number ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ -R|--regionsize Size[m|UNIT] ]
[ --[raid]minrecoveryrate Size[k|UNIT] ]
[ --[raid]maxrecoveryrate Size[k|UNIT] ]
[ --raidintegrity y|n ]
[ --raidintegritymode String ]
[ --raidintegrityblocksize Number ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a raid10 LV.

```
lvcreate -m|--mirrors Number -i|--stripes Number
-L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
```

```
[ -I|--stripesize Size[k|UNIT] ]
[ -R|--regionsize Size[m|UNIT] ]
[ --[raid]minrecoverrate Size[k|UNIT] ]
[ --[raid]maxrecoverrate Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a COW snapshot LV of an origin LV.

```
lvcreate -s|--snapshot -L|--size Size[m|UNIT] LV
[ -l|--extents Number[PERCENT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ -c|--chunksize Size[k|UNIT] ]
[ --type snapshot ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin pool.

```
lvcreate --type thin-pool -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --thinpool LV_new ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a cache pool.

```
lvcreate --type cache-pool -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -H|--cache ]
[ -c|--chunksize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --cachemetadataformat auto|1|2 ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV in a thin pool (infers --type thin).

```
lvcreate -V|--virtualsize Size[m|UNIT] --thinpool LV_thinpool VG
[ -T|--thin ]
[ --type thin ]
```

```
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
```

Create a thin LV that is a snapshot of an existing thin LV
(infers --type thin).

```
lvcreate -s|--snapshot LV_thin
[ --type thin ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
```

Create a thin LV that is a snapshot of an external origin LV.

```
lvcreate --type thin --thinpool LV_thinpool LV
[ -T|--thin ]
[ -c|--chunksize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
```

Create a LV that returns VDO when used.

```
lvcreate --type vdo -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -V|--virtualsize Size[m|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --vdo ]
[ --vdopool LV_new ]
[ --compression y|n ]
[ --deduplication y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV, first creating a thin pool for it,
where the new thin pool is named by the --thinpool arg.

```
lvcreate --type thin -V|--virtualsize Size[m|UNIT]
--thinpool LV_new
[ -L|--size Size[m|UNIT] --thinpool LV_new
[ -l|--extents Number[PERCENT] ]
[ -T|--thin ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
```

[*PV ...*]

Create a new LV, then attach the specified cachepool which converts the new LV to type cache.

```
lvcreate --type cache -L|--size Size[m|UNIT]
    --cachepool LV_cachepool VG
    [ -l|--extents Number[PERCENT] ]
    [ -H|--cache ]
    [ -c|--chunksize Size[k|UNIT] ]
    [ -i|--stripes Number ]
    [ -I|--stripesize Size[k|UNIT] ]
    [ --poolmetadatasize Size[m|UNIT] ]
    [ --poolmetadataspare y|n ]
    [ --cachemode writethrough|writeback|passthrough ]
    [ --cachepolicy String ]
    [ --cachesettings String ]
    [ --cachemetadataformat auto|1|2 ]
    [ COMMON_OPTIONS ]
    [ PV ... ]
```

Create a new LV, then attach the specified cachevol which converts the new LV to type cache.

```
lvcreate --type cache -L|--size Size[m|UNIT]
    --cachevol LV VG
    [ -l|--extents Number[PERCENT] ]
    [ -c|--chunksize Size[k|UNIT] ]
    [ -i|--stripes Number ]
    [ -I|--stripesize Size[k|UNIT] ]
    [ --cachemode writethrough|writeback|passthrough ]
    [ --cachepolicy String ]
    [ --cachesettings String ]
    [ --cachemetadataformat auto|1|2 ]
    [ COMMON_OPTIONS ]
    [ PV ... ]
```

Create a new LV, then attach a cachevol created from the specified cache device, which converts the new LV to type cache.

```
lvcreate --type cache -L|--size Size[m|UNIT]
    --cachedevice PV VG
    [ -l|--extents Number[PERCENT] ]
    [ -c|--chunksize Size[k|UNIT] ]
    [ -i|--stripes Number ]
    [ -I|--stripesize Size[k|UNIT] ]
    [ --cachemode writethrough|writeback|passthrough ]
    [ --cachepolicy String ]
    [ --cachesettings String ]
    [ --cachemetadataformat auto|1|2 ]
    [ --cachesize Size[m|UNIT] ]
    [ COMMON_OPTIONS ]
```

[*PV ...*]

Create a new LV, then attach the specified cachevol which converts the new LV to type writecache.

```
lvcREATE --type writecache -L|--size Size[m|UNIT]
    --cachevol LV VG
    [ -l|--extents Number[PERCENT] ]
    [ -i|--stripes Number ]
    [ -I|--stripesize Size[k|UNIT] ]
    [ --cachesettings String ]
    [ COMMON_OPTIONS ]
    [ PV ... ]
```

Create a new LV, then attach a cachevol created from the specified cache device, which converts the new LV to type writecache.

```
lvcREATE --type writecache -L|--size Size[m|UNIT]
    --cachedevice PV VG
    [ -l|--extents Number[PERCENT] ]
    [ -i|--stripes Number ]
    [ -I|--stripesize Size[k|UNIT] ]
    [ --cachesize Size[m|UNIT] ]
    [ --cachesettings String ]
    [ COMMON_OPTIONS ]
    [ PV ... ]
```

Common options for command:

- [-a|--activate *y|n|ay*]
- [-A|--autobackup *y|n*]
- [-C|--contiguous *y|n*]
- [-K|--ignoreactivationskip]
- [-j|--major *Number*]
- [-n|--name *String*]
- [-p|--permission *rw|r*]
- [-M|--persistent *y|n*]
- [-r|--readahead *auto|none|Number*]
- [-k|--setactivationskip *y|n*]
- [-W|--wipesignatures *y|n*]
- [-Z|--zero *y|n*]
- [--addtag *Tag*]
- [--alloc *contiguous|cling|cling_by_tags|normal|anywhere|inherit*]
- [--ignoremonitoring]
- [--metadataprofile *String*]
- [--minor *Number*]
- [--monitor *y|n*]
- [--nosync]
- [--noudevsync]
- [--reportformat *basic|json*]

Common options for lvm:

- [-d|--debug]

```
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-a|--activate y|n|ay

Controls the active state of the new LV. **y** makes the LV active, or available. New LVs are made active by default. **n** makes the LV inactive, or unavailable, only when possible. In some cases, creating an LV requires it to be active. For example, COW snapshots of an active origin LV can only be created in the active state (this does not apply to thin snapshots). The **--zero** option normally requires the LV to be active. If autoactivation **ay** is used, the LV is only activated if it matches an item in lvm.conf activation/auto_activation_volume_list. **ay** implies **--zero n** and **--wipesignatures n**. See **lvmlockd(8)** for more information about activation options for shared VGs.

--addtag Tag

Adds a tag to a PV, VG or LV. This option can be repeated to add multiple tags at once. See **lvm(8)** for information about tags.

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

-H|--cache

Specifies the command is handling a cache LV or cache pool. See **--type cache** and **--type cache-pool**. See **lvmcache(7)** for more information about LVM caching.

--cachedevice PV

The name of a device to use for a cache.

--cachemetadataformat auto|1|2

Specifies the cache metadata format used by cache target.

--cachemode writethrough|writeback|passthrough

Specifies when writes to a cache LV should be considered complete. **writeback** considers a write complete as soon as it is stored in the cache pool. **writethrough** considers a write complete only when it has been stored in both the cache pool and on the origin LV. While writethrough may be slower for writes, it is more resilient if something should happen to a device associated with the

cache pool LV. With **passthrough**, all reads are served from the origin LV (all reads miss the cache) and all writes are forwarded to the origin LV; additionally, write hits cause cache block invalidates. See **lvmcache(7)** for more information.

--cachepolicy *String*

Specifies the cache policy for a cache LV. See **lvmcache(7)** for more information.

--cachepool *LV*

The name of a cache pool.

--cachesettings *String*

Specifies tunable values for a cache LV in "Key = Value" form. Repeat this option to specify multiple values. (The default values should usually be adequate.) The special string value **default** switches settings back to their default kernel values and removes them from the list of settings stored in LVM metadata. See **lvmcache(7)** for more information.

--cachesize *Size[m|UNIT]*

The size of cache to use.

--cachevol *LV*

The name of a cache volume.

-c|--chunksize *Size[k|UNIT]*

The size of chunks in a snapshot, cache pool or thin pool. For snapshots, the value must be a power of 2 between 4KiB and 512KiB and the default value is 4. For a cache pool the value must be between 32KiB and 1GiB and the default value is 64. For a thin pool the value must be between 64KiB and 1GiB and the default value starts with 64 and scales up to fit the pool metadata size within 128MiB, if the pool metadata size is not specified. The value must be a multiple of 64KiB. See **lvmthin(7)** and **lvmcache(7)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--compression *y|n*

Controls whether compression is enabled or disable for VDO volume. See **lvmvdo(7)** for more information about VDO usage.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-C|--contiguous *y|n*

Sets or resets the contiguous allocation policy for LVs. Default is no contiguous allocation based on a next free principle. It is only possible to change a non-contiguous allocation policy to contiguous if all of the allocated physical extents in the LV are already contiguous.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--deduplication *y|n*

Controls whether deduplication is enabled or disable for VDO volume. See **lvmvdo(7)** for more information about VDO usage.

--discards *passdown|nopassdown|ignore*

Specifies how the device-mapper thin pool layer in the kernel should handle discards. **ignore** causes the thin pool to ignore discards. **nopassdown** causes the thin pool to process discards itself to allow reuse of unneeded extents in the thin pool. **passdown** causes the thin pool to process discards itself (like nopassdown) and pass the discards to the underlying device. See **lvmthin(7)** for more information.

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--errorwhenfull y|n

Specifies thin pool behavior when data space is exhausted. When yes, device-mapper will immediately return an error when a thin pool is full and an I/O request requires space. When no, device-mapper will queue these I/O requests for a period of time to allow the thin pool to be extended. Errors are returned if no space is available after the timeout. (Also see dm-thin-pool kernel module option no_space_timeout.) See **lvmthin(7)** for more information.

-I|--extents Number[PERCENT]

Specifies the size of the new LV in logical extents. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. An alternate syntax allows the size to be determined indirectly as a percentage of the size of a related VG, LV, or set of PVs. The suffix **%VG** denotes the total size of the VG, the suffix **%FREE** the remaining free space in the VG, and the suffix **%PVS** the free space in the specified PVs. For a snapshot, the size can be expressed as a percentage of the total size of the origin LV with the suffix **%ORIGIN** (**100%ORIGIN** provides space for the whole origin). When expressed as a percentage, the size defines an upper limit for the number of logical extents in the new LV. The precise number of logical extents in the new LV is not determined until the command has completed.

-h|--help

Display help text.

-K|--ignoreactivationskip

Ignore the "activation skip" LV flag during activation to allow LVs with the flag set to be activated.

--ignoremonitoring

Do not interact with dmeventd unless --monitor is specified. Do not use this if dmeventd is already monitoring a device.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-j|--major Number

Sets the major number of an LV block device.

--[raid]maxrecoveryrate Size[k|UNIT]

Sets the maximum recovery rate for a RAID LV. The rate value is an amount of data per second for each device in the array. Setting the rate to 0 means it will be unbounded. See **lvmraid(7)** for more information.

--metadataprofile String

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--minor Number

Sets the minor number of an LV block device.

--[raid]minrecoveryrate Size[k|UNIT]

Sets the minimum recovery rate for a RAID LV. The rate value is an amount of data per second for each device in the array. Setting the rate to 0 means it will be unbounded. See **lvmraid(7)** for more information.

--mirrorlog core|disk

Specifies the type of mirror log for LVs with the "mirror" type (does not apply to the "raid1" type.) **disk** is a persistent log and requires a small amount of storage space, usually on a separate device from the data being mirrored. **core** is not persistent; the log is kept only in memory. In this case,

the mirror must be synchronized (by copying LV data from the first device to others) each time the LV is activated, e.g. after reboot. **mirrored** is a persistent log that is itself mirrored, but should be avoided. Instead, use the raid1 type for log redundancy.

-m|--mirrors Number

Specifies the number of mirror images in addition to the original LV image, e.g. --mirrors 1 means there are two images of the data, the original and one mirror image. Optional positional PV args on the command line can specify the devices the images should be placed on. There are two mirroring implementations: "raid1" and "mirror". These are the names of the corresponding LV types, or "segment types". Use the --type option to specify which to use (raid1 is default, and mirror is legacy) Use lvm.conf global/mirror_segtypes_default and global/raid10_segtypes_default to configure the default types. See the --nosync option for avoiding initial image synchronization. See **lvmraid(7)** for more information.

--monitor y|n

Start (yes) or stop (no) monitoring an LV with dmeventd. dmeventd monitors kernel events for an LV, and performs automated maintenance for the LV in response to specific events. See **dmeventd(8)** for more information.

-n|--name String

Specifies the name of a new LV. When unspecified, a default name of "lvol#" is generated, where # is a number generated by LVM.

--nolocking

Disable locking.

--nosync

Causes the creation of mirror, raid1, raid4, raid5 and raid10 to skip the initial synchronization. In case of mirror, raid1 and raid10, any data written afterwards will be mirrored, but the original contents will not be copied. In case of raid4 and raid5, no parity blocks will be written, though any data written afterwards will cause parity blocks to be stored. This is useful for skipping a potentially long and resource intensive initial sync of an empty mirror/raid1/raid4/raid5 and raid10 LV. This option is not valid for raid6, because raid6 relies on proper parity (P and Q Syndromes) being created during initial synchronization in order to reconstruct proper user data in case of device failures. raid0 and raid0_meta do not provide any data copies or parity support and thus do not support initial synchronization.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

-p|--permission rw|r

Set access permission to read only **r** or read and write **rw**.

-M|--persistent y|n

When yes, makes the specified minor number persistent.

--poolmetadatasize Size[m|UNIT]

Specifies the size of the new pool metadata LV.

--poolmetadataspare y|n

Enable or disable the automatic creation and management of a spare pool metadata LV in the VG. A spare metadata LV is reserved space that can be used when repairing a pool.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--raidintegrity y|n

Enable or disable data integrity checksums for raid images.

--raidintegrityblocksize Number

The block size to use for dm-integrity on raid images. The integrity block size should usually match the device logical block size, or the file system block size. It may be less than the file system block size, but not less than the device logical block size. Possible values: 512, 1024, 2048, 4096.

--raidintegritymode String

Use a journal (default) or bitmap for keeping integrity checksums consistent in case of a crash. The bitmap areas are recalculated after a crash, so corruption in those areas would not be detected. A journal does not have this problem. The journal mode doubles writes to storage, but can improve performance for scattered writes packed into a single journal write. bitmap mode can in theory achieve full write throughput of the device, but would not benefit from the potential scattered write optimization.

-r|--readahead auto|none|Number

Sets read ahead sector count of an LV. **auto** is the default which allows the kernel to choose a suitable value automatically. **none** is equivalent to zero.

-R|--regionsize Size[m|UNIT]

Size of each raid or mirror synchronization region. lvm.conf activation/raid_region_size can be used to configure a default.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-k|--setactivationskip y|n

Persistently sets (yes) or clears (no) the "activation skip" flag on an LV. An LV with this flag set is not activated unless the --ignoreactivationskip option is used by the activation command. This flag is set by default on new thin snapshot LVs. The flag is not applied to deactivation. The current value of the flag is indicated in the lvs lv_attr bits.

-L|--size Size[m|UNIT]

Specifies the size of the new LV. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels.

-s|--snapshot

Create a snapshot. Snapshots provide a "frozen image" of an origin LV. The snapshot LV can be used, e.g. for backups, while the origin LV continues to be used. This option can create a COW (copy on write) snapshot, or a thin snapshot (in a thin pool.) Thin snapshots are created when the origin is a thin LV and the size option is NOT specified. Thin snapshots share the same blocks in the thin pool, and do not allocate new space from the VG. Thin snapshots are created with the "activation skip" flag, see --setactivationskip. A thin snapshot of a non-thin "external origin" LV is created when a thin pool is specified. Unprovisioned blocks in the thin snapshot LV are read from the external origin LV. The external origin LV must be read-only. See **lvmthin(7)** for more information about LVM thin provisioning. COW snapshots are created when a size is specified. The size is allocated from space in the VG, and is the amount of space that can be used for saving COW blocks as writes occur to the origin or snapshot. The size chosen should depend upon the amount of writes that are expected; often 20% of the origin LV is enough. If COW space runs low, it can be extended with lvextend (shrinking is also allowed with lvreduce.) A small amount of the COW snapshot LV size is used to track COW block locations, so the full size is not available for COW data blocks. Use lvs to check how much space is used, and see --monitor to automatically extend the size to avoid running out of space.

-i|--stripes *Number*

Specifies the number of stripes in a striped LV. This is the number of PVs (devices) that a striped LV is spread across. Data that appears sequential in the LV is spread across multiple devices in units of the stripe size (see **--stripesize**). This does not change existing allocated space, but only applies to space being allocated by the command. When creating a RAID 4/5/6 LV, this number does not include the extra devices that are required for parity. The largest number depends on the RAID type (raid0: 64, raid10: 32, raid4/5: 63, raid6: 62), and when unspecified, the default depends on the RAID type (raid0: 2, raid10: 2, raid4/5: 3, raid6: 5.) To stripe a new raid LV across all PVs by default, see lvm.conf allocation/raid_stripe_all_devices.

-I|--stripesize *Size[k|UNIT]*

The amount of data that is written to one device before moving to the next in a striped LV.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-T|--thin

Specifies the command is handling a thin LV or thin pool. See **--type thin**, **--type thin-pool**, and **--virtualsize**. See **lvmthin(7)** for more information about L VM thin provisioning.

--thinpool *LV*

The name of a thin pool LV.

--type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool

The LV type, also known as "segment type" or "segtype". See usage descriptions for the specific ways to use these types. For more information about redundancy and performance (**raid<N>**, **mirror**, **striped**, **linear**) see **lvmraid(7)**. For thin provisioning (**thin**, **thin-pool**) see **lvmthin(7)**. For performance caching (**cache**, **cache-pool**) see **lvmcache(7)**. For copy-on-write snapshots (**snapshot**) see usage definitions. For VDO (**vdo**) see **lvmvdo(7)**. Several commands omit an explicit type option because the type is inferred from other options or shortcuts (e.g. **--stripes**, **--mirrors**, **--snapshot**, **--virtualsize**, **--thin**, **--cache**, **--vdo**). Use inferred types with care because it can lead to unexpected results.

--vdo

Specifies the command is handling VDO LV. See **--type vdo**. See **lvmvdo(7)** for more information about VDO usage.

--vdopool *LV*

The name of a VDO pool LV. See **lvmvdo(7)** for more information about VDO usage.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-V|--virtualsize *Size[m|UNIT]*

The virtual size of a new thin LV. See **lvmthin(7)** for more information about L VM thin provisioning. Using virtual size (-V) and actual size (-L) together creates a sparse LV. lvm.conf global/sparse_segtype_default determines the default segment type used to create a sparse LV. Anything written to a sparse LV will be returned when reading from it. Reading from other areas of the LV will return blocks of zeros. When using a snapshot to create a sparse LV, a hidden virtual device is created using the zero target, and the LV has the suffix _vorigin. Snapshots are less efficient than thin provisioning when creating large sparse LVs (GiB).

-W|--wipesignatures *y|n*

Controls detection and subsequent wiping of signatures on new LVs. There is a prompt for each

signature detected to confirm its wiping (unless `--yes` is used to override confirmations.) When not specified, signatures are wiped whenever zeroing is done (see `--zero`). This behaviour can be configured with lvm.conf allocation/wipe_signatures_when_zeroing_new_lvs. If blkid wiping is used (lvm.conf allocation/use_blkid_wiping) and LVM is compiled with blkid wiping support, then the blkid(8) library is used to detect the signatures (use blkid -k to list the signatures that are recognized). Otherwise, native LVM code is used to detect signatures (only MD RAID, swap and LUKS signatures are detected in this case.) The LV is not wiped if the read only flag is set.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see `-qq`.)

-Z|--zero y|n

Controls zeroing of the first 4KiB of data in the new LV. Default is `y`. Snapshot COW volumes are always zeroed. For thin pools, this controls zeroing of provisioned blocks. LV is not zeroed if the read only flag is set. Warning: trying to mount an unzeroed LV can cause the system to hang.

VARIABLES*VG*

Volume Group name. See **[lvm\(8\)](#)** for valid names. For lvcreate, the required VG positional arg may be omitted when the VG name is included in another option, e.g. `--name VG/LV`.

LV

Logical Volume name. See **[lvm\(8\)](#)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. `VG/LV`. LV followed by `_<type>` indicates that an LV of the given type is required. (raid represents raid<N> type)

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): `PV[:PE-PE]...` Start and length range (counting from 0): `PV[:PE+PE]...`

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control `--units`, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **[lvm\(8\)](#)** for information about environment variables used by lvm. For example, `LVM_VG_NAME` can generally be substituted for a required VG parameter.

ADVANCED USAGE

Alternate command forms, advanced command usage, and listing of all valid syntax for completeness.

Create an LV that returns errors when used.

```
lvcreate --type error -L|--size Size[m|UNIT] VG
  [ -l|--extents Number[PERCENT] ]
  [ COMMON_OPTIONS ]
```

Create an LV that returns zeros when read.

```
lvcreate --type zero -L|--size Size[m|UNIT] VG
```

```
[ -l|--extents Number[PERCENT] ]
[ COMMON_OPTIONS ]
```

Create a linear LV.

```
lvcreate --type linear -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a striped LV (also see **lvcreate** --stripes).

```
lvcreate --type striped -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a mirror LV (also see --type raid1).

```
lvcreate --type mirror -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -m|--mirrors Number ]
[ -R|--regionsize Size[m|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --mirrorlog core|disk ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a COW snapshot LV of an origin LV
(also see --snapshot).

```
lvcreate --type snapshot -L|--size Size[m|UNIT] LV
[ -l|--extents Number[PERCENT] ]
[ -s|--snapshot ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ -c|--chunksize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a sparse COW snapshot LV of a virtual origin LV
(also see --snapshot).

```
lvcreate --type snapshot -L|--size Size[m|UNIT]
-V--virtualsize Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -s|--snapshot ]
[ -c|--chunksize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
```

[*PV ...*]

Create a sparse COW snapshot LV of a virtual origin LV.

```
lvcreate -s|--snapshot -L|--size Size[m|UNIT]
  -V|--virtualsize Size[m|UNIT] VG
  [ -l|--extents Number[PERCENT] ]
  [ -c|--chunksize Size[k|UNIT] ]
  [ --type snapshot ]
  [ COMMON_OPTIONS ]
  [ PV ... ]
```

Create a thin pool (infers --type thin-pool).

```
lvcreate -T|--thin -L|--size Size[m|UNIT] VG
  [ -l|--extents Number[PERCENT] ]
  [ -c|--chunksize Size[k|UNIT] ]
  [ -i|--stripes Number ]
  [ -I|--stripesize Size[k|UNIT] ]
  [ --type thin-pool ]
  [ --poolmetadatasize Size[m|UNIT] ]
  [ --poolmetadataspare y|n ]
  [ --discards passdown|nopassdown|ignore ]
  [ --errorwhenfull y|n ]
  [ COMMON_OPTIONS ]
  [ PV ... ]
```

Create a thin pool named by the --thinpool arg
(infers --type thin-pool).

```
lvcreate -L|--size Size[m|UNIT] --thinpool LV_new VG
  [ -l|--extents Number[PERCENT] ]
  [ -T|--thin ]
  [ -c|--chunksize Size[k|UNIT] ]
  [ -i|--stripes Number ]
  [ -I|--stripesize Size[k|UNIT] ]
  [ --type thin-pool ]
  [ --poolmetadatasize Size[m|UNIT] ]
  [ --poolmetadataspare y|n ]
  [ --discards passdown|nopassdown|ignore ]
  [ --errorwhenfull y|n ]
  [ COMMON_OPTIONS ]
  [ PV ... ]
```

Create a cache pool named by the --cachepool arg
(variant, uses --cachepool in place of --name).

```
lvcreate --type cache-pool -L|--size Size[m|UNIT]
  --cachepool LV_new VG
  [ -l|--extents Number[PERCENT] ]
  [ -H|--cache ]
  [ -c|--chunksize Size[k|UNIT] ]
  [ --poolmetadatasize Size[m|UNIT] ]
```

```
[ --poolmetadataspare y|n ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --cachemetadataformat auto|1|2 ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV in a thin pool.

```
lvcreate --type thin -V|--virtualsize Size[m|UNIT]
    --thinpool LV_thinpool VG
    [ -T|--thin ]
    [ -c|--chunksize Size[k|UNIT] ]
    [ --poolmetadatasize Size[m|UNIT] ]
    [ --poolmetadataspare y|n ]
    [ --discards passdown|nopassdown|ignore ]
    [ --errorwhenfull y|n ]
    [ COMMON_OPTIONS ]
```

Create a thin LV in a thin pool named in the first arg
(variant, also see --thinpool for naming pool).

```
lvcreate --type thin -V|--virtualsize Size[m|UNIT] LV_thinpool
    [ -T|--thin ]
    [ --discards passdown|nopassdown|ignore ]
    [ --errorwhenfull y|n ]
    [ COMMON_OPTIONS ]
```

Create a thin LV in the thin pool named in the first arg
(variant, infers --type thin, also see --thinpool for
naming pool.)

```
lvcreate -V|--virtualsize Size[m|UNIT] LV_thinpool
    [ -T|--thin ]
    [ --type thin ]
    [ --discards passdown|nopassdown|ignore ]
    [ --errorwhenfull y|n ]
    [ COMMON_OPTIONS ]
```

Create a thin LV that is a snapshot of an existing thin LV.

```
lvcreate --type thin LV_thin
    [ -T|--thin ]
    [ --discards passdown|nopassdown|ignore ]
    [ --errorwhenfull y|n ]
    [ COMMON_OPTIONS ]
```

Create a thin LV that is a snapshot of an existing thin LV
(infers --type thin).

```
lvcreate -T|--thin LV_thin
```

```
[ --type thin ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
```

Create a thin LV that is a snapshot of an external origin LV
(infers --type thin).

```
lvcreate -s|--snapshot --thinpool LV_thinpool LV
[ --type thin ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
```

Create a VDO LV with VDO pool.

```
lvcreate --vdo -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -V|--virtualsize Size[m|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --vdopool LV_new ]
[ --compression y|n ]
[ --deduplication y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a VDO LV with VDO pool.

```
lvcreate --vdopool LV_new -L|--size Size[m|UNIT] VG
[ -l|--extents Number[PERCENT] ]
[ -V|--virtualsize Size[m|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --vdo ]
[ --type vdo ]
[ --compression y|n ]
[ --deduplication y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV, first creating a thin pool for it,
where the new thin pool is named by the --thinpool arg
(variant, infers --type thin).

```
lvcreate -V|--virtualsize Size[m|UNIT] -L|--size Size[m|UNIT]
--thinpool LV_new
[ -l|--extents Number[PERCENT] ]
[ -T|--thin ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
```

```
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV, first creating a thin pool for it,
where the new thin pool is named by the --thinpool arg
(variant, infers --type thin).

```
lvcreate -V|--virtualsize Size[m|UNIT] -L|--size Size[m|UNIT]
--thinpool LV_new VG
[ -l|--extents Number[PERCENT] ]
[ -T|--thin ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV, first creating a thin pool for it,
where the new thin pool is named in the first arg,
or the new thin pool name is generated when the first
arg is a VG name.

```
lvcreate --type thin -V|--virtualsize Size[m|UNIT]
--size Size[m|UNIT] VG|LV_new
[ -l|--extents Number[PERCENT] ]
[ -T|--thin ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV, first creating a thin pool for it,
where the new thin pool is named in the first arg,
or the new thin pool name is generated when the first
arg is a VG name (variant, infers --type thin).

```
lvcreate -T|--thin -V|--virtualsize Size[m|UNIT]
--size Size[m|UNIT] VG|LV_new
[ -l|--extents Number[PERCENT] ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
```

```
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a thin LV, first creating a thin pool for it
(infers --type thin).

Create a sparse snapshot of a virtual origin LV
(infers --type snapshot).

Chooses --type thin or --type snapshot according to
config setting sparse_segtypes_default.

lvcREATE **-L|--size** *Size[m|UNIT]* **-V|--virtualsize** *Size[m|UNIT]* *VG*

```
[ -l|--extents Number[PERCENT] ]
[ -s|--snapshot ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --type snapshot ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --discards passdown|nopassdown|ignore ]
[ --errorwhenfull y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a new LV, then attach the specified cachepool
which converts the new LV to type cache
(variant, infers --type cache.)

lvcREATE **-L|--size** *Size[m|UNIT]* **--cachepool** *LV_cachepool* *VG*

```
[ -l|--extents Number[PERCENT] ]
[ -H|--cache ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --type cache ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --cachemetadataformat auto|1|2 ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Create a new LV, then attach the specified cachepool
which converts the new LV to type cache.
(variant, also use --cachepool).

lvcREATE **--type cache** **-L|--size** *Size[m|UNIT]* *LV_cachepool*

```
[ -l|--extents Number[PERCENT] ]
```

```
[ -H|--cache ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --cachemetadataformat auto|1|2 ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

When the LV arg is a cachepool, then create a new LV and attach the cachepool arg to it.

(variant, use --type cache and --cachepool.)

When the LV arg is not a cachepool, then create a new cachepool and attach it to the LV arg (alternative, use lvconvert.)

```
lvcreate -H|--cache -L|--size Size[m|UNIT] LV
[ -l|--extents Number[PERCENT] ]
[ -c|--chunksize Size[k|UNIT] ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --cachemode writethrough|writeback|passthrough ]
[ --cachepolicy String ]
[ --cachesettings String ]
[ --cachemetadataformat auto|1|2 ]
[ --poolmetadatasize Size[m|UNIT] ]
[ --poolmetadataspare y|n ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

EXAMPLES

Create a striped LV with 3 stripes, a stripe size of 8KiB and a size of 100MiB. The LV name is chosen by lvcreate.

lvcreate -i 3 -I 8 -L 100m vg00

Create a raid1 LV with two images, and a useable size of 500 MiB. This operation requires two devices, one for each mirror image. RAID metadata (superblock and bitmap) is also included on the two devices.

lvcreate --type raid1 -m1 -L 500m -n mylv vg00

Create a mirror LV with two images, and a useable size of 500 MiB. This operation requires three devices: two for mirror images and one for a disk log.

lvcreate --type mirror -m1 -L 500m -n mylv vg00

Create a mirror LV with 2 images, and a useable size of 500 MiB. This operation requires 2 devices because the log is in memory.

lvcreate --type mirror -m1 --mirrorlog core -L 500m -n mylv vg00

Create a copy-on-write snapshot of an LV:

lvcreate --snapshot --size 100m --name mysnap vg00/mylv

Create a copy-on-write snapshot with a size sufficient for overwriting 20% of the size of the original LV.
lvcreate -s -l 20%ORIGIN -n mysnap vg00/mylv

Create a sparse LV with 1TiB of virtual space, and actual space just under 100MiB.
lvcreate --snapshot --virtualsize 1t --size 100m --name mylv vg00

Create a linear LV with a usable size of 64MiB on specific physical extents.
lvcreate -L 64m -n mylv vg00 /dev/sda:0-7 /dev/sdb:0-7

Create a RAID5 LV with a usable size of 5GiB, 3 stripes, a stripe size of 64KiB, using a total of 4 devices (including one for parity).

lvcreate --type raid5 -L 5G -i 3 -I 64 -n mylv vg00

Create a RAID5 LV using all of the free space in the VG and spanning all the PVs in the VG (note that the command will fail if there are more than 8 PVs in the VG, in which case **-i 7** must be used to get to the current maximum of 8 devices including parity for RaidLVs).

**lvcreate --config allocation/raid_stripe_all_devices=1
--type raid5 -l 100%FREE -n mylv vg00**

Create RAID10 LV with a usable size of 5GiB, using 2 stripes, each on a two-image mirror. (Note that the **-i** and **-m** arguments behave differently: **-i** specifies the total number of stripes, but **-m** specifies the number of images in addition to the first image).

lvcreate --type raid10 -L 5G -i 2 -m 1 -n mylv vg00

Create a 1TiB thin LV mythin, with 256GiB thinpool tpool0 in vg00.
lvcreate --T --size 256G --name mythin vg00/tpool0

Create a 1TiB thin LV, first creating a new thin pool for it, where the thin pool has 100MiB of space, uses 2 stripes, has a 64KiB stripe size, and 256KiB chunk size.

**lvcreate --type thin --name mylv --thinpool mypool
-V 1t -L 100m -i 2 -I 64 -c 256 vg00**

Create a thin snapshot of a thin LV (the size option must not be used, otherwise a copy-on-write snapshot would be created).

lvcreate --snapshot --name mysnap vg00/thinvol

Create a thin snapshot of the read-only inactive LV named "origin" which becomes an external origin for the thin snapshot LV.

lvcreate --snapshot --name mysnap --thinpool mypool vg00/origin

Create a cache pool from a fast physical device. The cache pool can then be used to cache an LV.

lvcreate --type cache-pool -L 1G -n my_cpool vg00 /dev/fast1

Create a cache LV, first creating a new origin LV on a slow physical device, then combining the new origin LV with an existing cache pool.

**lvcreate --type cache --cachepool my_cpool
-L 100G -n mylv vg00 /dev/slow1**

Create a VDO LV vdo0 with VDOPoolLV size of 10GiB and name vpool1.

lvcreate --vdo --size 10G --name vdo0 vg00/vpool1

NAME

lvdisplay – Display information about a logical volume

SYNOPSIS

```
lvdisplay
  [ option_args ]
  [ position_args ]
```

DESCRIPTION

lvdisplay shows the attributes of LVs, like size, read/write status, snapshot information, etc.

lvs(8) is a preferred alternative that shows the same information and more, using a more compact and configurable output format.

USAGE

```
lvdisplay
  [ -a|--all ]
  [ -c|--colon ]
  [ -C|--columns ]
  [ -H|--history ]
  [ -m|--maps ]
  [ -o|--options String ]
  [ -O|--sort String ]
  [ -S|--select String ]
  [ --aligned ]
  [ --binary ]
  [ --configreport log|vg|lv|pv|pvseg|seg ]
  [ --foreign ]
  [ --ignorelockingfailure ]
  [ --logonly ]
  [ --noheadings ]
  [ --nosuffix ]
  [ --readonly ]
  [ --reportformat basic|json ]
  [ --segments ]
  [ --separator String ]
  [ --shared ]
  [ --unbuffered ]
  [ --units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E ]
  [ COMMON_OPTIONS ]
  [ VG|LV|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
```

[--version]

OPTIONS

--aligned

Use with --separator to align the output columns

-a|--all

Show information about internal LVs. These are components of normal LVs, such as mirrors, which are not independently accessible, e.g. not mountable.

--binary

Use binary values "0" or "1" instead of descriptive literal values for columns that have exactly two valid values to report (not counting the "unknown" value which denotes that the value could not be determined).

-c|--colon

Generate colon separated output for easier parsing in scripts or programs. Also see **vgs(8)** which provides considerably more control over the output.

-C|--columns

Display output in columns, the equivalent of **vgs(8)**. Options listed are the same as options given in **vgs(8)**.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--configreport log|vg|lv|pv|pvseg|seg

See **lvmreport(7)**.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

-H|--history

Include historical LVs in the output. (This has no effect unless LVs were removed while lvm.conf metadata/record_lvs_history was enabled.)

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--logonly

Suppress command report and display only log report.

--longhelp

Display long help text.

-m|---maps

Display the mapping of logical extents to PVs and physical extents. To map physical extents to logical extents use: pvs --segments -o+lv_name,seg_start_pe,segtype

--noheadings

Suppress the headings line that is normally the first line of output. Useful if grepping the output.

--nolocking

Disable locking.

--nosuffix

Suppress the suffix on output sizes. Use with --units (except h and H) if processing the output.

-o|--options String

Comma-separated, ordered list of fields to display in columns. String arg syntax is:

[+|-#]Field1[,Field2 ...] The prefix + will append the specified fields to the default fields, - will remove the specified fields from the default fields, and # will compact specified fields (removing them when empty for all rows.) Use **-o help** to view the list of all available fields. Use separate lists of fields to add, remove or compact by repeating the -o option: -o+field1,field2 -o-field3,field4 -o#field5. These lists are evaluated from left to right. Use field name **lv_all** to view all LV fields, **vg_all** all VG fields, **pv_all** all PV fields, **pvseg_all** all PV segment fields, **seg_all** all LV segment fields, and **pvseg_all** all PV segment columns. See the lvm.conf report section for more config options. See **Ivmreport(7)** for more information about reporting.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **Ivmreport(7)** for more information.

--segments**-S|--select String**

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **Ivmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--separator String

String to use to separate each column. Useful if grepping the output.

--shared

Report/display shared VGs that would otherwise be skipped when Ivmlockd is not being used on the host. See **Ivmlockd(8)** for more information about shared VGs.

-O|--sort String

Comma-separated ordered list of columns to sort by. Replaces the default selection. Precede any

column with – for a reverse sort on that column.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--unbuffered

Produce output immediately without sorting or aligning the columns properly.

--units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E

All sizes are output in these units: human-(r)eadable with '<' rounding indicator, (h)uman-readable, (b)ytes, (s)ectors, (k)ilobytes, (m)egabytes, (g)igabytes, (t)erabytes, (p)etabytes, (e)xabytes. Capitalise to use multiples of 1000 (S.I.) instead of 1024. Custom units can be specified, e.g. --units 3M.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmG-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control —units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

lvextend – Add space to a logical volume

SYNOPSIS

```
lvextend option_args position_args
      [ option_args ]
      [ position_args ]

      --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit
      -A|--autobackup y|n
      --commandprofile String
      --config String
      -d|--debug
      --driverloaded y|n
      -l|--extents [+]Number[PERCENT]
      -f|--force
      -h|--help
      --lockopt String
      --longhelp
      -m|--mirrors Number
      -n|--nofsck
      --nolocking
      --nosync
      --noudevsync
      --poolmetadatasize [+]Size[m|UNIT]
      --profile String
      -q|--quiet
      --reportformat basic|json
      -r|--resizefs
      -L|--size [+]Size[m|UNIT]
      -i|--stripes Number
      -I|--stripesize Size[k|UNIT]
      -t|--test
      --type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool
      --usepolicies
      -v|--verbose
      --version
      -y|--yes
```

DESCRIPTION

lvextend extends the size of an LV. This requires allocating logical extents from the VG's free physical extents. If the extension adds a new LV segment, the new segment will use the existing segment type of the LV.

Extending a copy-on-write snapshot LV adds space for COW blocks.

Use **lvconvert(8)** to change the number of data images in a RAID or mirrored LV.

In the usage section below, **--size** *Size* can be replaced with **--extents** *Number*. See both descriptions the options section.

USAGE

Extend an LV by a specified size.

```
lvextend -L|--size [+]Size[m|UNIT] LV
      [ -l|--extents [+]Number[PERCENT] ]
      [ -r|--resizefs ]
```

```
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --poolmetadatasize [+]Size[m|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Extend an LV by specified PV extents.

```
lvextend LV PV ...
[ -r|--resizesfs ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
```

Extend a pool metadata SubLV by a specified size.

```
lvextend --poolmetadatasize [+]Size[m|UNIT] LV_thinpool
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Extend an LV according to a predefined policy.

```
lvextend --usepolicies LV_snapshot_thinpool
[ -r|--resizesfs ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ -f|--force ]
[ -m|--mirrors Number ]
[ -n|--nofsck ]
[ --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit ]
[ --nosync ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ --type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
```

- [**--nolocking**]
- [**--profile** *String*]
- [**--version**]

OPTIONS

--alloc *contiguous|cling|cling_by_tags|normal|anywhere|inherit*

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup *y|n*

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-I|--extents [+]*Number*[**PERCENT**]

Specifies the new size of the LV in logical extents. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. An alternate syntax allows the size to be determined indirectly as a percentage of the size of a related VG, LV, or set of PVs. The suffix **%VG** denotes the total size of the VG, the suffix **%FREE** the remaining free space in the VG, and the suffix **%PVS** the free space in the specified PVs. For a snapshot, the size can be expressed as a percentage of the total size of the origin LV with the suffix **%ORIGIN** (**100%ORIGIN** provides space for the whole origin). When expressed as a percentage, the size defines an upper limit for the number of logical extents in the new LV. The precise number of logical extents in the new LV is not determined until the command has completed. When the plus + or minus - prefix is used, the value is not an absolute size, but is relative and added or subtracted from the current size.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-m|---mirrors Number

Not used.

-n|---nofsck

Do not perform fsck before resizing filesystem when filesystem requires it. You may need to use --force to proceed with this option.

--nolocking

Disable locking.

--nosync

Causes the creation of mirror, raid1, raid4, raid5 and raid10 to skip the initial synchronization. In case of mirror, raid1 and raid10, any data written afterwards will be mirrored, but the original contents will not be copied. In case of raid4 and raid5, no parity blocks will be written, though any data written afterwards will cause parity blocks to be stored. This is useful for skipping a potentially long and resource intensive initial sync of an empty mirror/raid1/raid4/raid5 and raid10 LV. This option is not valid for raid6, because raid6 relies on proper parity (P and Q Syndromes) being created during initial synchronization in order to reconstruct proper user data in case of device failures. raid0 and raid0_meta do not provide any data copies or parity support and thus do not support initial synchronization.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--poolmetadatasize [+]*Size[m|UNIT]*

Specifies the new size of the pool metadata LV. The plus prefix+ can be used, in which case the value is added to the current size.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|---quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **[lvmreport\(7\)](#)** for more information.

-r|---resizesfs

Resize underlying filesystem together with the LV using fsadm(8).

-L|---size [+]*Size[m|UNIT]*

Specifies the new size of the LV. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. When the plus+ or minus - prefix is used, the value is not an absolute size, but is relative and added or subtracted from the current size.

-i|---stripes Number

Specifies the number of stripes in a striped LV. This is the number of PVs (devices) that a striped LV is spread across. Data that appears sequential in the LV is spread across multiple devices in units of the stripe size (see --stripesize). This does not change existing allocated space, but only applies to space being allocated by the command. When creating a RAID 4/5/6 LV, this number does not include the extra devices that are required for parity. The largest number depends on the RAID type (raid0: 64, raid10: 32, raid4/5: 63, raid6: 62), and when unspecified, the default depends on the RAID type (raid0: 2, raid10: 2, raid4/5: 3, raid6: 5.) To stripe a new raid LV across all PVs by default, see lvm.conf allocation/raid_stripe_all_devices.

-I|--stripesize *Size[k|UNIT]*

The amount of data that is written to one device before moving to the next in a striped LV.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--type *linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool*

The LV type, also known as "segment type" or "segtype". See usage descriptions for the specific ways to use these types. For more information about redundancy and performance (**raid<N>**, **mirror**, **striped**, **linear**) see **lvmraid(7)**. For thin provisioning (**thin**, **thin-pool**) see **lvmthin(7)**. For performance caching (**cache**, **cache-pool**) see **lvmcache(7)**. For copy-on-write snapshots (**snapshot**) see usage definitions. For VDO (**vdo**) see **lvmvdo(7)**. Several commands omit an explicit type option because the type is inferred from other options or shortcuts (e.g. **--stripes**, **--mirrors**, **--snapshot**, **--virtualsize**, **--thin**, **--cache**, **--vdo**). Use inferred types with care because it can lead to unexpected results.

--usepolicies

Perform an operation according to the policy configured in lvm.conf or a profile.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

VARIABLES*LV*

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV. LV followed by _<type> indicates that an LV of the given type is required. (raid represents raid<N> type)

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Extend the size of an LV by 54MiB, using a specific PV.

lvextend -L +54 vg01/lvol10 /dev/sdk3

Extend the size of an LV by the amount of free space on PV /dev/sdk3. This is equivalent to specifying "-l +100%PVS" on the command line.

lvextend vg01/lvol01 /dev/sdk3

Extend an LV by 16MiB using specific physical extents.

lvextend -L+16m vg01/lvol01 /dev/sda:8-9 /dev/sdb:8-9

NAME

lvmconfig – Display and manipulate configuration information

SYNOPSIS

```
lvmconfig
[ option_args ]
[ position_args ]
```

DESCRIPTION

lvmconfig, **lvm config**, **lvm dumpconfig** (for compatibility reasons, to be phased out) produce formatted output from the LVM configuration tree. The sources of the configuration data include **lvm.conf(5)** and command line settings from **--config**.

USAGE

```
lvmconfig
[ -f|--file String ]
[ -l|--list ]
[ --atversion String ]
[ --typeconfig current|default|diff|full|list|missing|new|profilable|profilable-command|profilable-metadata ]
[ --ignoreadvanced ]
[ --ignoreunsupported ]
[ --ignorelocal ]
[ --mergedconfig ]
[ --metadataprofile String ]
[ --sinceversion String ]
[ --showdeprecated ]
[ --showunsupported ]
[ --validate ]
[ --withsummary ]
[ --withcomments ]
[ --withgeneralpreamble ]
[ --withlocalpreamble ]
[ --withspaces ]
[ --unconfigured ]
[ --withversions ]
[ COMMON_OPTIONS ]
[ String ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--atversion *String*

Specify an LVM version in x.y.z format where x is the major version, the y is the minor version and z is the patchlevel (e.g. 2.2.106). When configuration is displayed, the configuration settings recognized at this LVM version will be considered only. This can be used to display a configuration that a certain LVM version understands and which does not contain any newer settings for which LVM would issue a warning message when checking the configuration.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--file *String*

Write output to the named file.

-h|--help

Display help text.

--ignoreadvanced

Exclude advanced configuration settings from the output.

--ignorelocal

Ignore the local section. The local section should be defined in the lvmlocal.conf file, and should contain config settings specific to the local host which should not be copied to other hosts.

--ignoreunsupported

Exclude unsupported configuration settings from the output. These settings are either used for debugging and development purposes only or their support is not yet complete and they are not meant to be used in production. The **current** and **diff** types include unsupported settings in their output by default, all the other types ignore unsupported settings.

-l|--list

List config settings with summarizing comment. This is the same as using options --typeconfig list --withsummary.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--mergedconfig

When the command is run with --config and/or --commandprofile (or using LVM_COMMAND_PROFILE environment variable), --profile, or --metadataprofile, merge all the contents of the "config cascade" before displaying it. Without merging, only the configuration at the front of the cascade is displayed. See **lvm.conf(5)** for more information about config.

--metadataprofile *String*

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--showdeprecated

Include deprecated configuration settings in the output. These settings are deprecated after a certain version. If a concrete version is specified with --atversion, deprecated settings are automatically included if the specified version is lower than the version in which the settings were deprecated. The current and diff types include deprecated settings in their output by default, all the other types ignore deprecated settings.

--showunsupported

Include unsupported configuration settings in the output. These settings are either used for debugging or development purposes only, or their support is not yet complete and they are not meant to be used in production. The current and diff types include unsupported settings in their output by default, all the other types ignore unsupported settings.

--sinceversion String

Specify an LVM version in x.y.z format where x is the major version, the y is the minor version and z is the patchlevel (e.g. 2.2.106). This option is currently applicable only with --typeconfig new to display all configuration settings introduced since given version.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--typeconfig current|default|diff|full|list|missing|new|profilable|profilable-command|profilable-metadata

current prints the config settings that would be applied to an lvm command (assuming the command does not override them on the command line.) This includes: settings that have been modified in lvm config files, settings that get their default values from config files, and default settings that have been uncommented in config files. **default** prints all settings with their default values. Changes made in lvm config files are not reflected in the output. Some settings get their default values internally, and these settings are printed as comments. Other settings get their default values from config files, and these settings are not printed as comments. **diff** prints only config settings that have been modified from their default values in config files (the difference between current and default.) **full** prints every setting uncommented and set to the current value, i.e. how it would be used by an lvm command. This includes settings modified in config files, settings that usually get defaults internally, and settings that get defaults from config files. **list** prints all config names without values. **missing** prints settings that are missing from the lvm config files. A missing setting that usually gets its default from config files is printed uncommented and set to the internal default. Settings that get their default internally and are not set in config files are printed commented with the internal default. **new** prints config settings that have been added since the lvm version specified by --sinceversion. They are printed with their default values. **profilable** prints settings with their default values that can be set from a profile. **profilable-command** prints settings with their default values that can be set from a command profile. **profilable-metadata** prints settings with their default values that can be set from a metadata profile. Also see **lvm.conf(5)**.

--unconfigured

Internal option used for generating config file during build.

--validate

Validate current configuration used and exit with appropriate return code. The validation is done only for the configuration at the front of the "config cascade". To validate the whole merged configuration tree, also use --mergedconfig. The validation is done even if lvm.conf config/checks is disabled.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

--withcomments

Display a full comment for each configuration node. For deprecated settings, also display comments about deprecation.

--withgeneralpreamble

Include general config file preamble.

--withlocalpreamble

Include local config file preamble.

--withspaces

Where appropriate, add more spaces in output for better readability.

--withsummary

Display a one line comment for each configuration node.

--withversions

Also display a comment containing the version of introduction for each configuration node. If the setting is deprecated, also display the version since which it is deprecated.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*String*

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkKmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

lvm — LVM2 tools

SYNOPSIS

lvm [*command|file*]

DESCRIPTION

The Logical Volume Manager (LVM) provides tools to create virtual block devices from physical devices. Virtual devices may be easier to manage than physical devices, and can have capabilities beyond what the physical devices provide themselves. A Volume Group (VG) is a collection of one or more physical devices, each called a Physical Volume (PV). A Logical Volume (LV) is a virtual block device that can be used by the system or applications. Each block of data in an LV is stored on one or more PV in the VG, according to algorithms implemented by Device Mapper (DM) in the kernel.

The **lvm** command, and other commands listed below, are the command-line tools for LVM. A separate manual page describes each command in detail.

If **lvm** is invoked with no arguments it presents a readline prompt (assuming it was compiled with readline support). LVM commands may be entered interactively at this prompt with readline facilities including history and command name and option completion. Refer to **readline(3)** for details.

If **lvm** is invoked with argv[0] set to the name of a specific LVM command (for example by using a hard or soft link) it acts as that command.

On invocation, **lvm** requires that only the standard file descriptors stdin, stdout and stderr are available. If others are found, they get closed and messages are issued warning about the leak. This warning can be suppressed by setting the environment variable **LVM_SUPPRESS_FD_WARNINGS**.

Where commands take VG or LV names as arguments, the full path name is optional. An LV called "lvol0" in a VG called "vg0" can be specified as "vg0/lvol0". Where a list of VGs is required but is left empty, a list of all VGs will be substituted. Where a list of LVs is required but a VG is given, a list of all the LVs in that VG will be substituted. So **lvdisplay vg0** will display all the LVs in "vg0". Tags can also be used – see **--addtag** below.

One advantage of using the built-in shell is that configuration information gets cached internally between commands.

A file containing a simple script with one command per line can also be given on the command line. The script can also be executed directly if the first line is #! followed by the absolute path of **lvm**.

Additional hyphens within option names are ignored. For example, **--readonly** and **--read-only** are both accepted.

BUILT-IN COMMANDS

The following commands are built into lvm without links normally being created in the filesystem for them.

config	The same as lvmconfig(8) below.
devtypes	Display the recognised built-in block device types.
dumpconfig	The same as lvmconfig(8) below.
formats	Display recognised metadata formats.
fullreport	Report information about PVs, PV segments, VGs, LVs and LV segments, all at once.
help	Display the help text.
lastlog	Display log report of last command run in LVM shell if command log reporting is enabled.
lvpoll	Complete lvmpolld operations (Internal command).
segtypes	Display recognised Logical Volume segment types.
systemid	Display any system ID currently set on this host.
tags	Display any tags defined on this host.
version	Display version information.

COMMANDS

The following commands implement the core LVM functionality.

pvchange	Change attributes of a Physical Volume.
pvck	Check Physical Volume metadata.
pvcreate	Initialize a disk or partition for use by LVM.
pvdisk	Display attributes of a Physical Volume.
pvmove	Move Physical Extents.
pvremove	Remove a Physical Volume.
pvresize	Resize a disk or partition in use by LVM2.
pvs	Report information about Physical Volumes.
pvscan	Scan all disks for Physical Volumes.
vgcfgbackup	Backup Volume Group descriptor area.
vgcfgrestore	Restore Volume Group descriptor area.
vgchange	Change attributes of a Volume Group.
vgck	Check Volume Group metadata.
vgconvert	Convert Volume Group metadata format.
vgcreate	Create a Volume Group.
vgdisplay	Display attributes of Volume Groups.
vgexport	Make volume Groups unknown to the system.
vgextend	Add Physical Volumes to a Volume Group.
vgimport	Make exported Volume Groups known to the system.
vgimportclone	Import and rename duplicated Volume Group (e.g. a hardware snapshot).
vgmerge	Merge two Volume Groups.
vgmknodes	Recreate Volume Group directory and Logical Volume special files
vgreduce	Reduce a Volume Group by removing one or more Physical Volumes.
vgremove	Remove a Volume Group.
vgrename	Rename a Volume Group.
vgs	Report information about Volume Groups.
vgscan	Scan all disks for Volume Groups.
vgsplit	Split a Volume Group into two, moving any logical volumes from one Volume Group to another by moving entire Physical Volumes.
lvchange	Change attributes of a Logical Volume.
lvconvert	Convert a Logical Volume from linear to mirror or snapshot.
lvcreate	Create a Logical Volume in an existing Volume Group.
lvdisplay	Display attributes of a Logical Volume.
lvextend	Extend the size of a Logical Volume.
lvmconfig	Display the configuration information after loading lvm.conf(5) and any other configuration files.
lvmdiskscan	Scan for all devices visible to LVM2.
lvmdump	Create lvm2 information dumps for diagnostic purposes.
lvreduce	Reduce the size of a Logical Volume.
lvremove	Remove a Logical Volume.
lvrename	Rename a Logical Volume.
lvresize	Resize a Logical Volume.
lvs	Report information about Logical Volumes.
lvscan	Scan (all disks) for Logical Volumes.

The following LVM1 commands are not implemented in LVM2: **lvmchange**, **lvmsadc**, **lvmsar**, **pvdata**. For performance metrics, use **dmstats(8)** or to manipulate the kernel device-mapper driver used by LVM2 directly, use **dmsetup(8)**.

VALID NAMES

The valid characters for VG and LV names are: **a–z A–Z 0–9 + _ . –**

VG names cannot begin with a hyphen. The name of a new LV also cannot begin with a hyphen. However,

if the configuration setting **metadata/record_lvs_history** is enabled then an LV name with a hyphen as a prefix indicates that, although the LV was removed, it is still being tracked because it forms part of the history of at least one LV that is still present. This helps to record the ancestry of thin snapshots even after some links in the chain have been removed. A reference to the historical LV 'lvol1' in VG 'vg00' would be 'vg00\-\lvol1' or just '\lvol1' if the VG is already set. (The latter form must be preceded by '--' to terminate command line option processing before reaching this argument.)

There are also various reserved names that are used internally by lvm that can not be used as LV or VG names. A VG cannot be called anything that exists in */dev/* at the time of creation, nor can it be called '.' or '..'. An LV cannot be called '.', '..', 'snapshot' or 'pvmove'. The LV name may also not contain any of the following strings: '_cdata', '_cmeta', '_corig', '_mlog', '_mimage', '_pmsspare', '_rimage', '_rmeta', '_tdata', '_tmeta', '_vorigin' or '_vdata'. A directory bearing the name of each Volume Group is created under */dev* when any of its Logical Volumes are activated. Each active Logical Volume is accessible from this directory as a symbolic link leading to a device node. Links or nodes in */dev/mapper* are intended only for internal use and the precise format and escaping might change between releases and distributions. Other software and scripts should use the */dev/VolumeGroupName/LogicalVolumeName* format to reduce the chance of needing amendment when the software is updated. Should you need to process the node names in */dev/mapper*, you may use **dmsetup splitname** to separate out the original VG, LV and internal layer names.

UNIQUE NAMES

VG names should be unique. **vgcreate** will produce an error if the specified VG name matches an existing VG name. However, there are cases where different VGs with the same name can appear to LVM, e.g. after moving disks or changing filters.

When VGs with the same name exist, commands operating on all VGs will include all of the VGs with the same name. If the ambiguous VG name is specified on the command line, the command will produce an error. The error states that multiple VGs exist with the specified name. To process one of the VGs specifically, the --select option should be used with the UUID of the intended VG: '--select vg_uuid=<uuid>'.

An exception is if all but one of the VGs with the shared name is foreign (see **lvmsystemid**(7).) In this case, the one VG that is not foreign is assumed to be the intended VG and is processed.

LV names are unique within a VG. The name of an historical LV cannot be reused until the historical LV has itself been removed or renamed.

ALLOCATION

When an operation needs to allocate Physical Extents for one or more Logical Volumes, the tools proceed as follows:

First of all, they generate the complete set of unallocated Physical Extents in the Volume Group. If any ranges of Physical Extents are supplied at the end of the command line, only unallocated Physical Extents within those ranges on the specified Physical Volumes are considered.

Then they try each allocation policy in turn, starting with the strictest policy (**contiguous**) and ending with the allocation policy specified using **--alloc** or set as the default for the particular Logical Volume or Volume Group concerned. For each policy, working from the lowest-numbered Logical Extent of the empty Logical Volume space that needs to be filled, they allocate as much space as possible according to the restrictions imposed by the policy. If more space is needed, they move on to the next policy.

The restrictions are as follows:

Contiguous requires that the physical location of any Logical Extent that is not the first Logical Extent of a Logical Volume is adjacent to the physical location of the Logical Extent immediately preceding it.

Cling requires that the Physical Volume used for any Logical Extent to be added to an existing Logical

Volume is already in use by at least one Logical Extent earlier in that Logical Volume. If the configuration parameter **allocation/cling_tag_list** is defined, then two Physical Volumes are considered to match if any of the listed tags is present on both Physical Volumes. This allows groups of Physical Volumes with similar properties (such as their physical location) to be tagged and treated as equivalent for allocation purposes.

When a Logical Volume is striped or mirrored, the above restrictions are applied independently to each stripe or mirror image (leg) that needs space.

Normal will not choose a Physical Extent that shares the same Physical Volume as a Logical Extent already allocated to a parallel Logical Volume (i.e. a different stripe or mirror image/leg) at the same offset within that parallel Logical Volume.

When allocating a mirror log at the same time as Logical Volumes to hold the mirror data, Normal will first try to select different Physical Volumes for the log and the data. If that's not possible and the **allocation/mirror_logs_require_separate_pvs** configuration parameter is set to 0, it will then allow the log to share Physical Volume(s) with part of the data.

When allocating thin pool metadata, similar considerations to those of a mirror log in the last paragraph apply based on the value of the **allocation/thin_pool_metadata_require_separate_pvs** configuration parameter.

If you rely upon any layout behaviour beyond that documented here, be aware that it might change in future versions of the code.

For example, if you supply on the command line two empty Physical Volumes that have an identical number of free Physical Extents available for allocation, the current code considers using each of them in the order they are listed, but there is no guarantee that future releases will maintain that property. If it is important to obtain a specific layout for a particular Logical Volume, then you should build it up through a sequence of **lvmcreate(8)** and **lvmconvert(8)** steps such that the restrictions described above applied to each step leave the tools no discretion over the layout.

To view the way the allocation process currently works in any specific case, read the debug logging output, for example by adding **-vvvv** to a command.

LOGICAL VOLUME TYPES

Some logical volume types are simple to create and can be done with a single **lvmcreate(8)** command. The linear and striped logical volume types are an example of this. Other logical volume types may require more than one command to create. The cache (**lvmcache(7)**) and thin provisioning (**lvmthin(7)**) types are examples of this.

DIAGNOSTICS

All tools return a status code of zero on success or non-zero on failure. The non-zero codes distinguish only between the broad categories of unrecognised commands, problems processing the command line arguments and any other failures. As LVM remains under active development, the code used in a specific case occasionally changes between releases. Message text may also change.

ENVIRONMENT VARIABLES

HOME

Directory containing *.lvm_history* if the internal readline shell is invoked.

LVM_OUT_FD

File descriptor to use for common output from LVM commands.

LVM_ERR_FD

File descriptor to use for error output from LVM commands.

LVM_REPORT_FD

File descriptor to use for report output from LVM commands.

LVM_COMMAND_PROFILE

Name of default command profile to use for LVM commands. This profile is overriden by direct use of **--commandprofile** command line option.

LVM_RUN_BY_DMEVENTD

This variable is normally set by dmeventd plugin to inform lvm2 command it is running from dmeventd plugin so lvm2 takes some extra action to avoid communication and deadlocks with dmeventd.

LVM_SYSTEM_DIR

Directory containing **lvm.conf(5)** and other LVM system files. Defaults to "/etc/lvm".

LVM_SUPPRESS_FD_WARNINGS

Suppress warnings about unexpected file descriptors passed into LVM.

LVM_SUPPRESS_SYSLOG

Suppress contacting syslog.

LVM_VG_NAME

The Volume Group name that is assumed for any reference to a Logical Volume that doesn't specify a path. Not set by default.

LVM_LVMPOLLD_PIDFILE

Path to the file that stores the lvmpolld process ID.

LVM_LVMPOLLD_SOCKET

Path to the socket used to communicate with lvmpolld..

LVM_LOG_FILE_EPOCH

A string of up to 32 letters appended to the log filename and followed by the process ID and a startup timestamp using this format string "%s_%d_%llu". When set, each process logs to a separate file.

LVM_LOG_FILE_MAX_LINES

If more than this number of lines are sent to the log file, the command gets aborted. Automated tests use this to terminate looping commands.

LVM_EXPECTED_EXIT_STATUS

The status anticipated when the process exits. Use ">N" to match any status greater than N. If the actual exit status matches and a log file got produced, it is deleted. **LVM_LOG_FILE_EPOCH** and **LVM_EXPECTED_EXIT_STATUS** together allow automated test scripts to discard uninteresting log data.

LVM_SUPPRESS_LOCKING_FAILURE_MESSAGES

Used to suppress warning messages when the configured locking is known to be unavailable.

DM_ABORT_ON_INTERNAL_ERRORS

Abort processing if the code detects a non-fatal internal error.

DM_DISABLE_UDEV

Avoid interaction with udev. LVM will manage the relevant nodes in /dev directly.

DM_DEBUG_WITH_LINE_NUMBERS

Prepends source file name and code line number with libdm debugging.

FILES

/etc/lvm/lvm.conf
\$HOME/.lvm_history

NAME

lvm.conf — Configuration file for LVM2

SYNOPSIS

/etc/lvm/lvm.conf

DESCRIPTION

lvm.conf is loaded during the initialisation phase of **lvm(8)**. This file can in turn lead to other files being loaded – settings read in later override earlier settings. File timestamps are checked between commands and if any have changed, all the files are reloaded.

For a description of each lvm.conf setting, run:

lvmconfig --typeconfig default --withcomments --withspaces

The settings defined in lvm.conf can be overridden by any of these extended configuration methods:

direct config override on command line

The **--config ConfigurationString** command line option takes the ConfigurationString as direct string representation of the configuration to override the existing configuration. The ConfigurationString is of exactly the same format as used in any LVM configuration file.

profile config

A profile is a set of selected customizable configuration settings that are aimed to achieve a certain characteristics in various environments or uses. It's used to override existing configuration. Normally, the name of the profile should reflect that environment or use.

There are two groups of profiles recognised: **command profiles** and **metadata profiles**.

The **command profile** is used to override selected configuration settings at global LVM command level – it is applied at the very beginning of LVM command execution and it is used throughout the whole time of LVM command execution. The command profile is applied by using the **--commandprofile ProfileName** command line option that is recognised by all LVM2 commands.

The **metadata profile** is used to override selected configuration settings at Volume Group/Logical Volume level – it is applied independently for each Volume Group/Logical Volume that is being processed. As such, each Volume Group/Logical Volume can store the profile name used in its metadata so next time the Volume Group/Logical Volume is processed, the profile is applied automatically. If Volume Group and any of its Logical Volumes have different profiles defined, the profile defined for the Logical Volume is preferred. The metadata profile can be attached/detached by using the **lvchange** and **vgchange** commands and their **--metadataprofile ProfileName** and **--detachprofile** options or the **--metadataprofile** option during creation when using **vgcreate** or **lvcreate** command. The **vgs** and **lvs** reporting commands provide **-o vg_profile** and **-o lv_profile** output options to show the metadata profile currently attached to a Volume Group or a Logical Volume.

The set of options allowed for command profiles is mutually exclusive when compared to the set of options allowed for metadata profiles. The settings that belong to either of these two sets can't be mixed together and LVM tools will reject such profiles.

LVM itself provides a few predefined configuration profiles. Users are allowed to add more profiles with different values if needed. For this purpose, there's the **command_profile_template.profile** (for command profiles) and **metadata_profile_template.profile** (for metadata profiles) which contain all settings that are customizable by profiles of certain type. Users are encouraged to copy these template profiles and edit them as needed. Alternatively, the **lvmconfig --file <ProfileName.profile> --type profitable-command <section>** or **lvmconfig --file**

<ProfileName.profile> --type profilable-metadata <section> can be used to generate a configuration with profilable settings in either of the type for given section and save it to new Profile-Name.profile (if the section is not specified, all profilable settings are reported).

The profiles are stored in /etc/lvm/profile directory by default. This location can be changed by using the **config/profile_dir** setting. Each profile configuration is stored in **ProfileName.profile** file in the profile directory. When referencing the profile, the **.profile** suffix is left out.

tag config

See **tags** configuration setting description below.

When several configuration methods are used at the same time and when LVM looks for the value of a particular setting, it traverses this **config cascade** from left to right:

direct config override on command line → **command profile config** → **metadata profile config** → **tag config** → **lvmlocal.conf** → **lvm.conf**

No part of this cascade is compulsory. If there's no setting value found at the end of the cascade, a default value is used for that setting. Use lvmconfig to check what settings are in use and what the default values are.

SYNTAX

This section describes the configuration file syntax.

Whitespace is not significant unless it is within quotes. This provides a wide choice of acceptable indentation styles. Comments begin with # and continue to the end of the line. They are treated as whitespace.

Here is an informal grammar:

file = value*

A configuration file consists of a set of values.

value = section | assignment

A value can either be a new section, or an assignment.

section = identifier '{' value* '}'

A section groups associated values together. If the same section is encountered multiple times, the contents of all instances are concatenated together in the order of appearance.

It is denoted by a name and delimited by curly brackets.

e.g. backup {

...

}

assignment = identifier '=' (array | type)

An assignment associates a type with an identifier. If the identifier contains forward slashes, those are interpreted as path delimiters. The statement **section/key = value** is equivalent to **section { key = value }**. If multiple instances of the same key are encountered, only the last value is used (and a warning is issued).

e.g. level = 7

array = '[' (type ',')* type ']' | '[' ']

Inhomogeneous arrays are supported.

Elements must be separated by commas.

An empty array is acceptable.

type = integer | float | string

integer = [0-9]*

float = [0-9]* '.' [0-9]*

string = '"' .* '"'

Strings with spaces must be enclosed in double quotes, single words that start with a letter can be left unquoted.

SETTINGS

The **lvmconfig** command prints the LVM configuration settings in various ways. See the man page **lvmconfig(8)**.

Command to print a list of all possible config settings, with their default values:
lvmconfig --type default

Command to print a list of all possible config settings, with their default values, and a full description of each as a comment:

lvmconfig --type default --withcomments

Command to print a list of all possible config settings, with their current values (configured, non-default values are shown):

lvmconfig --type current

Command to print all config settings that have been configured with a different value than the default (configured, non-default values are shown):

lvmconfig --type diff

Command to print a single config setting, with its default value, and a full description, where "Section" refers to the config section, e.g. global, and "Setting" refers to the name of the specific setting, e.g. umask:

lvmconfig --type default --withcomments Section/Setting

FILES

*/etc/lvm/lvm.conf
/etc/lvm/lvmlocal.conf
/etc/lvm/archive
/etc/lvm/backup
/etc/lvm/cache/.cache
/run/lock/lvm
/etc/lvm/profile*

SEE ALSO

lvm(8) lvmconfig(8)

lvm_selinux(8) - Linux man page

Name

`lvm_selinux` - Security Enhanced Linux Policy for the lvm processes

Description

Security-Enhanced Linux secures the lvm processes via flexible mandatory access control.

The lvm processes execute with the `lvm_t` SELinux type. You can check if you have these processes running by executing the `ps` command with the `-Z` qualifier.

For example:

```
ps -eZ | grep lvm_t
```

Entrypoints

The `lvm_t` SELinux type can be entered via the
"mtrr_device_t,unlabeled_t,proc_type,sysctl_type,filesystem_type,file_type,lvm_exec_t"
file types. The default entrypoint paths for the `lvm_t` domain are the following:"

```
/dev/cpu/mtrr, all files on the system, /lib/lvm-10/.*, /lib/lvm-200/.*, /sbin/lvs, /sbin/vgs,  
/sbin/pvs, /sbin/lvm, /sbin/vgck, /sbin/pvdata, /sbin/pvmove, /sbin/pvscan, /sbin/lvscan,  
/sbin/kpartx, /sbin/lvmsar, /sbin/dmraid, /sbin/vgscan, /sbin/vgmerge, /sbin/dmsetup,  
/sbin/e2fsadm, /sbin/lvmsadc, /sbin/lvmetad, /sbin/vgsplit, /usr/sbin/lvm, /sbin/vgchange,  
/sbin/vgexport, /sbin/vgcreate, /sbin/vgextend, /sbin/vgimport, /sbin/vgreduce,  
/sbin/vgremove, /sbin/vgrename, /sbin/pvchange, /sbin/pvcreate, /sbin/pvremove,  
/sbin/lvreduce, /sbin/lvrename, /sbin/lvresize, /sbin/lvremove, /sbin/lvchange,  
/sbin/lvextend, /sbin/lvcreate, /sbin/vgdisplay, /sbin/vgmknodes, /sbin/pvdisplay,  
/sbin/lvdisplay, /sbin/lvmchange, /sbin/vgwrapper, /sbin/multipathd, /sbin/lvm.static,  
/sbin/cryptsetup, /sbin/vgcfgbackup, /sbin/lvmdiskscan, /sbin/mount.crypt,  
/sbin/vgcfgrestore, /sbin/lvmiopversion, /sbin/vgscan.static, /sbin/dmsetup.static,  
/sbin/vgchange.static, /sbin/multipath.static, /lib/udev/udisks-lvm-pv-export
```

Process Types

SELinux defines process types (domains) for each process running on the system

You can see the context of a process using the `-Z` option to `ps`

Policy governs the access confined processes have to files. SELinux lvm policy is very flexible allowing users to setup their lvm processes in as secure a method as possible.

The following process types are defined for lvm:

lvm_t

Note: **semanage permissive -a lvm_t**

can be used to make the process type lvm_t permissive. Permissive process types are not denied access by SELinux. AVC messages will still be generated.

File Contexts

SELinux requires files to have an extended attribute to define the file type.

You can see the context of a file using the **-Z** option to **ls**

Policy governs the access confined processes have to these files. SELinux lvm policy is very flexible allowing users to setup their lvm processes in as secure a method as possible.

The following file types are defined for lvm:

lvm_etc_t

- Set files with the lvm_etc_t type, if you want to store lvm files in the /etc directories.

lvm_exec_t

- Set files with the lvm_exec_t type, if you want to transition an executable to the lvm_t domain.

lvm_lock_t

- Set files with the lvm_lock_t type, if you want to treat the files as lvm lock data, stored under the /var/lock directory

lvm_metadata_t

- Set files with the lvm_metadata_t type, if you want to treat the files as lvm metadata data.

lvm_tmp_t

- Set files with the lvm_tmp_t type, if you want to store lvm temporary files in the /tmp directories.

lvm_var_lib_t

- Set files with the lvm_var_lib_t type, if you want to store the lvm files under the /var/lib directory.

lvm_var_run_t

- Set files with the lvm_var_run_t type, if you want to store the lvm files under the /run directory.

Note: File context can be temporarily modified with the chcon command. If you want to permanently change the file context you need to use the **semanage fcontext** command. This will modify the SELinux labeling database. You will need to use **restorecon** to apply the labels.

Managed Files

The SELinux process type lvm_t can manage files labeled with the following file types. The paths listed are the default paths for these file types. Note the processes UID still need to have DAC permissions.

file_type

all files on the system

Commands

semanage fcontext can also be used to manipulate default file context mappings.

semanage permissive can also be used to manipulate whether or not a process type is permissive.

semanage module can also be used to enable/disable/install/remove policy modules.

system-config-selinux is a GUI tool available to customize SELinux policy settings.

Author

This manual page was auto-generated using **sepolicy manpage** by mgrepl.

NAME

lvmconfig – Display and manipulate configuration information

SYNOPSIS

```
lvmconfig
[ option_args ]
[ position_args ]
```

DESCRIPTION

lvmconfig, **lvm config**, **lvm dumpconfig** (for compatibility reasons, to be phased out) produce formatted output from the LVM configuration tree. The sources of the configuration data include **lvm.conf(5)** and command line settings from **--config**.

USAGE

```
lvmconfig
[ -f|--file String ]
[ -l|--list ]
[ --atversion String ]
[ --typeconfig current|default|diff|full|list|missing|new|profilable|profilable-command|profilable-metadata ]
[ --ignoreadvanced ]
[ --ignoreunsupported ]
[ --ignorelocal ]
[ --mergedconfig ]
[ --metadataprofile String ]
[ --sinceversion String ]
[ --showdeprecated ]
[ --showunsupported ]
[ --validate ]
[ --withsummary ]
[ --withcomments ]
[ --withgeneralpreamble ]
[ --withlocalpreamble ]
[ --withspaces ]
[ --unconfigured ]
[ --withversions ]
[ COMMON_OPTIONS ]
[ String ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--atversion *String*

Specify an LVM version in x.y.z format where x is the major version, the y is the minor version and z is the patchlevel (e.g. 2.2.106). When configuration is displayed, the configuration settings recognized at this LVM version will be considered only. This can be used to display a configuration that a certain LVM version understands and which does not contain any newer settings for which LVM would issue a warning message when checking the configuration.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--file *String*

Write output to the named file.

-h|--help

Display help text.

--ignoreadvanced

Exclude advanced configuration settings from the output.

--ignorelocal

Ignore the local section. The local section should be defined in the lvmlocal.conf file, and should contain config settings specific to the local host which should not be copied to other hosts.

--ignoreunsupported

Exclude unsupported configuration settings from the output. These settings are either used for debugging and development purposes only or their support is not yet complete and they are not meant to be used in production. The **current** and **diff** types include unsupported settings in their output by default, all the other types ignore unsupported settings.

-l|--list

List config settings with summarizing comment. This is the same as using options --typeconfig list --withsummary.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--mergedconfig

When the command is run with --config and/or --commandprofile (or using LVM_COMMAND_PROFILE environment variable), --profile, or --metadataprofile, merge all the contents of the "config cascade" before displaying it. Without merging, only the configuration at the front of the cascade is displayed. See **lvm.conf(5)** for more information about config.

--metadataprofile *String*

The metadata profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--showdeprecated

Include deprecated configuration settings in the output. These settings are deprecated after a certain version. If a concrete version is specified with --atversion, deprecated settings are automatically included if the specified version is lower than the version in which the settings were deprecated. The current and diff types include deprecated settings in their output by default, all the other types ignore deprecated settings.

--showunsupported

Include unsupported configuration settings in the output. These settings are either used for debugging or development purposes only, or their support is not yet complete and they are not meant to be used in production. The current and diff types include unsupported settings in their output by default, all the other types ignore unsupported settings.

--sinceversion String

Specify an LVM version in x.y.z format where x is the major version, the y is the minor version and z is the patchlevel (e.g. 2.2.106). This option is currently applicable only with --typeconfig new to display all configuration settings introduced since given version.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--typeconfig current|default|diff|full|list|missing|new|profilable|profilable-command|profilable-metadata

current prints the config settings that would be applied to an lvm command (assuming the command does not override them on the command line.) This includes: settings that have been modified in lvm config files, settings that get their default values from config files, and default settings that have been uncommented in config files. **default** prints all settings with their default values. Changes made in lvm config files are not reflected in the output. Some settings get their default values internally, and these settings are printed as comments. Other settings get their default values from config files, and these settings are not printed as comments. **diff** prints only config settings that have been modified from their default values in config files (the difference between current and default.) **full** prints every setting uncommented and set to the current value, i.e. how it would be used by an lvm command. This includes settings modified in config files, settings that usually get defaults internally, and settings that get defaults from config files. **list** prints all config names without values. **missing** prints settings that are missing from the lvm config files. A missing setting that usually gets its default from config files is printed uncommented and set to the internal default. Settings that get their default internally and are not set in config files are printed commented with the internal default. **new** prints config settings that have been added since the lvm version specified by --sinceversion. They are printed with their default values. **profilable** prints settings with their default values that can be set from a profile. **profilable-command** prints settings with their default values that can be set from a command profile. **profilable-metadata** prints settings with their default values that can be set from a metadata profile. Also see **lvm.conf(5)**.

--unconfigured

Internal option used for generating config file during build.

--validate

Validate current configuration used and exit with appropriate return code. The validation is done only for the configuration at the front of the "config cascade". To validate the whole merged configuration tree, also use --mergedconfig. The validation is done even if lvm.conf config/checks is disabled.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

--withcomments

Display a full comment for each configuration node. For deprecated settings, also display comments about deprecation.

--withgeneralpreamble

Include general config file preamble.

--withlocalpreamble

Include local config file preamble.

--withspaces

Where appropriate, add more spaces in output for better readability.

--withsummary

Display a one line comment for each configuration node.

--withversions

Also display a comment containing the version of introduction for each configuration node. If the setting is deprecated, also display the version since which it is deprecated.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*String*

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkKmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

`lvmraid` — LVM RAID

DESCRIPTION

lvm(8) RAID is a way to create a Logical Volume (LV) that uses multiple physical devices to improve performance or tolerate device failures. In LVM, the physical devices are Physical Volumes (PVs) in a single Volume Group (VG).

How LV data blocks are placed onto PVs is determined by the RAID level. RAID levels are commonly referred to as 'raid' followed by a number, e.g. raid1, raid5 or raid6. Selecting a RAID level involves making tradeoffs among: physical device requirements, fault tolerance, and performance. A description of the RAID levels can be found at

www.snia.org/sites/default/files/SNIA_DDF_Technical_Position_v2.0.pdf

LVM RAID uses both Device Mapper (DM) and Multiple Device (MD) drivers from the Linux kernel. DM is used to create and manage visible LVM devices, and MD is used to place data on physical devices.

LVM creates hidden LVs (dm devices) layered between the visible LV and physical devices. LVs in the middle layers are called sub LVs. For LVM raid, a sub LV pair to store data and metadata (raid superblock and write intent bitmap) is created per raid image/leg (see `lvs` command examples below).

Create a RAID LV

To create a RAID LV, use `lvcreate` and specify an LV type. The LV type corresponds to a RAID level. The basic RAID levels that can be used are: **raid0, raid1, raid4, raid5, raid6, raid10**.

lvcreate --type RaidLevel [OPTIONS] --name Name --size Size VG [PVs]

To display the LV type of an existing LV, run:

lvs -o name,segtype LV

(The LV type is also referred to as "segment type" or "segtype".)

LVs can be created with the following types:

raid0

Also called striping, raid0 spreads LV data across multiple devices in units of stripe size. This is used to increase performance. LV data will be lost if any of the devices fail.

lvcreate --type raid0 [--stripes Number --stripesize Size] VG [PVs]

--stripes specifies the number of devices to spread the LV across.

--stripesize specifies the size of each stripe in kilobytes. This is the amount of data that is written to one device before moving to the next.

PVs specifies the devices to use. If not specified, lvm will choose *Number* devices, one for each stripe based on the number of PVs available or supplied.

raid1

Also called mirroring, raid1 uses multiple devices to duplicate LV data. The LV data remains available if all but one of the devices fail. The minimum number of devices (i.e. sub LV pairs) required is 2.

lvmcreate --type raid1 [--mirrors Number] VG [PVs]

--mirrors specifies the number of mirror images in addition to the original LV image, e.g. **--mirrors 1** means there are two images of the data, the original and one mirror image.

PVs specifies the devices to use. If not specified, lvm will choose *Number* devices, one for each image.

raid4

raid4 is a form of striping that uses an extra, first device dedicated to storing parity blocks. The LV data remains available if one device fails. The parity is used to recalculate data that is lost from a single device. The minimum number of devices required is 3.

lvmcreate --type raid4 [--stripes Number --stripesize Size] VG [PVs]

--stripes specifies the number of devices to use for LV data. This does not include the extra device lvm adds for storing parity blocks. A raid4 LV with *Number* stripes requires *Number+1* devices. *Number* must be 2 or more.

--stripesize specifies the size of each stripe in kilobytes. This is the amount of data that is written to one device before moving to the next.

PVs specifies the devices to use. If not specified, lvm will choose *Number+1* separate devices.

raid4 is called non-rotating parity because the parity blocks are always stored on the same device.

raid5

raid5 is a form of striping that uses an extra device for storing parity blocks. LV data and parity blocks are stored on each device, typically in a rotating pattern for performance reasons. The LV data remains available if one device fails. The parity is used to recalculate data that is lost from a single device. The minimum number of devices required is 3 (unless converting from 2 legged raid1 to reshape to more stripes; see reshaping).

lvmcreate --type raid5 [--stripes Number --stripesize Size] VG [PVs]

--stripes specifies the number of devices to use for LV data. This does not include the extra device lvm adds for storing parity blocks. A raid5 LV with *Number* stripes requires *Number+1* devices. *Number* must be 2 or more.

--stripesize specifies the size of each stripe in kilobytes. This is the amount of data that is written to one device before moving to the next.

PVs specifies the devices to use. If not specified, lvm will choose *Number+1* separate devices.

raid5 is called rotating parity because the parity blocks are placed on different devices in a round-robin sequence. There are variations of raid5 with different algorithms for placing the parity blocks. The default variant is raid5_ls (raid5 left symmetric, which is a rotating parity 0 with data restart.) See **RAID5 variants** below.

raid6

raid6 is a form of striping like raid5, but uses two extra devices for parity blocks. LV data and parity blocks are stored on each device, typically in a rotating pattern for performance reasons. The LV data remains available if up to two devices fail. The parity is used to recalculate data that is lost from one or two devices. The minimum number of devices required is 5.

lvmcreate --type raid6 [--stripes Number --stripesize Size] VG [PVs]

--stripes specifies the number of devices to use for LV data. This does not include the extra two devices lvm adds for storing parity blocks. A raid6 LV with *Number* stripes requires *Number+2* devices. *Number* must be 3 or more.

--stripesize specifies the size of each stripe in kilobytes. This is the amount of data that is written to one device before moving to the next.

PVs specifies the devices to use. If not specified, lvm will choose *Number+2* separate devices.

Like raid5, there are variations of raid6 with different algorithms for placing the parity blocks. The default variant is raid6_zr (raid6 zero restart, aka left symmetric, which is a rotating parity 0 with data restart.) See **RAID6 variants** below.

raid10

raid10 is a combination of raid1 and raid0, striping data across mirrored devices. LV data remains available if one or more devices remain in each mirror set. The minimum number of devices required is 4.

lvmcreate --type raid10
[--mirrors NumberMirrors]
[--stripes NumberStripes --stripesize Size]
VG [PVs]

--mirrors specifies the number of mirror images within each stripe. e.g. --mirrors 1 means there are two images of the data, the original and one mirror image.

--stripes specifies the total number of devices to use in all raid1 images (not the number of raid1 devices to spread the LV across, even though that is the effective result). The number of devices in each raid1 mirror will be *NumberStripes/NumberMirrors+1*, e.g. mirrors 1 and stripes 4 will stripe data across two raid1 mirrors, where each mirror is 2 devices.

--stripesize specifies the size of each stripe in kilobytes. This is the amount of data that is written to one device before moving to the next.

PVs specifies the devices to use. If not specified, lvm will choose the necessary devices. Devices are used to create mirrors in the order listed, e.g. for mirrors 1, stripes 2, listing PV1 PV2 PV3 PV4 results in mirrors PV1/PV2 and PV3/PV4.

RAID10 is not mirroring on top of stripes, which would be RAID01, which is less tolerant of device failures.

Synchronization

Synchronization is the process that makes all the devices in a RAID LV consistent with each other.

In a RAID1 LV, all mirror images should have the same data. When a new mirror image is added, or a mirror image is missing data, then images need to be synchronized. Data blocks are copied from an existing image to a new or outdated image to make them match.

In a RAID 4/5/6 LV, parity blocks and data blocks should match based on the parity calculation. When the devices in a RAID LV change, the data and parity blocks can become inconsistent and need to be synchronized. Correct blocks are read, parity is calculated, and recalculated blocks are written.

The RAID implementation keeps track of which parts of a RAID LV are synchronized. When a RAID LV is first created and activated the first synchronization is called initialization. A pointer stored in the raid metadata keeps track of the initialization process thus allowing it to be restarted after a deactivation of the RaidLV or a crash. Any writes to the RaidLV dirties the respective region of the write intent bitmap which allow for fast recovery of the regions after a crash. Without this, the entire LV would need to be synchronized every time it was activated.

Automatic synchronization happens when a RAID LV is activated, but it is usually partial because the bitmaps reduce the areas that are checked. A full sync becomes necessary when devices in the RAID LV are replaced.

The synchronization status of a RAID LV is reported by the following command, where "Cpy%Sync" = "100%" means sync is complete:

```
lvs -a -o name,sync_percent
```

Scrubbing

Scrubbing is a full scan of the RAID LV requested by a user. Scrubbing can find problems that are missed by partial synchronization.

Scrubbing assumes that RAID metadata and bitmaps may be inaccurate, so it verifies all RAID metadata, LV data, and parity blocks. Scrubbing can find inconsistencies caused by hardware errors or degradation. These kinds of problems may be undetected by automatic synchronization which excludes areas outside of the RAID write-intent bitmap.

The command to scrub a RAID LV can operate in two different modes:

```
lvchange --syncaction check|repair LV
```

check Check mode is read-only and only detects inconsistent areas in the RAID LV, it does not correct them.

repair Repair mode checks and writes corrected blocks to synchronize any inconsistent areas.

Scrubbing can consume a lot of bandwidth and slow down application I/O on the RAID LV. To control the I/O rate used for scrubbing, use:

--maxrecoveryrate *Size[k|UNIT]*

Sets the maximum recovery rate for a RAID LV. *Size* is specified as an amount per second for each device in the array. If no suffix is given, then KiB/sec/device is used. Setting the recovery rate to **0** means it will be unbounded.

--minrecoveryrate *Size[k|UNIT]*

Sets the minimum recovery rate for a RAID LV. *Size* is specified as an amount per second for each device in the array. If no suffix is given, then KiB/sec/device is used. Setting the recovery rate to **0** means it will be unbounded.

To display the current scrubbing in progress on an LV, including the syncaction mode and percent complete, run:

```
lvs -a -o name,raid_sync_action,sync_percent
```

After scrubbing is complete, to display the number of inconsistent blocks found, run:

```
lvs -o name,raid_mismatch_count
```

Also, if mismatches were found, the lvs attr field will display the letter "m" (mismatch) in the 9th position, e.g.

```
# lvs -o name,vgname,segtype,attr vg/lv
LV VG Type Attr
lv vg raid1 Rwi-a-r-m-
```

Scrubbing Limitations

The **check** mode can only report the number of inconsistent blocks, it cannot report which blocks are inconsistent. This makes it impossible to know which device has errors, or if the errors affect file system data, metadata or nothing at all.

The **repair** mode can make the RAID LV data consistent, but it does not know which data is correct. The result may be consistent but incorrect data. When two different blocks of data must be made consistent, it chooses the block from the device that would be used during RAID initialization. However, if the PV holding corrupt data is known, lvchange --rebuild can be used in place of scrubbing to reconstruct the data on the bad device.

Future developments might include:

Allowing a user to choose the correct version of data during repair.

Using a majority of devices to determine the correct version of data to use in a 3-way RAID1 or RAID6 LV.

Using a checksumming device to pin-point when and where an error occurs, allowing it to be rewritten.

SubLVs

An LV is often a combination of other hidden LVs called SubLVs. The SubLVs either use physical devices, or are built from other SubLVs themselves. SubLVs hold LV data blocks, RAID parity blocks, and RAID metadata. SubLVs are generally hidden, so the lvs -a option is required to display them:

lvs -a -o name,segtype,devices

SubLV names begin with the visible LV name, and have an automatic suffix indicating its role:

- SubLVs holding LV data or parity blocks have the suffix _rimage_#. These SubLVs are sometimes referred to as DataLVs.
- SubLVs holding RAID metadata have the suffix _rmeta#. RAID metadata includes superblock information, RAID type, bitmap, and device health information. These SubLVs are sometimes referred to as MetaLVs.

SubLVs are an internal implementation detail of LVM. The way they are used, constructed and named may change.

The following examples show the SubLV arrangement for each of the basic RAID LV types, using the fewest number of devices allowed for each.

Examples**raid0**

Each rimage SubLV holds a portion of LV data. No parity is used. No RAID metadata is used.

```
# lvcreate --type raid0 --stripes 2 --name lvr0 ...
```

```
# lvs -a -o name,segtype,devices
lvr0      raid0  lvr0_rimage_0(0),lvr0_rimage_1(0)
[lvr0_rimage_0] linear /dev/sda(...)
[lvr0_rimage_1] linear /dev/sdb(...)
```

raid1

Each rimage SubLV holds a complete copy of LV data. No parity is used. Each rmeta SubLV holds RAID metadata.

```
# lvcreate --type raid1 --mirrors 1 --name lvr1 ...
```

```
# lvs -a -o name,segtype,devices
lvr1      raid1  lvr1_rimage_0(0),lvr1_rimage_1(0)
[lvr1_rimage_0] linear /dev/sda(...)
[lvr1_rimage_1] linear /dev/sdb(...)
[lvr1_rmeta_0] linear /dev/sda(...)
[lvr1_rmeta_1] linear /dev/sdb(...)
```

raid4

At least three rimage SubLVs each hold a portion of LV data and one rimage SubLV holds parity. Each rmeta SubLV holds RAID metadata.

```
# lvcreate --type raid4 --stripes 2 --name lvr4 ...
```

```
# lvs -a -o name,segtype,devices
lvr4      raid4  lvr4_rimage_0(0),\
            lvr4_rimage_1(0),\
            lvr4_rimage_2(0)
[lvr4_rimage_0] linear /dev/sda(...)
[lvr4_rimage_1] linear /dev/sdb(...)
```

```
[lvr4_rimage_2] linear /dev/sdc(...)
[lvr4_rmeta_0] linear /dev/sda(...)
[lvr4_rmeta_1] linear /dev/sdb(...)
[lvr4_rmeta_2] linear /dev/sdc(...)
```

raid5

At least three rimage SubLVs each typically hold a portion of LV data and parity (see section on raid5)
Each rmeta SubLV holds RAID metadata.

```
# lvcreate --type raid5 --stripes 2 --name lvr5 ...
```

```
# lvs -a -o name,segtype,devices
lvr5      raid5  lvr5_rimage_0(0),\
            lvr5_rimage_1(0),\
            lvr5_rimage_2(0)
[lvr5_rimage_0] linear /dev/sda(...)
[lvr5_rimage_1] linear /dev/sdb(...)
[lvr5_rimage_2] linear /dev/sdc(...)
[lvr5_rmeta_0] linear /dev/sda(...)
[lvr5_rmeta_1] linear /dev/sdb(...)
[lvr5_rmeta_2] linear /dev/sdc(...)
```

raid6

At least five rimage SubLVs each typically hold a portion of LV data and parity. (see section on raid6)
Each rmeta SubLV holds RAID metadata.

```
# lvcreate --type raid6 --stripes 3 --name lvr6
```

```
# lvs -a -o name,segtype,devices
lvr6      raid6  lvr6_rimage_0(0),\
            lvr6_rimage_1(0),\
            lvr6_rimage_2(0),\
            lvr6_rimage_3(0),\
            lvr6_rimage_4(0),\
            lvr6_rimage_5(0)
[lvr6_rimage_0] linear /dev/sda(...)
[lvr6_rimage_1] linear /dev/sdb(...)
[lvr6_rimage_2] linear /dev/sdc(...)
[lvr6_rimage_3] linear /dev/sdd(...)
[lvr6_rimage_4] linear /dev/sde(...)
[lvr6_rimage_5] linear /dev/sdf...
[lvr6_rmeta_0] linear /dev/sda(...)
[lvr6_rmeta_1] linear /dev/sdb(...)
[lvr6_rmeta_2] linear /dev/sdc...
[lvr6_rmeta_3] linear /dev/sdd...
[lvr6_rmeta_4] linear /dev/sde...
[lvr6_rmeta_5] linear /dev/sdf...)
```

raid10

At least four rimage SubLVs each hold a portion of LV data. No parity is used. Each rmeta SubLV holds RAID metadata.

```
# lvcreate --type raid10 --stripes 2 --mirrors 1 --name lvr10
```

```
# lvs -a -o name,segtype,devices
lvr10      raid10 lvr10_rimage_0(0),\
             lvr10_rimage_1(0),\
             lvr10_rimage_2(0),\
             lvr10_rimage_3(0)
[lvr10_rimage_0] linear /dev/sda(...)

```

Device Failure

Physical devices in a RAID LV can fail or be lost for multiple reasons. A device could be disconnected, permanently failed, or temporarily disconnected. The purpose of RAID LVs (levels 1 and higher) is to continue operating in a degraded mode, without losing LV data, even after a device fails. The number of devices that can fail without the loss of LV data depends on the RAID level:

- RAID0 (striped) LVs cannot tolerate losing any devices. LV data will be lost if any devices fail.
- RAID1 LVs can tolerate losing all but one device without LV data loss.
- RAID4 and RAID5 LVs can tolerate losing one device without LV data loss.
- RAID6 LVs can tolerate losing two devices without LV data loss.
- RAID10 is variable, and depends on which devices are lost. It stripes across multiple mirror groups with raid1 layout thus it can tolerate losing all but one device in each of these groups without LV data loss.

If a RAID LV is missing devices, or has other device-related problems, lvs reports this in the health_status (and attr) fields:

lvs -o name,lv_health_status

partial

Devices are missing from the LV. This is also indicated by the letter "p" (partial) in the 9th position of the lvs attr field.

refresh needed

A device was temporarily missing but has returned. The LV needs to be refreshed to use the device again (which will usually require partial synchronization). This is also indicated by the letter "r" (refresh needed) in the 9th position of the lvs attr field. See **Refreshing an LV**. This could also indicate a problem with the device, in which case it should be replaced, see **Replacing Devices**.

mismatches exist

See **Scrubbing**.

Most commands will also print a warning if a device is missing, e.g.

WARNING: Device for PV uItL3Z-wBME-DQy0-... not found or rejected ...

This warning will go away if the device returns or is removed from the VG (see **vgreduce --removemissing**).

Activating an LV with missing devices

A RAID LV that is missing devices may be activated or not, depending on the "activation mode" used in lvchange:

lvchange -ay --activationmode complete|degraded|partial LV

complete

The LV is only activated if all devices are present.

degraded

The LV is activated with missing devices if the RAID level can tolerate the number of missing devices without LV data loss.

partial

The LV is always activated, even if portions of the LV data are missing because of the missing device(s). This should only be used to perform extreme recovery or repair operations.

lvm.conf(5) activation/activation_mode

controls the activation mode when not specified by the command.

The default value is printed by:

lvmconfig --type default activation/activation_mode

Replacing Devices

Devices in a RAID LV can be replaced by other devices in the VG. When replacing devices that are no longer visible on the system, use lvconvert --repair. When replacing devices that are still visible, use lvconvert --replace. The repair command will attempt to restore the same number of data LVs that were previously in the LV. The replace option can be repeated to replace multiple PVs. Replacement devices can be optionally listed with either option.

lvconvert --repair LV [NewPVs]

lvconvert --replace OldPV LV [NewPV]

lvconvert --replace OldPV1 --replace OldPV2 LV [NewPVs]

New devices require synchronization with existing devices, see **Synchronization**.

Refreshing an LV

Refreshing a RAID LV clears any transient device failures (device was temporarily disconnected) and returns the LV to its fully redundant mode. Restoring a device will usually require at least partial synchronization (see **Synchronization**). Failure to clear a transient failure results in the RAID LV operating in degraded mode until it is reactivated. Use the lvchange command to refresh an LV:

lvchange --refresh LV

```
# lvs -o name,vgname,segtype,attr,size vg
```

```

LV VG Type Attr   LSize
lv vg  raid1 Rwi-a-r-r- 100.00g

# lvchange --refresh vg/lv

# lvs -o name,vgname,segtype,attr,size vg
LV VG Type Attr   LSize
lv vg  raid1 Rwi-a-r--- 100.00g

```

Automatic repair

If a device in a RAID LV fails, device-mapper in the kernel notifies the **dmeventd(8)** monitoring process (see **Monitoring**). dmeventd can be configured to automatically respond using:

lvm.conf(5) activation/raid_fault_policy

Possible settings are:

warn

A warning is added to the system log indicating that a device has failed in the RAID LV. It is left to the user to repair the LV, e.g. replace failed devices.

allocate

dmeventd automatically attempts to repair the LV using spare devices in the VG. Note that even a transient failure is treated as a permanent failure under this setting. A new device is allocated and full synchronization is started.

The specific command run by dmeventd to warn or repair is:

lvconvert --repair --use-policies LV

Corrupted Data

Data on a device can be corrupted due to hardware errors without the device ever being disconnected or there being any fault in the software. This should be rare, and can be detected (see **Scrubbing**).

Rebuild specific PVs

If specific PVs in a RAID LV are known to have corrupt data, the data on those PVs can be reconstructed with:

lvchange --rebuild PV LV

The rebuild option can be repeated with different PVs to replace the data on multiple PVs.

Monitoring

When a RAID LV is activated the **dmeventd(8)** process is started to monitor the health of the LV. Various events detected in the kernel can cause a notification to be sent from device-mapper to the monitoring process, including device failures and synchronization completion (e.g. for initialization or scrubbing).

The LVM configuration file contains options that affect how the monitoring process will respond to failure events (e.g. `raid_fault_policy`). It is possible to turn on and off monitoring with `lvchange`, but it is not recommended to turn this off unless you have a thorough knowledge of the consequences.

Configuration Options

There are a number of options in the LVM configuration file that affect the behavior of RAID LVs. The tunable options are listed below. A detailed description of each can be found in the LVM configuration file itself.

```
mirror_sectype_default
raid10_sectype_default
raid_region_size
raid_fault_policy
activation_mode
```

Data Integrity

The device mapper integrity target can be used in combination with RAID levels 1,4,5,6,10 to detect and correct data corruption in RAID images. A dm-integrity layer is placed above each RAID image, and an extra sub LV is created to hold integrity metadata (data checksums) for each RAID image. When data is read from an image, integrity checksums are used to detect corruption. If detected, dm-raid reads the data from another (good) image to return to the caller. dm-raid will also automatically write the good data back to the image with bad data to correct the corruption.

When creating a RAID LV with integrity, or adding integrity, space is required for integrity metadata. Every 500MB of LV data requires an additional 4MB to be allocated for integrity metadata, for each RAID image.

Create a RAID LV with integrity:

```
lvcreate --type raidN --raidintegrity y
```

Add integrity to an existing RAID LV:

```
lvconvert --raidintegrity y LV
```

Remove integrity from a RAID LV:

```
lvconvert --raidintegrity n LV
```

Integrity options

--raidintegritymode journal|bitmap

Use a journal (default) or bitmap for keeping integrity checksums consistent in case of a crash. The bitmap areas are recalculated after a crash, so corruption in those areas would not be detected. A journal does not have this problem. The journal mode doubles writes to storage, but can improve performance for scattered writes packed into a single journal write. bitmap mode can in theory achieve full write throughput of the device, but would not benefit from the potential scattered write optimization.

--raidintegrityblocksize 512|1024|2048|4096

The block size to use for dm-integrity on raid images. The integrity block size should usually match the device logical block size, or the file system sector/block sizes. It may be less than the file system sector/block size, but not less than the device logical block size. Possible values: 512, 1024, 2048, 4096.

Integrity initialization

When integrity is added to an LV, the kernel needs to initialize the integrity metadata (checksums) for all blocks in the LV. The data corruption checking performed by dm-integrity will only operate on areas of the

LV that are already initialized. The progress of integrity initialization is reported by the "syncpercent" LV reporting field (and under the Cpy%Sync lvs column.)

Integrity limitations

To work around some limitations, it is possible to remove integrity from the LV, make the change, then add integrity again. (Integrity metadata would need to be initialized when added again.)

LVM must be able to allocate the integrity metadata sub LV on a single PV that is already in use by the associated RAID image. This can potentially cause a problem during lvextend if the original PV holding the image and integrity metadata is full. To work around this limitation, remove integrity, extend the LV, and add integrity again.

Additional RAID images can be added to raid1 LVs, but not to other raid levels.

A raid1 LV with integrity cannot be converted to linear (remove integrity to do this.)

RAID LVs with integrity cannot yet be used as sub LVs with other LV types.

The following are not yet permitted on RAID LVs with integrity: lvreduce, pvmove, snapshots, splitmirror, raid syncaction commands, raid rebuild.

RAID1 Tuning

A RAID1 LV can be tuned so that certain devices are avoided for reading while all devices are still written to.

lvchange --[raid]writemostly PV[:y|n|t] LV

The specified device will be marked as "write mostly", which means that reading from this device will be avoided, and other devices will be preferred for reading (unless no other devices are available.) This minimizes the I/O to the specified device.

If the PV name has no suffix, the write mostly attribute is set. If the PV name has the suffix :**n**, the write mostly attribute is cleared, and the suffix :**t** toggles the current setting.

The write mostly option can be repeated on the command line to change multiple devices at once.

To report the current write mostly setting, the lvs attr field will show the letter "w" in the 9th position when write mostly is set:

lvs -a -o name,attr

When a device is marked write mostly, the maximum number of outstanding writes to that device can be configured. Once the maximum is reached, further writes become synchronous. When synchronous, a write to the LV will not complete until writes to all the mirror images are complete.

lvchange --[raid]writebehind Number LV

To report the current write behind setting, run:

lvs -o name,raid_write_behind

When write behind is not configured, or set to 0, all LV writes are synchronous.

RAID Takeover

RAID takeover is converting a RAID LV from one RAID level to another, e.g. raid5 to raid6. Changing the RAID level is usually done to increase or decrease resilience to device failures or to restripe LVs. This is done using `lvconvert` and specifying the new RAID level as the LV type:

```
lvconvert --type RaidLevel LV [PVs]
```

The most common and recommended RAID takeover conversions are:

linear to raid1

Linear is a single image of LV data, and converting it to raid1 adds a mirror image which is a direct copy of the original linear image.

striped/raid0 to raid4/5/6

Adding parity devices to a striped volume results in raid4/5/6.

Unnatural conversions that are not recommended include converting between striped and non-striped types. This is because file systems often optimize I/O patterns based on device striping values. If those values change, it can decrease performance.

Converting to a higher RAID level requires allocating new SubLVs to hold RAID metadata, and new SubLVs to hold parity blocks for LV data. Converting to a lower RAID level removes the SubLVs that are no longer needed.

Conversion often requires full synchronization of the RAID LV (see [Synchronization](#)). Converting to RAID1 requires copying all LV data blocks to N new images on new devices. Converting to a parity RAID level requires reading all LV data blocks, calculating parity, and writing the new parity blocks. Synchronization can take a long time depending on the throughput of the devices used and the size of the RaidLV. It can degrade performance (rate controls also apply to conversion; see `--minrecoverystart` and `--maxrecoverystart`.)

Warning: though it is possible to create **striped** LVs with up to 128 stripes, a maximum of 64 stripes can be converted to **raid0**, 63 to **raid4/5** and 62 to **raid6** because of the added parity SubLVs. **A striped** LV with a maximum of 32 stripes can be converted to **raid10**.

The following takeover conversions are currently possible:

- between striped and raid0.
- between linear and raid1.
- between mirror and raid1.
- between raid1 with two images and raid4/5.
- between striped/raid0 and raid4.
- between striped/raid0 and raid5.
- between striped/raid0 and raid6.
- between raid4 and raid5.
- between raid4/raid5 and raid6.
- between striped/raid0 and raid10.
- between striped and raid4.

Indirect conversions

Converting from one raid level to another may require multiple steps, converting first to intermediate raid levels.

linear to raid6

To convert an LV from linear to raid6:

1. convert to raid1 with two images
2. convert to raid5 (internally raid5_ls) with two images
3. convert to raid5 with three or more stripes (reshape)
4. convert to raid6 (internally raid6_ls_6)
5. convert to raid6 (internally raid6_zr, reshape)

The commands to perform the steps above are:

1. lvconvert --type raid1 --mirrors 1 LV
2. lvconvert --type raid5 LV
3. lvconvert --stripes 3 LV
4. lvconvert --type raid6 LV
5. lvconvert --type raid6 LV

The final conversion from raid6_ls_6 to raid6_zr is done to avoid the potential write/recovery performance reduction in raid6_ls_6 because of the dedicated parity device. raid6_zr rotates data and parity blocks to avoid this.

linear to striped

To convert an LV from linear to striped:

1. convert to raid1 with two images
2. convert to raid5_n
3. convert to raid5_n with five 128k stripes (reshape)
4. convert raid5_n to striped

The commands to perform the steps above are:

1. lvconvert --type raid1 --mirrors 1 LV
2. lvconvert --type raid5_n LV
3. lvconvert --stripes 5 --stripesize 128k LV
4. lvconvert --type striped LV

The raid5_n type in step 2 is used because it has dedicated parity SubLVs at the end, and can be converted to striped directly. The stripe size is increased in step 3 to add extra space for the conversion process. This step grows the LV size by a factor of five. After conversion, this extra space can be reduced (or used to grow the file system using the LV).

Reversing these steps will convert a striped LV to linear.

raid6 to striped

To convert an LV from raid6_nr to striped:

1. convert to raid6_n_6
2. convert to striped

The commands to perform the steps above are:

1. lvconvert --type raid6_n_6 LV
2. lvconvert --type striped LV

Examples

Converting an LV from **linear** to **raid1**.

```
# lvs -a -o name,segtype,size vg
  LV  Type  LSize
  lv  linear 300.00g

# lvconvert --type raid1 --mirrors 1 vg/lv

# lvs -a -o name,segtype,size vg
  LV      Type  LSize
  lv      raid1  300.00g
  [lv_rimage_0] linear 300.00g
  [lv_rimage_1] linear 300.00g
  [lv_rmeta_0]  linear  3.00m
  [lv_rmeta_1]  linear  3.00m
```

Converting an LV from **mirror** to **raid1**.

```
# lvs -a -o name,segtype,size vg
  LV      Type  LSize
  lv      mirror 100.00g
  [lv_mimage_0] linear 100.00g
  [lv_mimage_1] linear 100.00g
  [lv_mlog]    linear  3.00m

# lvconvert --type raid1 vg/lv

# lvs -a -o name,segtype,size vg
  LV      Type  LSize
  lv      raid1  100.00g
  [lv_rimage_0] linear 100.00g
  [lv_rimage_1] linear 100.00g
  [lv_rmeta_0]  linear  3.00m
  [lv_rmeta_1]  linear  3.00m
```

Converting an LV from **linear** to **raid1** (with 3 images).

```
# lvconvert --type raid1 --mirrors 2 vg/lv
```

Converting an LV from **striped** (with 4 stripes) to **raid6_n_6**.

```
# lvcreate --stripes 4 -L64M -n lv vg

# lvconvert --type raid6 vg/lv

# lvs -a -o lv_name,segtype,sync_percent,data_copies
  LV      Type  Cpy%Sync #Cpy
  lv      raid6_n_6 100.00   3
  [lv_rimage_0] linear
  [lv_rimage_1] linear
  [lv_rimage_2] linear
  [lv_rimage_3] linear
  [lv_rimage_4] linear
```

```
[lv_rimage_5] linear
[lv_rmeta_0] linear
[lv_rmeta_1] linear
[lv_rmeta_2] linear
[lv_rmeta_3] linear
[lv_rmeta_4] linear
[lv_rmeta_5] linear
```

This convert begins by allocating MetaLVs (rmeta_#) for each of the existing stripe devices. It then creates 2 additional MetaLV/DataLV pairs (rmeta_#/rimage_#) for dedicated raid6 parity.

If rotating data/parity is required, such as with raid6_nr, it must be done by reshaping (see below).

RAID Reshaping

RAID reshaping is changing attributes of a RAID LV while keeping the same RAID level. This includes changing RAID layout, stripe size, or number of stripes.

When changing the RAID layout or stripe size, no new SubLVs (MetaLVs or DataLVs) need to be allocated, but DataLVs are extended by a small amount (typically 1 extent). The extra space allows blocks in a stripe to be updated safely, and not be corrupted in case of a crash. If a crash occurs, reshaping can just be restarted.

(If blocks in a stripe were updated in place, a crash could leave them partially updated and corrupted. Instead, an existing stripe is quiesced, read, changed in layout, and the new stripe written to free space. Once that is done, the new stripe is unquiesced and used.)

Examples

(Command output shown in examples may change.)

Converting raid6_n_6 to raid6_nr with rotating data/parity.

This conversion naturally follows a previous conversion from striped/raid0 to raid6_n_6 (shown above). It completes the transition to a more traditional RAID6.

```
# lvs -o lv_name,segtype,sync_percent,data_copies
  LV      Type    Cpy%Sync #Cpy
  lv      raid6_n_6 100.00    3
  [lv_rimage_0] linear
  [lv_rimage_1] linear
  [lv_rimage_2] linear
  [lv_rimage_3] linear
  [lv_rimage_4] linear
  [lv_rimage_5] linear
  [lv_rmeta_0] linear
  [lv_rmeta_1] linear
  [lv_rmeta_2] linear
  [lv_rmeta_3] linear
  [lv_rmeta_4] linear
  [lv_rmeta_5] linear

# lvconvert --type raid6_nr vg/lv

# lvs -a -o lv_name,segtype,sync_percent,data_copies
```

```

LV      Type   Cpy%Sync #Cpy
lv      raid6_nr 100.00    3
[lv_rimage_0] linear
[lv_rimage_0] linear
[lv_rimage_1] linear
[lv_rimage_1] linear
[lv_rimage_2] linear
[lv_rimage_2] linear
[lv_rimage_3] linear
[lv_rimage_3] linear
[lv_rimage_4] linear
[lv_rimage_5] linear
[lv_rmeta_0] linear
[lv_rmeta_1] linear
[lv_rmeta_2] linear
[lv_rmeta_3] linear
[lv_rmeta_4] linear
[lv_rmeta_5] linear

```

The DataLVs are larger (additional segment in each) which provides space for out-of-place reshaping. The result is:

```

# lvs -a -o lv_name,segtype,seg_pe_ranges,dataoffset
LV      Type   PE Ranges     DOff
lv      raid6_nr lv_rimage_0:0-32 \
          lv_rimage_1:0-32 \
          lv_rimage_2:0-32 \
          lv_rimage_3:0-32
[lv_rimage_0] linear /dev/sda:0-31  2048
[lv_rimage_0] linear /dev/sda:33-33
[lv_rimage_1] linear /dev/sdaa:0-31  2048
[lv_rimage_1] linear /dev/sdaa:33-33
[lv_rimage_2] linear /dev/sdab:1-33  2048
[lv_rimage_3] linear /dev/sdac:1-33  2048
[lv_rmeta_0] linear /dev/sda:32-32
[lv_rmeta_1] linear /dev/sdaa:32-32
[lv_rmeta_2] linear /dev/sdab:0-0
[lv_rmeta_3] linear /dev/sdac:0-0

```

All segments with PE ranges '33-33' provide the out-of-place reshape space. The dataoffset column shows that the data was moved from initial offset 0 to 2048 sectors on each component DataLV.

For performance reasons the raid6_nr RaidLV can be restriped. Convert it from 3-way striped to 5-way-striped.

```

# lvconvert --stripes 5 vg/lv
Using default stripesize 64.00 KiB.
WARNING: Adding stripes to active logical volume vg/lv will \
grow it from 99 to 165 extents!
Run "lvresize -l99 vg/lv" to shrink it or use the additional \
capacity.
Logical volume vg/lv successfully converted.

```

```
# lvs vg/lv
```

```

LV  VG   Attr   LSize  Cpy%Sync
lv  vg    rwi-a-r-s- 652.00m 52.94

# lvs -a -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
LV      Attr     Type   PE Ranges      DOff
lv      rwi-a-r--- raid6_nr lv_rimage_0:0-33 \
                  lv_rimage_1:0-33 \
                  lv_rimage_2:0-33 ... \
                  lv_rimage_5:0-33 \
                  lv_rimage_6:0-33  0
[lv_rimage_0] iwi-aor--- linear /dev/sda:0-32  0
[lv_rimage_0] iwi-aor--- linear /dev/sda:34-34
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:0-32  0
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:34-34
[lv_rimage_2] iwi-aor--- linear /dev/sdab:0-32  0
[lv_rimage_2] iwi-aor--- linear /dev/sdab:34-34
[lv_rimage_3] iwi-aor--- linear /dev/sdac:1-34  0
[lv_rimage_4] iwi-aor--- linear /dev/sdad:1-34  0
[lv_rimage_5] iwi-aor--- linear /dev/sdae:1-34  0
[lv_rimage_6] iwi-aor--- linear /dev/sdaf:1-34  0
[lv_rmeta_0] ewi-aor--- linear /dev/sda:33-33
[lv_rmeta_1] ewi-aor--- linear /dev/sdaa:33-33
[lv_rmeta_2] ewi-aor--- linear /dev/sdab:33-33
[lv_rmeta_3] ewi-aor--- linear /dev/sdac:0-0
[lv_rmeta_4] ewi-aor--- linear /dev/sdad:0-0
[lv_rmeta_5] ewi-aor--- linear /dev/sdae:0-0
[lv_rmeta_6] ewi-aor--- linear /dev/sdaf:0-0

```

Stripes also can be removed from raid5 and 6. Convert the 5-way striped raid6_nr LV to 4-way-striped. The force option needs to be used, because removing stripes (i.e. image SubLVs) from a RaidLV will shrink its size.

```

# lvconvert --stripes 4 vg/lv
Using default stripesize 64.00 KiB.
WARNING: Removing stripes from active logical volume vg/lv will \
shrink it from 660.00 MiB to 528.00 MiB!
THIS MAY DESTROY (PARTS OF) YOUR DATA!
If that leaves the logical volume larger than 206 extents due \
to stripe rounding,
you may want to grow the content afterwards (filesystem etc.)
WARNING: to remove freed stripes after the conversion has finished,\n
you have to run "lvconvert --stripes 4 vg/lv"
Logical volume vg/lv successfully converted.

```

```

# lvs -a -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
LV      Attr     Type   PE Ranges      DOff
lv      rwi-a-r-s- raid6_nr lv_rimage_0:0-33 \
                  lv_rimage_1:0-33 \
                  lv_rimage_2:0-33 ... \
                  lv_rimage_5:0-33 \
                  lv_rimage_6:0-33  0
[lv_rimage_0] Iwi-aor--- linear /dev/sda:0-32  0
[lv_rimage_0] Iwi-aor--- linear /dev/sda:34-34
[lv_rimage_1] Iwi-aor--- linear /dev/sdaa:0-32  0

```

```
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:34-34
[lv_rimage_2] iwi-aor--- linear /dev/sdab:0-32 0
[lv_rimage_2] iwi-aor--- linear /dev/sdab:34-34
[lv_rimage_3] iwi-aor--- linear /dev/sdac:1-34 0
[lv_rimage_4] iwi-aor--- linear /dev/sdad:1-34 0
[lv_rimage_5] iwi-aor--- linear /dev/sdae:1-34 0
[lv_rimage_6] iwi-aor-R- linear /dev/sdaf:1-34 0
[lv_rmeta_0] ewi-aor--- linear /dev/sda:33-33
[lv_rmeta_1] ewi-aor--- linear /dev/sdaa:33-33
[lv_rmeta_2] ewi-aor--- linear /dev/sdab:33-33
[lv_rmeta_3] ewi-aor--- linear /dev/sdac:0-0
[lv_rmeta_4] ewi-aor--- linear /dev/sdad:0-0
[lv_rmeta_5] ewi-aor--- linear /dev/sdae:0-0
[lv_rmeta_6] ewi-aor-R- linear /dev/sdaf:0-0
```

The 's' in column 9 of the attribute field shows the RaidLV is still reshaping. The 'R' in the same column of the attribute field shows the freed image Sub LVs which will need removing once the reshaping finished.

```
# lvs -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
LV Attr Type PE Ranges DOff
lv rwi-a-r-R- raid6_nr lv_rimage_0:0-33 \
    lv_rimage_1:0-33 \
    lv_rimage_2:0-33 ... \
    lv_rimage_5:0-33 \
    lv_rimage_6:0-33 8192
```

Now that the reshape is finished the 'R' attribute on the RaidLV shows images can be removed.

```
# lvs -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
LV Attr Type PE Ranges DOff
lv rwi-a-r-R- raid6_nr lv_rimage_0:0-33 \
    lv_rimage_1:0-33 \
    lv_rimage_2:0-33 ... \
    lv_rimage_5:0-33 \
    lv_rimage_6:0-33 8192
```

This is achieved by repeating the command ("lvconvert --stripes 4 vg/lv" would be sufficient).

```
# lvconvert --stripes 4 vg/lv
Using default stripesize 64.00 KiB.
Logical volume vg/lv successfully converted.
```

```
# lvs -a -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
LV      Attr   Type   PE Ranges   DOff
lv      rwi-a-r--- raid6_nr lv_rimage_0:0-33 \
    lv_rimage_1:0-33 \
    lv_rimage_2:0-33 ... \
    lv_rimage_5:0-33 8192
[lv_rimage_0] iwi-aor--- linear /dev/sda:0-32 8192
[lv_rimage_0] iwi-aor--- linear /dev/sda:34-34
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:0-32 8192
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:34-34
[lv_rimage_2] iwi-aor--- linear /dev/sdab:0-32 8192
[lv_rimage_2] iwi-aor--- linear /dev/sdab:34-34
```

```
[lv_rimage_3] iwi-aor--- linear /dev/sdac:1-34 8192
[lv_rimage_4] iwi-aor--- linear /dev/sdad:1-34 8192
[lv_rimage_5] iwi-aor--- linear /dev/sdae:1-34 8192
[lv_rmeta_0] ewi-aor--- linear /dev/sda:33-33
[lv_rmeta_1] ewi-aor--- linear /dev/sdaa:33-33
[lv_rmeta_2] ewi-aor--- linear /dev/sdab:33-33
[lv_rmeta_3] ewi-aor--- linear /dev/sdac:0-0
[lv_rmeta_4] ewi-aor--- linear /dev/sdad:0-0
[lv_rmeta_5] ewi-aor--- linear /dev/sdae:0-0
```

```
# lvs -a -o lv_name,attr,segtype,reshapelen vg
LV      Attr  Type   RSize
lv      rwi-a-r--- raid6_nr 24.00m
[lv_rimage_0] iwi-aor--- linear  4.00m
[lv_rimage_0] iwi-aor--- linear
[lv_rimage_1] iwi-aor--- linear  4.00m
[lv_rimage_1] iwi-aor--- linear
[lv_rimage_2] iwi-aor--- linear  4.00m
[lv_rimage_2] iwi-aor--- linear
[lv_rimage_3] iwi-aor--- linear  4.00m
[lv_rimage_4] iwi-aor--- linear  4.00m
[lv_rimage_5] iwi-aor--- linear  4.00m
[lv_rmeta_0] ewi-aor--- linear
[lv_rmeta_1] ewi-aor--- linear
[lv_rmeta_2] ewi-aor--- linear
[lv_rmeta_3] ewi-aor--- linear
[lv_rmeta_4] ewi-aor--- linear
[lv_rmeta_5] ewi-aor--- linear
```

Future developments might include automatic removal of the freed images.

If the reshape space shall be removed any lvconvert command not changing the layout can be used:

```
# lvconvert --stripes 4 vg/lv
Using default stripesize 64.00 KiB.
No change in RAID LV vg/lv layout, freeing reshape space.
Logical volume vg/lv successfully converted.
```

```
# lvs -a -o lv_name,attr,segtype,reshapelen vg
LV      Attr  Type   RSize
lv      rwi-a-r--- raid6_nr  0
[lv_rimage_0] iwi-aor--- linear  0
[lv_rimage_0] iwi-aor--- linear
[lv_rimage_1] iwi-aor--- linear  0
[lv_rimage_1] iwi-aor--- linear
[lv_rimage_2] iwi-aor--- linear  0
[lv_rimage_2] iwi-aor--- linear
[lv_rimage_3] iwi-aor--- linear  0
[lv_rimage_4] iwi-aor--- linear  0
[lv_rimage_5] iwi-aor--- linear  0
[lv_rmeta_0] ewi-aor--- linear
[lv_rmeta_1] ewi-aor--- linear
[lv_rmeta_2] ewi-aor--- linear
[lv_rmeta_3] ewi-aor--- linear
```

```
[lv_rmeta_4] ewi-aor--- linear
[lv_rmeta_5] ewi-aor--- linear
```

In case the RaidLV should be converted to striped:

```
# lvconvert --type striped vg/lv
Unable to convert LV vg/lv from raid6_nr to striped.
Converting vg/lv from raid6_nr is directly possible to the \
following layouts:
    raid6_nc
    raid6_zr
    raid6_la_6
    raid6_ls_6
    raid6_ra_6
    raid6_rs_6
    raid6_n_6
```

A direct conversion isn't possible thus the command informed about the possible ones. raid6_n_6 is suitable to convert to striped so convert to it first (this is a reshape changing the raid6 layout from raid6_nr to raid6_n_6).

```
# lvconvert --type raid6_n_6
Using default stripesize 64.00 KiB.
Converting raid6_nr LV vg/lv to raid6_n_6.
Are you sure you want to convert raid6_nr LV vg/lv? [y/n]: y
Logical volume vg/lv successfully converted.
```

Wait for the reshape to finish.

```
# lvconvert --type striped vg/lv
Logical volume vg/lv successfully converted.
```

```
# lvs -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
  LV Attr Type PE Ranges DOff
  lv -wi-a----- striped /dev/sda:2-32 \
    /dev/sdaa:2-32 \
    /dev/sdab:2-32 \
    /dev/sdac:3-33
  lv -wi-a----- striped /dev/sda:34-35 \
    /dev/sdaa:34-35 \
    /dev/sdab:34-35 \
    /dev/sdac:34-35
```

From striped we can convert to raid10

```
# lvconvert --type raid10 vg/lv
Using default stripesize 64.00 KiB.
Logical volume vg/lv successfully converted.
```

```
# lvs -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
  LV Attr Type PE Ranges DOff
  lv rwi-a-r--- raid10 lv_rimage_0:0-32 \
    lv_rimage_4:0-32 \
    lv_rimage_1:0-32 ... \
```

```

lv_rimage_3:0-32 \
lv_rimage_7:0-32 0

# lvs -a -o lv_name,attr,segtype,seg_pe_ranges,dataoffset vg
WARNING: Cannot find matching striped segment for vg/lv_rimage_3.
LV      Attr   Type  PE Ranges    DOff
lv      rwi-a-r--- raid10 lv_rimage_0:0-32 \
                  lv_rimage_4:0-32 \

                  lv_rimage_3:0-32 \
                  lv_rimage_7:0-32 0
[lv_rimage_0] iwi-aor--- linear /dev/sda:2-32  0
[lv_rimage_0] iwi-aor--- linear /dev/sda:34-35
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:2-32  0
[lv_rimage_1] iwi-aor--- linear /dev/sdaa:34-35
[lv_rimage_2] iwi-aor--- linear /dev/sdab:2-32  0
[lv_rimage_2] iwi-aor--- linear /dev/sdab:34-35
[lv_rimage_3] iwi-XXr--- linear /dev/sdac:3-35  0
[lv_rimage_4] iwi-aor--- linear /dev/sdad:1-33  0
[lv_rimage_5] iwi-aor--- linear /dev/sdae:1-33  0
[lv_rimage_6] iwi-aor--- linear /dev/sdaf:1-33  0
[lv_rimage_7] iwi-aor--- linear /dev/sdag:1-33  0
[lv_rmeta_0] ewi-aor--- linear /dev/sda:0-0
[lv_rmeta_1] ewi-aor--- linear /dev/sdaa:0-0
[lv_rmeta_2] ewi-aor--- linear /dev/sdab:0-0
[lv_rmeta_3] ewi-aor--- linear /dev/sdac:0-0
[lv_rmeta_4] ewi-aor--- linear /dev/sdad:0-0
[lv_rmeta_5] ewi-aor--- linear /dev/sdae:0-0
[lv_rmeta_6] ewi-aor--- linear /dev/sdaf:0-0
[lv_rmeta_7] ewi-aor--- linear /dev/sdag:0-0

```

raid10 allows to add stripes but can't remove them.

A more elaborate example to convert from linear to striped with interim conversions to raid1 then raid5 followed by restripe (4 steps).

We start with the linear LV.

```
# lvs -a -o name,size,segtype,syncpercent,datastripes,\
      stripesize,reshapeable,devices vg
LV  LSize  Type  Cpy%Sync #DStr Stripe RSize Devices
lv  128.00m linear     1   0    /dev/sda(0)
```

Then convert it to a 2-way raid1.

```
# lvconvert --mirrors 1 vg/lv
Logical volume vg/lv successfully converted.
```

```
# lvs -a -o name,size,segtype,datastripes,\
      stripesize,reshapeable,devices vg
LV      LSize  Type  #DStr Stripe RSize Devices
lv      128.00m raid1    2   0    lv_rimage_0(0),\
                  lv_rimage_1(0)
```

```
[lv_rimage_0] 128.00m linear 1 0 /dev/sda(0)
[lv_rimage_1] 128.00m linear 1 0 /dev/sdhx(1)
[lv_rmeta_0] 4.00m linear 1 0 /dev/sda(32)
[lv_rmeta_1] 4.00m linear 1 0 /dev/sdhx(0)
```

Once the raid1 LV is fully synchronized we convert it to raid5_n (only 2-way raid1 LVs can be converted to raid5). We select raid5_n here because it has dedicated parity SubLVs at the end and can be converted to striped directly without any additional conversion.

```
# lvconvert --type raid5_n vg/lv
Using default stripesize 64.00 KiB.
Logical volume vg/lv successfully converted.
```

```
# lvs -a -o name,size,segtype,syncpercent,datastripes,\
      stripesize,reshapelevenle,devices vg
  LV      LSize  Type #DStr Stripe RSize Devices
  lv      128.00m raid5_n 1 64.00k 0 lv_rimage_0(0),\
                  lv_rimage_1(0)
[lv_rimage_0] 128.00m linear 1 0 0 /dev/sda(0)
[lv_rimage_1] 128.00m linear 1 0 0 /dev/sdhx(1)
[lv_rmeta_0] 4.00m linear 1 0 /dev/sda(32)
[lv_rmeta_1] 4.00m linear 1 0 /dev/sdhx(0)
```

Now we'll change the number of data stripes from 1 to 5 and request 128K stripe size in one command. This will grow the size of the LV by a factor of 5 (we add 4 data stripes to the one given). That additional space can be used by e.g. growing any contained filesystem or the LV can be reduced in size after the re-shaping conversion has finished.

```
# lvconvert --stripesize 128k --stripes 5 vg/lv
Converting stripesize 64.00 KiB of raid5_n LV vg/lv to 128.00 KiB.
WARNING: Adding stripes to active logical volume vg/lv will grow \
it from 32 to 160 extents!
Run "lvresize -l32 vg/lv" to shrink it or use the additional capacity.
Logical volume vg/lv successfully converted.
```

```
# lvs -a -o name,size,segtype,datastripes,\
      stripesize,reshapelevenle,devices
  LV      LSize  Type #DStr Stripe RSize Devices
  lv      640.00m raid5_n 5 128.00k 6 lv_rimage_0(0),\
                  lv_rimage_1(0),\
                  lv_rimage_2(0),\
                  lv_rimage_3(0),\
                  lv_rimage_4(0),\
                  lv_rimage_5(0)
[lv_rimage_0] 132.00m linear 1 0 1 /dev/sda(33)
[lv_rimage_0] 132.00m linear 1 0 /dev/sda(0)
[lv_rimage_1] 132.00m linear 1 0 1 /dev/sdhx(33)
[lv_rimage_1] 132.00m linear 1 0 /dev/sdhx(1)
[lv_rimage_2] 132.00m linear 1 0 1 /dev/sdhw(33)
[lv_rimage_2] 132.00m linear 1 0 /dev/sdhw(1)
[lv_rimage_3] 132.00m linear 1 0 1 /dev/sdhv(33)
[lv_rimage_3] 132.00m linear 1 0 /dev/sdhv(1)
[lv_rimage_4] 132.00m linear 1 0 1 /dev/sdhu(33)
[lv_rimage_4] 132.00m linear 1 0 /dev/sdhu(1)
```

```
[lv_rimage_5] 132.00m linear 1 0 1 /dev/sdht(33)
[lv_rimage_5] 132.00m linear 1 0 /dev/sdht(1)
[lv_rmeta_0] 4.00m linear 1 0 /dev/sda(32)
[lv_rmeta_1] 4.00m linear 1 0 /dev/sdhx(0)
[lv_rmeta_2] 4.00m linear 1 0 /dev/sdhw(0)
[lv_rmeta_3] 4.00m linear 1 0 /dev/sdhv(0)
[lv_rmeta_4] 4.00m linear 1 0 /dev/sdhu(0)
[lv_rmeta_5] 4.00m linear 1 0 /dev/sdht(0)
```

Once the conversion has finished we can convert to striped.

```
# lvconvert --type striped vg/lv
Logical volume vg/lv successfully converted.
```

```
# lvs -a -o name,size,segtype,datastripes,\
      stripesize,reshapelen,devices vg
LV LSize Type #DStr Stripe RSize Devices
lv 640.00m striped 5 128.00k /dev/sda(33),\
      /dev/sdhx(33),\
      /dev/sdhw(33),\
      /dev/sdhv(33),\
      /dev/sdhu(33)
lv 640.00m striped 5 128.00k /dev/sda(0),\
      /dev/sdhx(1),\
      /dev/sdhw(1),\
      /dev/sdhv(1),\
      /dev/sdhu(1)
```

Reversing these steps will convert a given striped LV to linear.

Mind the facts that stripes are removed thus the capacity of the RaidLV will shrink and that changing the RaidLV layout will influence its performance.

"lvconvert --stripes 1 vg/lv" for converting to 1 stripe will inform upfront about the reduced size to allow for resizing the content or growing the RaidLV before actually converting to 1 stripe. The **--force** option is needed to allow stripe removing conversions to prevent data loss.

Of course any interim step can be the intended last one (e.g. striped-> raid1).

RAID5 Variants

raid5_ls

- RAID5 left symmetric
- Rotating parity N with data restart

raid5_la

- RAID5 left symmetric
- Rotating parity N with data continuation

raid5_rs

- RAID5 right symmetric
- Rotating parity 0 with data restart

raid5_ra

- RAID5 right asymmetric

- Rotating parity 0 with data continuation

raid5_n

- RAID5 parity n
- Dedicated parity device n used for striped/raid0 conversions
- Used for RAID Takeover

RAID6 Variants

raid6

- RAID6 zero restart (aka left symmetric)
- Rotating parity 0 with data restart
- Same as raid6_zr

raid6_zr

- RAID6 zero restart (aka left symmetric)
- Rotating parity 0 with data restart

raid6_nr

- RAID6 N restart (aka right symmetric)
- Rotating parity N with data restart

raid6_nc

- RAID6 N continue
- Rotating parity N with data continuation

raid6_n_6

- RAID6 last parity devices
- Fixed dedicated last devices (P–Syndrome N–1 and Q–Syndrome N) with striped data used for striped/raid0 conversions
- Used for RAID Takeover

raid6_{ls,rs,la,ra}_6

- RAID6 last parity device
- Dedicated last parity device used for conversions from/to raid5_{ls,rs,la,ra}

raid6_ls_6

- RAID6 N continue
- Same as raid5_ls for N–1 devices with fixed Q–Syndrome N
- Used for RAID Takeover

raid6_la_6

- RAID6 N continue
- Same as raid5_la for N–1 devices with fixed Q–Syndrome N
- Used for RAID Takeover

raid6_rs_6

- RAID6 N continue
- Same as raid5_rs for N–1 devices with fixed Q–Syndrome N
- Used for RAID Takeover

raid6_ra_6

- RAID6 N continue
- Same as raid5_ra for N–1 devices with fixed Q–Syndrome N

- Used for RAID Takeover

History

The 2.6.38-rc1 version of the Linux kernel introduced a device-mapper target to interface with the software RAID (MD) personalities. This provided device-mapper with RAID 4/5/6 capabilities and a larger development community. Later, support for RAID1, RAID10, and RAID1E (RAID 10 variants) were added. Support for these new kernel RAID targets was added to LVM version 2.02.87. The capabilities of the LVM **raid1** type have surpassed the old **mirror** type. **raid1** is now recommended instead of **mirror**. **raid1** became the default for mirroring in LVM version 2.02.100.

NAME

`lvmreport` — LVM reporting and related features

DESCRIPTION

LVM uses single reporting infrastructure that sets standard on LVM command's output and it provides wide range of configuration settings and command line options to customize report and filter the report's output.

Categorization based on reporting facility

Based on functionality, commands which make use of the reporting infrastructure are divided in two groups:

Report-oriented

These commands inform about current LVM state and their primary role is to display this information in compendious way. To make a distinction, we will name this report as **main report**. The set of report-only commands include: `pvs`, `vgs`, `lvs`, `pvdisplay`, `vgdisplay`, `lvdisplay`, `lvm devtypes`, `lvm fullreport`. For further information about main report, see **main report specifics**.

Processing-oriented

These commands are responsible for changing LVM state and they do not contain any main report as identified for report-oriented commands, they only perform some kind of processing. The set of processing-oriented commands includes: `pvccreate`, `vgcreate`, `lvcreate`, `pvchange`, `vgchange`, `lvchange`, `pvremove`, `vgremove`, `lvremove`, `pvresize`, `vgextend`, `vgreduce`, `lvextend`, `lvreduce`, `lvresize`, `lvrename`, `pvscan`, `vgscan`, `lvscan`, `pvmove`, `vgcfgbackup`, `vgck`, `vgconvert`, `vgexport`, `vgimport`, `vgmknodes`.

If enabled, so called **log report** is either displayed solely (for processing-oriented commands) or in addition to main report (for report-oriented commands). The log report contains a log of operations, messages and per-object status with complete object identification collected during LVM command execution. See **log report specifics** for more information about this report type.

Terms

When describing reporting functionality and features in this text, we will use terms **row** and **column**. By row we mean series of values reported for single entity (for example single PV, VG or LV). Each value from the row then belongs to a column of certain type. The columns have **column headings** which are short descriptions for the columns. The columns are referenced by **column names**. Please note that this text is also using term **field** interchangeably with the term **column**. Most of the time the term columns is abbreviated as **col** in configuration.

Common report configuration settings and command line options

There are common configuration settings and command line options which apply to both **main report** and **log report**. Following lists contain all of them, separated into groups based on their use.

Common configuration settings:

- Changing report output format, composition and other output modifiers:
 - `global/units`
 - `global/suffix`
 - `report/output_format`
 - `report/compact_output`

- report/compact_output_cols
- report/aligned
- report/headings
- report/separator
- report/list_item_separator
- report/prefixes
- report/quoted
- report/columns_as_rows
- report/binary_values_as_numeric
- report/time_format
- report/mark_hidden_devices
- report/two_word_unknown_device
- Special settings
 - report/buffered

This document does not describe these settings in more detail – if you need detailed information, including values which are accepted for the settings, please run **lvmconfig --type default --withcomments <setting>**. There are more configuration settings in addition to the common set listed above, but they are specific to either **main report** or **log report**, see **main report specifics** and **log report specifics** for these settings. Besides configuring reports globally by using configuration settings, there are also command line options you can use to extend, override or further specify the report configuration.

Common command line options:

- Definition of the set set of fields to use
 - --options|-o FieldSet

Field set to use. See **main report specifics** and **log report specifics** for information about field sets configured with global configuration settings that this option overrides.
 - --options|-o+ FieldSet

Fields to include to current field set. See **main report specifics** and **log report specifics** for information about field sets configured with global configuration settings that this option extends.
 - --options|-o- FieldSet

Fields to exclude from current field set. See **main report specifics** and **log report specifics** for information about field sets configured with global configuration settings that this option reduces.
 - --options|-o# FieldSet

Compaction of unused fields. Overrides report/compact_output_cols configuration setting.
- Sorting

- --sort|–O+ FieldSet
Fields to sort by in ascending order. See **main report specifics** and **log report specifics** for information about field sets configured with global configuration settings that this option overrides.
- --sort|–O- FieldSet
Fields to sort by in descending order. See **main report specifics** and **log report specifics** for information about fields sets configured with global configuration settings that this options overrides.
- Selection
 - --select|–S Selection
Define selection criteria for report output. For **log report**, this also overrides log/command_log_selection configuration setting, see also **log report specifics**.
- Changing output format and composition
 - --reportformat
Overrides report/output_format configuration setting.
 - --aligned
Overrides report/aligned configuration setting.
 - --binary
Overrides report/binary_values_as_numeric configuration setting.
 - --nameprefixes
Overrides report/prefixes configuration setting.
 - --noheadings
Overrides report/noheadings configuration setting.
 - --nosuffix
Overrides global/suffix configuration setting.
 - --rows
Overrides report/columns_as_rows configuration setting.
 - --separator
Overrides report/separator configuration setting.
 - --units
Overrides global/units configuration setting.
 - --unquoted
Overrides report/quoted configuration setting.
- Special options
 - --configreport **ReportName**
This defines the **ReportName** for which any subsequent –o--columns, -O--sort or –S--select applies to. See also **main report specifics** and **log report specifics** for possible **ReportName** values.
 - --logonly
When an LVM command contains both **main report** and **log report**, this option suppresses the **main report** output and it causes the **log report** output to be displayed only.
 - --unbuffered
Overrides report/buffered configuration setting.

The **FieldSet** mentioned in the lists above is a set of field names where each field name is delimited by "," character. Field set definition, sorting and selection may be repeated on command line (-o+/-o- includes/excludes fields to/from current list, for all the other repeatable options, the last value typed for the option on the command line is used). The **Selection** is a string with **selection criteria**, see also **Selection** paragraph below for more information about constructing these criteria.

Main report specifics

The **main report** currently encompasses these distinct subtypes, referenced by their name - **ReportName** as listed below. The command in parenthesis is representative command that uses the main report subtype by default. Each subtype has its own configuration setting for global field set definition as well as sort field definition (listed below each individual **ReportName**):

- **pv** representing report about Physical Volumes (**pvs**)
 - report/pvs_cols
 - report/pvs_sort
- **pvseg** representing report about Physical Volume Segments (**pvs --segments**)
 - report/pvseg_cols
 - report/pvseg_sort
- **vg** representing report about Volume Groups (**vgs**)
 - report/vgs_cols
 - report/vgs_sort
- **lv** representing report about Logical Volumes (**lvs**)
 - report/lvs_cols
 - report/lvs_sort
- **seg** representing report about Logical Volume Segments (**lvs --segments**)
 - report/segs_cols
 - report/segs_sort
- **full** representing report combining all of the above as a whole (**lvm fullreport**)
 - report/pvs_cols_full
 - report/pvs_sort_full
 - report/pvsegs_cols_full
 - report/pvseg_sort_full
 - report/vgs_cols_full
 - report/vgs_sort_full
 - report/lvs_cols_full
 - report/lvs_sort_full

- report/segs_cols_full
- report/segs_sort_full
- **devtype** representing report about device types (**lvm devtypes**)
 - report/devtypes_cols
 - report/devtypes_sort

Use **pvs**, **vgs**, **lvs -o help** or **lvm devtypes -o help** to get complete list of fields that you can use for main report. The list of fields in the help output is separated in groups based on which report type they belong to. Note that LVM can change final report type used if fields from different groups are combined together. Some of these combinations are not allowed in which case LVM will issue an error.

For all main report subtypes except **full**, it's not necessary to use **--configreport ReportName** to denote which report any subsequent **-o**, **-O** or **-S** option applies to as they always apply to the single main report type. Currently, **lvm fullreport** is the only command that includes more than one **main report** subtype. Therefore, the **--configreport** is particularly suitable for the full report if you need to configure each of its subreports in a different way.

Log report specifics

You can enable log report with **log/report_command_log** configuration setting – this functionality is disabled by default. The **log report** contains a log collected during LVM command execution and then the log is displayed just like any other report known from main report. There is only one log report subtype as shown below together with related configuration settings for fields, sorting and selection:

- **log** representing log report
 - log/command_log_cols
 - log/command_log_sort
 - log/command_log_selection

You always need to use **--configreport log** together with **-o--options**, **-O--sort** or **-S--selection** to override configuration settings directly on command line for **log report**. When compared to **main report**, in addition to usual configuration settings for report fields and sorting, the **log report** has also configuration option for selection - **report/command_log_selection**. This configuration setting is provided for convenience so it's not necessary to use **-S--select** on command line each time an LVM command is executed and we need the same selection criteria to be applied for **log report**. Default selection criteria used for **log report** are **log/command_log_selection="!(log_type=status && message=success)"**. This means that, by default, **log report** doesn't display status messages about successful operation and it displays only rows with error, warning, print-type messages and messages about failure states (for more information, see **log report content** below).

Log report coverage

Currently, when running LVM commands directly (not in LVM shell), the log report covers command's **processing stage** which is the moment when LVM entities are iterated and processed one by one. It does not cover any command initialization nor command finalization stage. If there is any message issued out of log report's coverage range, such message goes directly to output, bypassing the **log report**. By default, that is **standard error output** for error and warning messages and **standard output** for common print-like messages.

When running LVM commands in **LVM shell**, the log report covers the whole LVM command's execution, including command's **processing** as well as **initialization** and **finalization stage**. So from this point of view, the log report coverage is complete for executed LVM commands. Note that there are still a few moments when LVM shell needs to initialize itself before it even enters the main loop in which it executes LVM commands. Also, there is a moment when **LVM shell** needs to prepare **log report** properly for next command executed in the shell and then, after the command's run, the shell needs to display the log report for that recently executed command. If there is a failure or any other message issued during this time, the LVM will bypass **log report** and display messages on output directly.

For these reasons and for completeness, it's not possible to rely fully on **log report** as the only indicator of LVM command's status and the only place where all messages issued during LVM command execution are collected. You always need to check whether the command has not failed out of log report's range by checking the non-report output too.

To help with this, LVM can separate output which you can then redirect to any **custom file descriptor** that you prepare before running an LVM command or LVM shell and then you make LVM to use these file descriptors for different kinds of output by defining environment variables with file descriptor numbers. See also **LVM_OUT_FD**, **LVM_ERR_FD** and **LVM_REPORT_FD** environment variable description in **lvm(8)** man page.

Also note that, by default, reports use the same file descriptor as common print-like messages, which is **standard output**. If you plan to use **log report** in your scripts or any external tool, you should use **LVM_OUT_FD**, **LVM_ERR_FD** and **LVM_REPORT_FD** to separate all output types to different file descriptors. For example, with bash, that would be:

```
LVM_OUT_FD=3 LVM_ERR_FD=4 LVM_REPORT_FD=5 <lvm command> 3>out_file
4>err_file 5>report_file
```

Where the <lvm_command> is either direct LVM command or LVM shell. You can collect all three types of output in particular files then.

Log report content

Each item in the log report consists of these set of fields providing various information:

- Basic information (mandatory):
 - **log_seq_num**
Item sequence number. The sequence number is unique for each log item and it increases in the order of the log items as they appeared during LVM command execution.
 - **log_type**
Type of log for the item. Currently, these types are used:
 - status** for any status information that is logged
 - print** for any common message printed while the log is collected
 - error** for any error message printed while the log is collected
 - warn** for any warning message printed while the log is collected
 - **log_context**
Context of the log for the item. Currently, two contexts are identified:
 - shell** for the log collected in the outermost code before and after executing concrete LVM commands

processing for the log collected while processing LVM entities during LVM command execution

- Message (mandatory):
 - **log_message**
Any message associated with current item. For **status** log type, the message contains either **success** or **failure** denoting current state. For **print**, **error** and **warn** log types, the message contains the exact message of that type that got issued.
- Object information (used only if applicable):
 - **log_object_type** field
Type of the object processed. Currently, these object types are recognized:
 - cmd** for command as a whole
 - orphan** for processing group of PVs not in any VG yet
 - pv** for PV processing
 - label** for direct PV label processing (without VG metadata)
 - vg** for VG processing
 - lv** for LV processing
 - **log_object_name**
Name of the object processed.
 - **log_object_id**
ID of the object processed.
 - **log_object_group**
A group where the processed object belongs to.
 - **log_object_group_id**
An ID of a group where the processed object belongs to.
- Numeric status (used only if applicable)
 - **log_errno**
Error number associated with current item.
 - **log_ret_code**
Return code associated with current item.

You can also run **<lvm_command> --configreport log -o help** to display complete list of fields that you may use for the **log report**.

Selection

Selection is used for a report to display only rows that match **selection criteria**. All rows are displayed with the additional **selected** field (**-o selected**) displaying 1 if the row matches the *Selection* and 0 otherwise. The **selection criteria** are a set of **statements** combined by **logical and grouping operators**. The

statement consists of a **field** name for which a set of valid **values** is defined using **comparison operators**. For complete list of fields names that you can use in selection, see the output of **<lvm_command> -S help**. The help output also contains type of values that each field displays enclosed in brackets.

List of operators recognized in selection criteria

- Comparison operators (cmp_op)
 - =~ matching regular expression.
 - !~ not matching regular expression.
 - = equal to.
 - != not equal to.
 - >= greater than or equal to.
 - > greater than
 - <= less than or equal to.
 - < less than.
- Binary logical operators (cmp_log)
 - && all fields must match
 - , all fields must match
 - || at least one field must match
 - # at least one field must match
- Unary logical operators
 - ! logical negation
- Grouping operators
 - (left parenthesis
 -) right parenthesis
 - [list start
 -] list end
 - { list subset start
 - } list subset end

Field types and selection operands

Field type restricts the set of operators and values that you may use with the field when defining selection criteria. You can see field type for each field if you run **<lvm command> -S help** where you can find the type name enclosed in square brackets. Currently, LVM recognizes these field types in reports:

- **string** for set of characters (for each string field type, you can use either string or regular expression – regex for the value used in selection criteria)
- **string list** for set of strings
- **number** for integer value
- **size** for integer or floating point number with size unit suffix (see also **lvcreate(8)** man page and description for “**-L--size**” option for the list of recognized suffixes)

- **percent** for floating point number with or without "%" suffix (e.g. 50 or 50%)
- **time** for time values

When using **string list** in selection criteria, there are several ways how LVM can match string list fields from report, depending on what list grouping operator is used and what item separator is used within that set of items. Also, note that order of items does not matter here.

- **matching the set strictly** where all items must match – use [], e.g. ["a","b","c"]
- **matching a subset of the set** – use { } with "," or "&&&" as item delimiter, e.g. {"a","b","c"}
- **matching an intersection with the set** – use { } with "#" or "||" as item delimiter, e.g. {"a" || "b" || "c"}

When using **time** in your selection criteria, LVM can recognize various time formats using standard, absolute or freeform expressions. For examples demonstrating time expressions in selection criteria, see **EXAMPLES** section.

- **Standard time format**

- date

YYYY-MM-DD

YYYY-MM, auto DD=1

YYYY, auto MM=01 and DD=01

- time

hh:mm:ss

hh:mm, auto ss=0

hh, auto mm=0, auto ss=0

- timezone

+hh:mm or -hh:mm

+hh or -hh

The full date/time specification is YYYY-MM-DD hh:mm:ss. Users are able to leave date/time parts from right to left. Whenever these parts are left out, a range is assumed automatically with second granularity. For example:

"2015-07-07 9:51" means range of "2015-07-07 9:51:00" - "2015-07-07 9:51:59".

"2015-07" means range of "2015-07-01 0:00:00" - "2015-07-31 23:59:59"

"2015" means range of "2015-01-01 0:00:00" - "2015-12-31 23:59:59"

- **Absolute time format**

Absolute time is defined as number of seconds since the Epoch (1970:01:01 00:00 +00:00).

- @seconds
- **Freeform time format**
 - weekday names ("Sunday" - "Saturday" or abbreviated as "Sun" - "Sat")
 - labels for points in time ("noon", "midnight")
 - labels for a day relative to current day ("today", "yesterday")
 - points back in time with relative offset from today (N is a number)
 - "N" "seconds" / "minutes" / "hours" / "days" / "weeks" / "years" "ago"
 - "N" "secs" / "mins" / "hrs" ... "ago"
 - "N" "s" / "m" / "h" ... "ago"
 - time specification either in hh:mm:ss format or with AM/PM suffixes
 - month names ("January" - "December" or abbreviated as "Jan" - "Dec")

Informal grammar specification

STATEMENT = column cmp_op **VALUE** | **STATEMENT** log_op **STATEMENT** | (**STATEMENT**) | !(**STATEMENT**)

VALUE = [**VALUE** log_op **VALUE**]

For list-based types: string list. Matches strictly. The log_op must always be of one type within the whole list value.

VALUE = { **VALUE** log_op **VALUE** }

For list-based types: string list. Matches a subset. The log_op must always be of one type within the whole list value.

VALUE = **value**

For scalar types: number, size, percent, string (or string regex).

EXAMPLES

Basic usage

We start our examples with default configuration - **lvmconfig(8)** is helpful command to display configuration settings which are currently used, including all configuration related to reporting. We will use it throughout examples below to display current configuration.

```
# lvmconfig --type full global/global/suffix \
report/output_format report/compact_output \
report/compact_output_cols report/aligned \
report/headings report/sePARATOR \
report/list_item_separator report/prefixes \
report/quoted report/columns_as_rows \
report/binary_values_as_numeric report/time_format \
report/mark_hidden_devices report/two_word_unknown_device \
report/buffered
units="h"
suffix=1
output_format="basic"
compact_output=0
compact_output_cols=""
aligned=1
headings=1
```

```

separator=" "
list_item_separator ","
prefixes=0
quoted=1
columns_as_rows=0
binary_values_as_numeric=0
time_format="%Y-%m-%d %T %z"
mark_hidden_devices=1
two_word_unknown_device=0
buffered=1

```

Also, we start with simple LVM layout with two PVs (/dev/sda, /dev/sdb), VG (vg) and two LVs (lvol0 and lvol1) in the VG. We display all possible reports as single commands here, see also **pvs(8)**, **vgs(8)**, **lvs(8)** man pages for more information. The field set for each report type is configured with configuration settings as we already mentioned in **main report specifics** section in this man page.

```

# lvmconfig --type full report/pvs_cols report/pvs_sort \
    report/pvsegs_cols report/pvsegs_sort report/vgs_cols \
    report/vgs_sort report/lvs_cols report/lvs_sort \
    report/segs_cols report/segs_sort
pvs_cols="pv_name,vg_name,pv_fmt,pv_attr,pv_size,pv_free"
pvs_sort="pv_name"
pvsegs_cols="pv_name,vg_name,pv_fmt,pv_attr,pv_size,pv_free,
            pvseg_start,pvseg_size"
pvsegs_sort="pv_name,pvseg_start"
vgs_cols="vg_name,pv_count,lv_count,snap_count,vg_attr,vg_size,vg_free"
vgs_sort="vg_name"
lvs_cols="lv_name,vg_name,lv_attr,lv_size,pool_lv,origin,move_pv,
         mirror_log,copy_percent,convert_lv"
lvs_sort="vg_name,lv_name"
segs_cols="lv_name,vg_name,lv_attr,stripes,segtype,seg_size"
segs_sort="vg_name,lv_name,seg_start"

# pvs
PV      VG Fmt Attr PSize  PFree
/dev/sda  vg lvm2 a-- 100.00m 88.00m
/dev/sdb  vg lvm2 a-- 100.00m 92.00m

# pvs --segments
PV      VG Fmt Attr PSize  PFree Start SSize
/dev/sda  vg lvm2 a-- 100.00m 88.00m  0   1
/dev/sda  vg lvm2 a-- 100.00m 88.00m  1   1
/dev/sda  vg lvm2 a-- 100.00m 88.00m  2   1
/dev/sda  vg lvm2 a-- 100.00m 88.00m  3   22
/dev/sdb  vg lvm2 a-- 100.00m 92.00m  0   1
/dev/sdb  vg lvm2 a-- 100.00m 92.00m  1   1
/dev/sdb  vg lvm2 a-- 100.00m 92.00m  2   23

# vgs
VG #PV #LV #SN Attr  VSize  VFree
vg 2 2 0 wz--n- 200.00m 180.00m

# lvs
LV  VG Attr     LSize Pool Origin Move Log Cpy%Sync Convert

```

```

lvol0 vg -wi-a----- 4.00m
lvol1 vg rwi-a-r--- 4.00m          100.00

# lvs --segments
LV  VG Attr #Str Type SSize
lvol0 vg -wi-a----- 1 linear 4.00m
lvol1 vg rwi-a-r--- 2 raid1 4.00m

```

We will use **report/lvs_cols** and **report/lvs_sort** configuration settings to define our own list of fields to use and to sort by that is different from defaults. You can do this for other reports in same manner with **report/{pvs,pvseg,vgs,seg}_{cols,sort}** configuration settings. Also note that in the example below, we don't display the "lv_time" field even though we're using it for sorting – this is allowed.

```
# lvmconfig --type full report/lvs_cols report/lvs_sort
lvs_cols="lv_name,lv_size,origin,pool_lv,copy_percent"
lvs_sort="-lv_time"
```

```
# lvs
LV  LSize Origin Pool Cpy%Sync
lvol1 4.00m      100.00
lvol0 4.00m
```

You can use **-o--options** command line option to override current configuration directly on command line.

```
# lvs -o lv_name,lv_size
LV  LSize
lvol1 4.00m
lvol0 4.00m

# lvs -o+lv_layout
LV  LSize Origin Pool Cpy%Sync Layout
lvol1 4.00m      100.00  raid,raid1
lvol0 4.00m      linear

# lvs -o-origin
LV  LSize Pool Cpy%Sync
lvol1 4.00m    100.00
lvol0 4.00m

# lvs -o lv_name,lv_size,origin -o+lv_layout -o-origin -O lv_name
LV  LSize Layout
lvol0 4.00m linear
lvol1 4.00m raid,raid1
```

You can obtain the same information with single command where all the information about PVs, PV segments, LVs and LV segments are obtained per VG under a single VG lock for consistency, see also **lvm-fullreport(8)** man page for more information. The fullreport has its own configuration settings to define field sets to use, similar to individual reports as displayed above, but configuration settings have "_full" suffix now. This way, it's possible to configure different sets of fields to display and to sort by for individual reports as well as the full report.

```
# lvmconfig --type full report/pvs_cols_full \
report/pvs_sort_full report/pvsegs_cols_full \
report/pvsegs_sort_full report/vgs_cols_full \
```

```

report/vgs_sort_full report/lvs_cols_full \
report/lvs_sort_full report/segs_cols_full \
report/segs_sort_full
pvs_cols_full="pv_name,vg_name"
pvs_sort_full="pv_name"
pvsegs_cols_full="pv_name,pvseg_start,pvseg_size"
pvsegs_sort_full="pv_uuid,pvseg_start"
vgs_cols_full="vg_name"
vgs_sort_full="vg_name"
lvs_cols_full="lv_name,vg_name"
lvs_sort_full="vg_name,lv_name"
segs_cols_full="lv_name,seg_start,seg_size"
segs_sort_full="lv_uuid,seg_start"

# lvm fullreport
VG
vg
PV      VG
/dev/sda  vg
/dev/sdb  vg
LV      VG
lvol0 vg
lvol1 vg
PV      Start SSize
/dev/sda  0   1
/dev/sda  1   1
/dev/sda  2   1
/dev/sda  3   22
/dev/sdb  0   1
/dev/sdb  1   1
/dev/sdb  2   23
LV      Start SSize
lvol0  0  4.00m
lvol1  0  4.00m

```

Automatic output compaction

If you look at the lvs output above, you can see that the report also contains fields for which there is no information to display (e.g. the columns under "Origin" and "Pool" heading – the "origin" and "pool_lv" fields). LVM can automatically compact report output so such fields are not included in final output. To enable this feature and to compact all fields, use **report/compact_output=1** in your configuration.

```
# lvmconfig --type full report/compact_output
compact_output=1
```

```

# lvs
LV  LSize Cpy%Sync
lvol1 4.00m 100.00
lvol0 4.00m

# lvs vg/lvol0
LV  LSize
lvol0 4.00m

```

Alternatively, you can define which fields should be compacted by configuring

report/compact_output_cols configuration setting (or **-o--options** # command line option).

```
# lvmconfig --type full report/compact_output report/compact_output_cols
compact_output=0
compact_output_cols="origin"

# lvs
LV  LSize Pool Cpy%Sync
lvol1 4.00m    100.00
lvol0 4.00m

# lvs vg/lvol0
LV  LSize Pool
lvol0 4.00m

# lvs -o#pool_lv
LV  LSize Origin Cpy%Sync
lvol1 4.00m    100.00
lvol0 4.00m
```

We will use **report/compact_output=1** for subsequent examples.

Further formatting options

By default, LVM displays sizes in reports in human-readable form which means that the most suitable unit is used so it's easy to read. You can use **report/units** configuration setting (or **--units** option directly on command line) and **report/suffix** configuration setting (or **--nosuffix** command line option) to change this.

```
# lvs --units b --nosuffix
LV  LSize  Cpy%Sync
lvol1 4194304 100.00
lvol0 4194304
```

If you want to configure whether report headings are displayed or not, use **report/headings** configuration settings (or **--noheadings** command line option).

```
# lvs --noheadings
lvol1 4.00m 100.00
lvol0 4.00m
```

In some cases, it may be useful to display report content as key=value pairs where key here is actually the field name. Use **report/prefixes** configuration setting (or **--nameprefixes** command line option) to switch between standard output and the key=value output. The key=value pair is the output that is suitable for use in scripts and for other tools to parse easily. Usually, you also don't want to display headings with the output that has these key=value pairs.

```
# lvs --noheadings --nameprefixes
LVM2_LV_NAME='lvol1' LVM2_LV_SIZE='4.00m' LVM2_COPY_PERCENT='100.00'
LVM2_LV_NAME='lvol0' LVM2_LV_SIZE='4.00m' LVM2_COPY_PERCENT=""
```

To define whether quotation marks in key=value pairs should be used or not, use **report/quoted** configuration setting (or **--unquoted** command line option).

```
# lvs --noheadings --nameprefixes --unquoted
LVM2_LV_NAME=lvol1 LVM2_LV_SIZE=4.00m LVM2_COPY_PERCENT=100.00
```

```
LVM2_LV_NAME=lvol0 LVM2_LV_SIZE=4.00m LVM2_COPY_PERCENT=
```

For easier parsing, you can even transpose the report so each column now becomes a row in the output. This is done with **report/output_as_rows** configuration setting (or **--rows** command line option).

```
# lvs --noheadings --nameprefixes --unquoted --rows
LVM2_LV_NAME=lvol1 LVM2_LV_NAME=lvol0
LVM2_LV_SIZE=4.00m LVM2_LV_SIZE=4.00m
LVM2_COPY_PERCENT=100.00 LVM2_COPY_PERCENT=
```

Use **report/separator** configuration setting (or **--separator** command line option) to define your own field separator to use.

```
# lvs --noheadings --nameprefixes --unquoted --separator " | "
LVM2_LV_NAME=lvol1 | LVM2_LV_SIZE=4.00m | LVM2_COPY_PERCENT=100.00
LVM2_LV_NAME=lvol0 | LVM2_LV_SIZE=4.00m | LVM2_COPY_PERCENT=
```

If you are using your own separator, the columns in the output are not aligned by default. Use **report/aligned** configuration setting (or **--aligned** command line option) for LVM to add extra spaces in report to align the output properly.

```
# lvs --separator " | "
LV | LSize | Cpy%Sync
lvol1 | 4.00m | 100.00
lvol0 | 4.00m |
```

```
# lvs --separator " | " --aligned
LV | LSize | Cpy%Sync
lvol1 | 4.00m | 100.00
lvol0 | 4.00m |
```

Let's display one more field in addition ("lv_tags" in this example) for the lvs report output.

```
# lvs -o+lv_tags
LV  LSize Cpy%Sync LV Tags
lvol1 4.00m 100.00
lvol0 4.00m      tagA,tagB
```

The "LV Tags" column in the example above displays two list values, separated by "," character for LV lvol0. If you need different list item separator, use **report/list_item_separator** configuration setting its definition.

```
# lvmconfig --type full report/list_item_separator
list_item_separator=";"

# lvs -o+tags
LV  LSize Cpy%Sync LV Tags
lvol1 4.00m 100.00
lvol0 4.00m      tagA;tagB
```

But let's still use the original "," character for list_item_separator for subsequent examples.

Format for any of time values displayed in reports can be configured with **report/time_format** configuration setting. By default complete date and time is displayed, including timezone.

```
# lvmconfig --type full report/time_format
time_format="%Y-%m-%d %T %z"

# lvs -o+time
LV  LSize Cpy%Sync CTime
lvol1 4.00m 100.00 2016-08-29 12:53:36 +0200
lvol0 4.00m      2016-08-29 10:15:17 +0200
```

We can change time format in similar way as we do when using **date(1)** command or **strftime(3)** function (**lvmconfig --type default --withcomments report/time_format** will give you complete list of available formatting options). In the example below, we decided to use **%s** for number of seconds since Epoch (1970-01-01 UTC).

```
# lvmconfig --type full report/time_format
time_format="%s"

# lvs
LV Attr LSize Cpy%Sync LV Tags CTime
lvol1 rwi-a-r--- 4.00m 100.00      1472468016
lvol0 -wi-a----- 4.00m          tagA,tagB 1472458517
```

The **lvs** does not display hidden LVs by default – to include these LVs in the output, you need to use **-a--all** command line option. Names for these hidden LVs are displayed within square brackets.

```
# lvs -a
LV      LSize Cpy%Sync
lvol1    4.00m 100.00
[lvol1_rimage_0] 4.00m
[lvol1_rmeta_0] 4.00m
[lvol1_rimage_1] 4.00m
[lvol1_rmeta_1] 4.00m
lvol0    4.00m
```

You can configure LVM to display the square brackets for hidden LVs or not with **report/mark_hidden_devices** configuration setting.

```
# lvmconfig --type full report/mark_hidden_devices
mark_hidden_devices=0

# lvs -a
LV      LSize Cpy%Sync
lvol1    4.00m 100.00
lvol1_rimage_0 4.00m
lvol1_rmeta_0 4.00m
lvol1_rimage_1 4.00m
lvol1_rmeta_1 4.00m
lvol0    4.00m
```

It's not recommended to use LV marks for hidden devices to decide whether the LV is the one to use by end users or not. Please, use "lv_role" field instead which can report whether the LV is "public" or "private". The private LVs are used by LVM only and they should not be accessed directly by end users.

```
# lvs -a -o+lv_role
LV      LSize Cpy%Sync Role
```

```

lvol1      4.00m 100.00  public
lvol1_rimage_0 4.00m      private,raid,image
lvol1_rmeta_0 4.00m      private,raid,metadata
lvol1_rimage_1 4.00m      private,raid,image
lvol1_rmeta_1 4.00m      private,raid,metadata
lvol0      4.00m      public

```

Some of the reporting fields that LVM reports are of binary nature. For such fields, it's either possible to display word representation of the value (this is used by default) or numeric value (0/1 or -1 in case the value is undefined).

```

# lvs -o+lv_active_locally
LV  LSize Cpy%Sync ActLocal
lvol1 4.00m 100.00  active locally
lvol0 4.00m      active locally

```

We can change the way how these binary values are displayed with **report/binary_values_as_numeric** configuration setting.

```

# lvmconfig --type full report/binary_values_as_numeric
binary_values_as_numeric=1

# lvs -o+lv_active_locally
LV  LSize Cpy%Sync ActLocal
lvol1 4.00m 100.00      1
lvol0 4.00m            1

```

Changing output format

LVM can output reports in different formats – use **report/output_format** configuration setting (or **--reportformat** command line option) to switch the report output format. Currently, LVM supports "**basic**" (all the examples we used above used this format) and "**JSON**" output format.

```

# lvs -o lv_name,lv_size --reportformat json
{
  "report": [
    {
      "lv": [
        {"lv_name": "lvol1", "lv_size": "4.00m"},  

        {"lv_name": "lvol0", "lv_size": "4.00m"}
      ]
    }
  ]
}

```

Note that some configuration settings and command line options have no effect with certain report formats. For example, with **JSON** output, it doesn't have any meaning to use **report/aligned** (**--aligned**), **report/noheadings** (**--noheadings**), **report/columns_as_rows** (**--rows**) or **report/buffered** (**--unbuffered**). All these configuration settings and command line options are ignored if using the **JSON** report output format.

Selection

If you need to select only specific rows from report, you can use LVM's report selection feature. If you call **<lvmt command> -S help**, you'll get quick help on selection. The help contains list of all fields that LVM can use in reports together with its type enclosed in square brackets. The example below contains a line

from lvs -S help.

```
# lvs -S help
...
lv_size      - Size of LV in current units. [size]
...
```

This line tells you that the "lv_size" field is of "size" type. If you look at the bottom of the help output, you can see section about "Selection operators" and its "Comparison operators".

```
# lvs -S help
...
Selection operators
-----
Comparison operators:
=~= - Matching regular expression. [regex]
!~= - Not matching regular expression. [regex]
= - Equal to. [number, size, percent, string, string_list, time]
!= - Not equal to. [number, size, percent, string, string_list, time]
>= - Greater than or equal to. [number, size, percent, time]
> - Greater than. [number, size, percent, time]
<= - Less than or equal to. [number, size, percent, time]
< - Less than. [number, size, percent, time]
since - Since specified time (same as '>='). [time]
after - After specified time (same as '>'). [time]
until - Until specified time (same as '<='). [time]
before - Before specified time (same as '<'). [time]
...

```

Here you can match comparison operators that you may use with the "lv_size" field which is of type "size" - it's =, !=, >=, >, <= and <. You can find applicable comparison operators for other fields and other field types the same way.

To demonstrate selection functionality in LVM, we will create more LVs in addition to lvol0 and lvol1 we used in our previous examples.

```
# lvs -o name,size,origin,snap_percent,tags,time
LV  LSize Origin Snap% LV Tags      CTime
lvol4 4.00m lvol2 24.61      2016-09-09 16:57:44 +0200
lvol3 4.00m lvol2 5.08      2016-09-09 16:56:48 +0200
lvol2 8.00m          tagA,tagC,tagD 2016-09-09 16:55:12 +0200
lvol1 4.00m          2016-08-29 12:53:36 +0200
lvol0 4.00m          tagA,tagB   2016-08-29 10:15:17 +0200
```

When selecting size and percent fields, we don't need to use units. For sizes, default "m" (for MiB) is used – this is the same behaviour as already used for LVM commands when specifying sizes (e.g. lvcreate -L). For percent fields, "%" is assumed automatically if it's not specified. The example below also demonstrates how several criteria can be combined together.

```
# lvs -o name,size,snap_percent -S 'size=8m'
LV  LSize
lvol2 8.00m
```

```
# lvs -o name,size,snap_percent -S 'size=8'
```

```

LV  LSize
lvol2 8.00m

# lvs -o name,size,snap_percent -S 'size < 5000k'
LV  LSize Snap%
lvol4 4.00m 24.61
lvol3 4.00m 5.08
lvol1 4.00m
lvol0 4.00m

# lvs -o name,size,snap_percent -S 'size < 5000k && snap_percent > 20'
LV  LSize Snap%
lvol4 4.00m 24.61

# lvs -o name,size,snap_percent \
-S '(size < 5000k && snap_percent > 20%) || name=lvol2'
LV  LSize Snap%
lvol4 4.00m 24.61
lvol2 8.00m

```

You can also use selection together with processing-oriented commands.

```

# lvchange ---addtag test -S 'size < 5000k'
Logical volume vg/lvol1 changed.
Logical volume vg/lvol0 changed.
Logical volume vg/lvol3 changed.
Logical volume vg/lvol4 changed.

# lvchange ---deltag test -S 'tags = test'
Logical volume vg/lvol1 changed.
Logical volume vg/lvol0 changed.
Logical volume vg/lvol3 changed.
Logical volume vg/lvol4 changed.

```

LVM can recognize more complex values used in selection criteria for string list and time field types. For string lists, you can match whole list strictly, its subset or intersection. Let's take "lv_tags" field as an example – we select only rows which contain "tagA" within tags field. We're using { } to denote that we're interested in subset that matches. If the subset has only one item, we can leave out { }.

```

# lvs -o name,tags -S 'tags={tagA}'
LV  LV Tags
lvol2 tagA,tagC,tagD
lvol0 tagA,tagB

# lvs -o name,tags -S 'tags=tagA'
LV  LV Tags
lvol2 tagA,tagC,tagD
lvol0 tagA,tagB

```

Depending on whether we use "&&" (or ",") or "||" (or "#") as delimiter for items in the set we define in selection criterion for string list, we either match subset ("&&" or ",") or even intersection ("||" or "#").

```

# lvs -o name,tags -S 'tags={tagA,tagC,tagD}'
LV  LV Tags

```

```

lvol2 tagA,tagC,tagD

# lvs -o name,tags -S 'tags={tagA || tagC || tagD}'
LV  LV Tags
lvol2 tagA,tagC,tagD
lvol0 tagA,tagB

```

To match the complete set, use [] with "&&&" (or ",") as delimiter for items. Also note that the order in which we define items in the set is not relevant.

```

# lvs -o name,tags -S 'tags=[tagA]'

# lvs -o name,tags -S 'tags=[tagB,tagA]'
LV  LV Tags
lvol0 tagA,tagB

```

If you use [] with "||" (or "#"), this is exactly the same as using { }.

```

# lvs -o name,tags -S 'tags=[tagA || tagC || tagD]'
LV  LV Tags
lvol2 tagA,tagC,tagD
lvol0 tagA,tagB

```

To match a set with no items, use "" to denote this (note that we have output compaction enabled so the "LV Tags" column is not displayed in the example below because it's blank and so it gets compacted).

```

# lvs -o name,tags -S 'tags=""'
LV
lvol4
lvol3
lvol1

# lvs -o name,tags -S 'tags!=""'
LV  LV Tags
lvol2 tagA,tagC,tagD
lvol0 tagA,tagB

```

When doing selection based on time fields, we can use either standard, absolute or freeform time expressions in selection criteria. Examples below are using standard forms.

```

# lvs -o name,time
LV  CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
lvol2 2016-09-09 16:55:12 +0200
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200

# lvs -o name,time -S 'time since "2016-09-01"'
LV  CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
lvol2 2016-09-09 16:55:12 +0200

```

```
# lvs -o name,time -S 'time since "2016-09-09 16:56"'
LV CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200

# lvs -o name,time -S 'time since "2016-09-09 16:57:30"'
LV CTime
lvol4 2016-09-09 16:57:44 +0200

# lvs -o name,time \
-S 'time since "2016-08-29" && time until "2016-09-09 16:55:12"'
LV CTime
lvol2 2016-09-09 16:55:12 +0200
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200

# lvs -o name,time \
-S 'time since "2016-08-29" && time before "2016-09-09 16:55:12"'
LV CTime
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200
```

Time operators have synonyms: ">=" for since, "<=" for until, ">" for "after" and "<" for "before".

```
# lvs -o name,time \
-S 'time >= "2016-08-29" && time <= "2016-09-09 16:55:30"'
LV CTime
lvol2 2016-09-09 16:55:12 +0200
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200

# lvs -o name,time \
-S 'time since "2016-08-29" && time < "2016-09-09 16:55:12"'
LV CTime
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200
```

Example below demonstrates using absolute time expression.

```
# lvs -o name,time --config report/time_format="%s"
LV CTime
lvol4 1473433064
lvol3 1473433008
lvol2 1473432912
lvol1 1472468016
lvol0 1472458517

# lvs -o name,time -S 'time since @1473433008'
LV CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
```

Examples below demonstrates using freeform time expressions.

```
# lvs -o name,time -S 'time since "2 weeks ago"'
LV CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
lvol2 2016-09-09 16:55:12 +0200
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200

# lvs -o name,time -S 'time since "1 week ago"'
LV CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
lvol2 2016-09-09 16:55:12 +0200

# lvs -o name,time -S 'time since "2 weeks ago"'
LV CTime
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200

# lvs -o name,time -S 'time before "1 week ago"'
LV CTime
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200

# lvs -o name,time -S 'time since "68 hours ago"'
LV CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
lvol2 2016-09-09 16:55:12 +0200

# lvs -o name,time -S 'time since "1 year 3 months ago"'
LV CTime
lvol4 2016-09-09 16:57:44 +0200
lvol3 2016-09-09 16:56:48 +0200
lvol2 2016-09-09 16:55:12 +0200
lvol1 2016-08-29 12:53:36 +0200
lvol0 2016-08-29 10:15:17 +0200
```

Command log reporting

As described in **categorization based on reporting facility** section at the beginning of this document, both **report-oriented** and **processing-oriented** LVM commands can report the command log if this is enabled with **log/report_command_log** configuration setting. Just like any other report, we can set the set of fields to display (**log/command_log_cols**) and to sort by (**log/command_log_sort**) for this report.

```
# lvmconfig --type full log/report_command_log log/command_log_cols \
    log/command_log_sort log/command_log_selection
report_command_log=1
command_log_cols="log_seq_num,log_type,log_context,log_object_type,
    log_object_name,log_object_group,log_message,
    log_errno,log_ret_code"
command_log_sort="log_seq_num"
command_log_selection="!(log_type=status && message=success)"
```

```
# lvs
Logical Volume
=====
LV  LSize Cpy%Sync
lvol1 4.00m 100.00
lvol0 4.00m

Command Log
=====
Seq LogType Context ObjType ObjName ObjGrp Msg  Errno RetCode
```

As you can see, the command log is empty (it contains only field names). By default, LVM uses selection on the command log report and this case no row matched the selection criteria, see also **log report specifics** section in this document for more information. We're displaying complete log report in the example below where we can see that both LVs lvol0 and lvol1 were successfully processed as well as the VG vg they are part of.

```
# lvmconfig --type full log/command_log_selection
command_log_selection="all"

# lvs
Logical Volume
=====
LV  LSize Cpy%Sync
lvol1 4.00m 100.00
lvol0 4.00m

Command Log
=====
Seq LogType Context  ObjType ObjName ObjGrp Msg  Errno RetCode
 1 status processing lv    lvol0  vg    success  0   1
 2 status processing lv    lvol1  vg    success  0   1
 3 status processing vg    vg      success  0   1

# lvchange -an vg/lvol1
Command Log
=====
Seq LogType Context  ObjType ObjName ObjGrp Msg  Errno RetCode
 1 status processing lv    lvol1  vg    success  0   1
 2 status processing vg    vg      success  0   1
```

Handling multiple reports per single command

To configure the log report directly on command line, we need to use **--configreport** option before we start any **-o--options**, **-O--sort** or **-S--select** that is targeted for log report.

```
# lvs -o lv_name,lv_size --configreport log -o log_object_type, \
  log_object_name,log_message,log_ret_code
Logical Volume
=====
LV  LSize
lvol1 4.00m
lvol0 4.00m

Command Log
```

```
=====
ObjType ObjName Msg  RetCode
lv    lvol0  success  1
lv    lvol1  success  1
vg    vg     success  1
```

The **lvm fullreport**, with or without log report, consists of several reports – the **--configreport** is also used to target particular subreport here.

Below is an extended example with **lvm fullreport** to illustrate combination of various options. The report output is in JSON format. Also, we configure "vg", "pvseg", "seg" and "log" subreport to contain only specified fields. For the "pvseg" subreport, we're interested only in PV names having "sda" in their name. For the "log" subreport we're interested only in log lines related to either "lvol0" object or object having "sda" in its name. Also, for the log subreport we define ordering to be based on "log_object_type" field.

```
# lvm fullreport --reportformat json \
--configreport vg -o vg_name,vg_size \
--configreport pvseg -o pv_name,pvseg_start \
-S 'pv_name=~sda' \
--configreport seg -o lv_name,seg_start \
--configreport log -o log_object_type,log_object_name \
-O log_object_type \
-S 'log_object_name=lvol0 || \
log_object_name=~sda'
{
  "report": [
    {
      "vg": [
        {"vg_name": "vg", "vg_size": "200.00m"}
      ],
      "pv": [
        {"pv_name": "/dev/sda", "vg_name": "vg"},
        {"pv_name": "/dev/sdb", "vg_name": "vg"}
      ],
      "lv": [
        {"lv_name": "lvol0", "vg_name": "vg"},
        {"lv_name": "lvol1", "vg_name": "vg"}
      ],
      "pvseg": [
        {"pv_name": "/dev/sda", "pvseg_start": "0"}, 
        {"pv_name": "/dev/sda", "pvseg_start": "1"}, 
        {"pv_name": "/dev/sda", "pvseg_start": "2"}, 
        {"pv_name": "/dev/sda", "pvseg_start": "3"}
      ],
      "seg": [
        {"lv_name": "lvol0", "seg_start": "0 "}, 
        {"lv_name": "lvol1", "seg_start": "0 "}
      ]
    }
  ]
}
```

```

    ,
    "log": [
        {"log_object_type":"lv", "log_object_name":"lvol0"},  

        {"log_object_type":"lv", "log_object_name":"lvol0"},  

        {"log_object_type":"pv", "log_object_name":"/dev/sda"},  

        {"log_object_type":"pv", "log_object_name":"/dev/sda"},  

    ]
}

```

Report extensions for LVM shell

As already stated in **log report coverage** paragraph under **log report specifics** in this documentation, when using **LVM shell** the **log report** coverage is wider. There's also special command designed to query last command's log report in the **LVM shell** - the **lastlog** command.

The example below illustrates a situation where we called lvs command. After that, we inspected the log report with the **lastlog**, without any selection so all the log report is displayed on output. Then we called **lastlog** further, giving various selection criteria. Then we ran unknown LVM command "abc" for which the log report displays appropriate failure state.

```

NAME

lvreduce – Reduce the size of a logical volume

SYNOPSIS

```
lvreduce option_args position_args
      [ option_args ]
```

DESCRIPTION

lvreduce reduces the size of an LV. The freed logical extents are returned to the VG to be used by other LVs. A copy-on-write snapshot LV can also be reduced if less space is needed to hold COW blocks. Use **lvconvert(8)** to change the number of data images in a RAID or mirrored LV.

Be careful when reducing an LV's size, because data in the reduced area is lost. Ensure that any file system on the LV is resized **before** running **lvreduce** so that the removed extents are not in use by the file system.

Sizes will be rounded if necessary. For example, the LV size must be an exact number of extents, and the size of a striped segment must be a multiple of the number of stripes.

In the usage section below, **--size** *Size* can be replaced with **--extents** *Number*. See both descriptions the options section.

USAGE

```
lvreduce -L|--size [ -Size[m|UNIT] ] LV
      [ -l|--extents [ -Number[PERCENT] ] ]
      [ -A|--autobackup y|n ]
      [ -f|--force ]
      [ -n|--nofsck ]
      [ -r|--resizefs ]
      [ --noudevsync ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-A|--autobackup *y|n*

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-l|--extents [-]Number[PERCENT]

Specifies the new size of the LV in logical extents. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. An alternate syntax allows the size to be determined indirectly as a percentage of the size of a related VG, LV, or set of PVs. The suffix **%VG** denotes the total size of the VG, the suffix **%FREE** the remaining free space in the VG, and the suffix **%PVS** the free space in the specified PVs. For a snapshot, the size can be expressed as a percentage of the total size of the origin LV with the suffix **%ORIGIN (100%ORIGIN** provides space for the whole origin). When expressed as a percentage, the size defines an upper limit for the number of logical extents in the new LV. The precise number of logical extents in the new LV is not determined until the command has completed. When the plus + or minus – prefix is used, the value is not an absolute size, but is relative and added or subtracted from the current size.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-n|--nofsck

Do not perform fsck before resizing filesystem when filesystem requires it. You may need to use --force to proceed with this option.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat **basic|json**

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-r|--resizesfs

Resize underlying filesystem together with the LV using fsadm(8).

-L|--size [-]Size[m|UNIT]

Specifies the new size of the LV. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. When the plus+ or minus – prefix is used, the value is not an absolute size, but is relative and added or subtracted from the current size.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*LV*

Logical Volume name. See lvm(8) for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See lvm(8) for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Reduce the size of an LV by 3 logical extents:

lvreduce -l -3 vg00/lvol1

NAME

lvremove – Remove logical volume(s) from the system

SYNOPSIS

```
lvremove position_args
      [ option_args ]
```

DESCRIPTION

lvremove removes one or more LVs. For standard LVs, this returns the logical extents that were used by the LV to the VG for use by other LVs.

Confirmation will be requested before deactivating any active LV prior to removal. LVs cannot be deactivated or removed while they are open (e.g. if they contain a mounted filesystem). Removing an origin LV will also remove all dependent snapshots.

When a single force option is used, LVs are removed without confirmation, and the command will try to deactivate unused LVs.

To remove damaged LVs, two force options may be required (**-ff**).

Historical LVs

If the configuration setting **metadata/record_lvs_history** is enabled and the LV being removed forms part of the history of at least one LV that is still present, then a simplified representation of the LV will be retained. This includes the time of removal (**lv_time_removed** reporting field), creation time (**lv_time**), name (**lv_name**), LV uuid (**lv_uuid**) and VG name (**vg_name**). This allows later reporting to see the ancestry chain of thin snapshot volumes, even after some intermediate LVs have been removed. The names of such historical LVs acquire a hyphen as a prefix (e.g. '-lvol1') and cannot be reactivated. Use **lvremove** a second time, with the hyphen, to remove the record of the former LV completely.

USAGE

```
lvremove VG|LV|Tag|Select ...
      [ -A|--autobackup y|n ]
      [ -f|--force ]
      [ -S|--select String ]
      [ --nohistory ]
      [ --noudevsync ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**-A|--autobackup y|n**

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vfcfgbackup(8)** for more information.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nohistory

Do not record history of LVs being removed. This has no effect unless the configuration setting metadata/record_lvs_history is enabled.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by **--select help** and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See **--options help** for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the

selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

Select

Select indicates that a required positional parameter can be omitted if the **--select** option is used. No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGgTtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Remove an active LV without asking for confirmation.

lvremove -f vg00/lvol1

Remove all LVs the specified VG.

lvremove vg00

NAME

lvrename – Rename a logical volume

SYNOPSIS

```
lvrename position_args
        [ option_args ]
```

DESCRIPTION

lvrename renames an existing LV or a historical LV (see **lvremove** for historical LV information.)

USAGE

```
lvrename VG LV LV_new
        [ COMMON_OPTIONS ]
```

```
lvrename LV LV_new
        [ COMMON_OPTIONS ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ --noudevsync ]
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vfcfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*VG*

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmGg-TtPpEe**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is

TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Rename "lvold" to "lvnew":

```
lvrename /dev/vg02/lvold vg02/lvnew
```

An alternate syntax to rename "lvold" to "lvnew":

```
lvrename vg02 lvold lvnew
```

NAME

lvresize – Resize a logical volume

SYNOPSIS

```
lvresize option_args position_args
[ option_args ]
[ position_args ]
--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit
-A|--autobackup y|n
--commandprofile String
--config String
-d|--debug
--driverloaded y|n
-l|--extents [+|-]Number[PERCENT]
-f|--force
-h|--help
--lockopt String
--longhelp
-n|--nofsck
--nolocking
--nosync
--noudevsync
--poolmetadatasize [+Size[m|UNIT]]
--profile String
-q|--quiet
--reportformat basic|json
-r|--resizesfs
-L|--size [+|-]Size[m|UNIT]
-i|--stripes Number
-I|--stripesize Size[k|UNIT]
-t|--test
--type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool
-v|--verbose
--version
-y|--yes
```

DESCRIPTION

lvresize resizes an LV in the same way as **lvextend** and **lvreduce**. See **lvextend(8)** and **lvreduce(8)** for more information.

In the usage section below, **--size** *Size* can be replaced with **--extents** *Number*. See both descriptions the options section.

USAGE

Resize an LV by a specified size.

```
lvresize -L|--size [+|-]Size[m|UNIT] LV
[ -l|--extents [+|-]Number[PERCENT] ]
[ -r|--resizesfs ]
[ --poolmetadatasize [+Size[m|UNIT] ] ]
[ COMMON_OPTIONS ]
[ PV ... ]
```

Resize an LV by specified PV extents.

```
lvresize LV PV ...
```

```
[ -r|--resizesfs ]
[ COMMON_OPTIONS ]
```

Resize a pool metadata SubLV by a specified size.

```
lvresize --poolmetadatasize [+]Size[m|UNIT] LV_thinpool
[ COMMON_OPTIONS ]
[ PV ... ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ -f|--force ]
[ -n|--nofsck ]
[ -i|--stripes Number ]
[ -I|--stripesize Size[k|UNIT] ]
[ --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit ]
[ --nosync ]
[ --noudevsync ]
[ --reportformat basic|json ]
[ --type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgecfgbackup(8)** for more information.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information

about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-l|--extents [+|-]Number[PERCENT]

Specifies the new size of the LV in logical extents. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. An alternate syntax allows the size to be determined indirectly as a percentage of the size of a related VG, LV, or set of PVs. The suffix **%VG** denotes the total size of the VG, the suffix **%FREE** the remaining free space in the VG, and the suffix **%PVS** the free space in the specified PVs. For a snapshot, the size can be expressed as a percentage of the total size of the origin LV with the suffix **%ORIGIN (100%ORIGIN** provides space for the whole origin). When expressed as a percentage, the size defines an upper limit for the number of logical extents in the new LV. The precise number of logical extents in the new LV is not determined until the command has completed. When the plus + or minus – prefix is used, the value is not an absolute size, but is relative and added or subtracted from the current size.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-n|--nofsck

Do not perform fsck before resizing filesystem when filesystem requires it. You may need to use --force to proceed with this option.

--nolocking

Disable locking.

--nosync

Causes the creation of mirror, raid1, raid4, raid5 and raid10 to skip the initial synchronization. In case of mirror, raid1 and raid10, any data written afterwards will be mirrored, but the original contents will not be copied. In case of raid4 and raid5, no parity blocks will be written, though any data written afterwards will cause parity blocks to be stored. This is useful for skipping a potentially long and resource intensive initial sync of an empty mirror/raid1/raid4/raid5 and raid10 LV. This option is not valid for raid6, because raid6 relies on proper parity (P and Q Syndromes) being created during initial synchronization in order to reconstruct proper user data in case of device failures. raid0 and raid0_meta do not provide any data copies or parity support and thus do not support initial synchronization.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--poolmetadatasize [+]*Size[m|UNIT]*

Specifies the new size of the pool metadata LV. The plus prefix+ can be used, in which case the value is added to the current size.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-r|--resizesfs

Resize underlying filesystem together with the LV using fsadm(8).

-L|--size [+|-]*Size[m|UNIT]*

Specifies the new size of the LV. The --size and --extents options are alternate methods of specifying size. The total number of physical extents used will be greater when redundant data is needed for RAID levels. When the plus+ or minus – prefix is used, the value is not an absolute size, but is relative and added or subtracted from the current size.

-i|--stripes *Number*

Specifies the number of stripes in a striped LV. This is the number of PVs (devices) that a striped LV is spread across. Data that appears sequential in the LV is spread across multiple devices in units of the stripe size (see --stripesize). This does not change existing allocated space, but only applies to space being allocated by the command. When creating a RAID 4/5/6 LV, this number does not include the extra devices that are required for parity. The largest number depends on the RAID type (raid0: 64, raid10: 32, raid4/5: 63, raid6: 62), and when unspecified, the default depends on the RAID type (raid0: 2, raid10: 2, raid4/5: 3, raid6: 5.) To stripe a new raid LV across all PVs by default, see lvm.conf allocation/raid_stripe_all_devices.

-I|--stripesize *Size[k|UNIT]*

The amount of data that is written to one device before moving to the next in a striped LV.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--type linear|striped|snapshot|mirror|raid|thin|cache|vdo|thin-pool|cache-pool|vdo-pool

The LV type, also known as "segment type" or "segtype". See usage descriptions for the specific ways to use these types. For more information about redundancy and performance (**raid<N>**, **mirror**, **striped**, **linear**) see **lvmraid(7)**. For thin provisioning (**thin**, **thin-pool**) see **lvmthin(7)**. For performance caching (**cache**, **cache-pool**) see **lvmcache(7)**. For copy-on-write snapshots (**snapshot**) see usage definitions. For VDO (**vdo**) see **lvmvdo(7)**. Several commands omit an explicit type option because the type is inferred from other options or shortcuts (e.g. --stripes, --mirrors, --snapshot, --virtualsize, --thin, --cache, --vdo). Use inferred types with care because it can lead to unexpected results.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **--qq**.)

VARIABLES*LV*

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV. LV followed by _<type> indicates that an LV of the given type is required. (raid represents raid<N> type)

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Extend an LV by 16MB using specific physical extents:
lvresize -L+16M vg1/lv1 /dev/sda:0-1 /dev/sdb:0-1

NAME

lvs – Display information about logical volumes

SYNOPSIS

```
lvs
  [ option_args ]
  [ position_args ]
```

DESCRIPTION

lvs produces formatted output about LVs.

USAGE

```
lvs
  [ -H|--history ]
  [ -a|--all ]
  [ -o|--options String ]
  [ -S|--select String ]
  [ -O|--sort String ]
  [ --segments ]
  [ --aligned ]
  [ --binary ]
  [ --configreport log|vg|lv|pv|pvseg|seg ]
  [ --foreign ]
  [ --ignorelockingfailure ]
  [ --logonly ]
  [ --nameprefixes ]
  [ --noheadings ]
  [ --nosuffix ]
  [ --readonly ]
  [ --reportformat basic|json ]
  [ --rows ]
  [ --separator String ]
  [ --shared ]
  [ --unbuffered ]
  [ --units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E ]
  [ --unquoted ]
  [ COMMON_OPTIONS ]
  [ VG|LV|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--aligned

Use with --separator to align the output columns

-a|--all

Show information about internal LVs. These are components of normal LVs, such as mirrors, which are not independently accessible, e.g. not mountable.

--binary

Use binary values "0" or "1" instead of descriptive literal values for columns that have exactly two valid values to report (not counting the "unknown" value which denotes that the value could not be determined).

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--configreport log|vg|lv|pv|pvseg|seg

See **lvmreport(7)**.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

-H|--history

Include historical LVs in the output. (This has no effect unless LVs were removed while lvm.conf metadata/record_lvs_history was enabled.)

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--logonly

Suppress command report and display only log report.

--longhelp

Display long help text.

--nameprefixes

Add an "LVM2_" prefix plus the field name to the output. Useful with --noheadings to produce a list of field=value pairs that can be used to set environment variables (for example, in udev rules).

--noheadings

Suppress the headings line that is normally the first line of output. Useful if grepping the output.

--nolocking

Disable locking.

--nosuffix

Suppress the suffix on output sizes. Use with **--units** (except h and H) if processing the output.

-o|--options String

Comma-separated, ordered list of fields to display in columns. String arg syntax is:
`[+|-#]Field1[,Field2 ...]` The prefix + will append the specified fields to the default fields, - will remove the specified fields from the default fields, and # will compact specified fields (removing them when empty for all rows.) Use **-o help** to view the list of all available fields. Use separate lists of fields to add, remove or compact by repeating the **-o** option: `-o+field1,field2 -o- field3,field4 -o#field5`. These lists are evaluated from left to right. Use field name **lv_all** to view all LV fields, **vg_all** all VG fields, **pv_all** all PV fields, **pvseg_all** all PV segment fields, **seg_all** all LV segment fields, and **pvseg_all** all PV segment columns. See the lvm.conf report section for more config options. See **Ivmreport(7)** for more information about reporting.

--profile String

An alias for **--commandprofile** or **--metadataprofile**, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides **--debug** and **--verbose**. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **Ivmreport(7)** for more information.

--rows

Output columns as rows.

--segments

Use default columns that emphasize segment information.

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by **--select help** and **Ivmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See **--options help** for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--separator String

String to use to separate each column. Useful if grepping the output.

--shared

Report/display shared VGs that would otherwise be skipped when lvmlockd is not being used on the host. See **Ivmlockd(8)** for more information about shared VGs.

-O|--sort String

Comma-separated ordered list of columns to sort by. Replaces the default selection. Precede any column with - for a reverse sort on that column.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes

has changed but hasn't.

--unbuffered

Produce output immediately without sorting or aligning the columns properly.

--units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E

All sizes are output in these units: human-(r)eadable with '<' rounding indicator, (h)uman-read-able, (b)ytes, (s)ectors, (k)ilobytes, (m)egabytes, (g)igabytes, (t)erabytes, (p)etabytes, (e)xabytes.

Capitalise to use multiples of 1000 (S.I.) instead of 1024. Custom units can be specified, e.g.
--units 3M.

--unquoted

When used with --nameprefixes, output values in the field=value pairs are not quoted.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES

VG

Volume Group name. See **lvm(8)** for valid names.

LV

Logical Volume name. See **lvm(8)** for valid names. An LV positional arg generally includes the VG name and LV name, e.g. VG/LV.

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NOTES

The lv_attr bits are:

- 1 Volume type: (C)ache, (m)irrored, (M)irrored without initial sync, (o)rigin, (O)rigin with merging snapshot, (r)aid, (R)aid without initial sync, (s)napshot, merging (S)napshot, (p)vmove, (v)irtual, mirror or raid (i)mage, mirror or raid (I)mage out-of-sync, mirror (l)og device, under (c)onversion, thin (V)olume, (t)hin pool, (T)hin pool data, v(d)o pool, v(D)o pool data, raid or pool m(e)tadata or pool metadata spare.
- 2 Permissions: (w)riteable, (r)ead-only, (R)ead-only activation of non-read-only volume
- 3 Allocation policy: (a)nywhere, (c)ontiguous, (i)nherited, c(l)ing, (n)ormal This is capitalised if the volume is currently locked against allocation changes, for example during **pvmove(8)**.

- 4 fixed (m)inor
- 5 State: (a)ctive, (h)istorical, (s)suspended, (I)nvalid snapshot, invalid (S)suspended snapshot, snapshot (m)erge failed, suspended snapshot (M)erge failed, mapped (d)evice present without tables, mapped device present with (i)nactive table, thin-pool (c)heck needed, suspended thin-pool (C)heck needed, (X) unknown
- 6 device (o)pen, (X) unknown
- 7 Target type: (C)ache, (m)irror, (r)aid, (s)napshot, (t)hin, (u)nknown, (v)irtual. This groups logical volumes related to the same kernel target together. So, for example, mirror images, mirror logs as well as mirrors themselves appear as (m) if they use the original device-mapper mirror kernel driver; whereas the raid equivalents using the md raid kernel driver all appear as (r). Snapshots using the original device-mapper driver appear as (s); whereas snapshots of thin volumes using the new thin provisioning driver appear as (t).
- 8 Newly-allocated data blocks are overwritten with blocks of (z)eroes before use.
- 9 Volume Health, where there are currently three groups of attributes identified:
 - Common ones for all Logical Volumes: (p)artial, (X) unknown.
 - (p)artial signifies that one or more of the Physical Volumes this Logical Volume uses is missing from the system. (X) unknown signifies the status is unknown.
 - Related to RAID Logical Volumes: (r)efresh needed, (m)ismatches exist, (w)ritemostly.
 - (r)efresh signifies that one or more of the Physical Volumes this RAID Logical Volume uses had suffered a write error. The write error could be due to a temporary failure of that Physical Volume or an indication that it is failing. The device should be refreshed or replaced.
 - (m)ismatches signifies that the RAID logical volume has portions of the array that are not coherent. Inconsistencies are detected by initiating a "check" on a RAID logical volume. (The scrubbing operations, "check" and "repair", can be performed on a RAID logical volume via the 'lvchange' command.)
 - (w)ritemostly signifies the devices in a RAID 1 logical volume that have been marked write-mostly. Re(s)haping signifies a RAID Logical Volume is either undergoing a stripe addition/removal, a stripe size or RAID algorithm change.
 - (R)emove after reshape signifies freed striped raid images to be removed.
 - Related to Thin pool Logical Volumes: (F)ailed, out of (D)ata space, (M)etadata read only.
 - (F)ailed is set if thin pool encounters serious failures and hence no further I/O is permitted at all.
 - The out of (D)ata space is set if thin pool has run out of data space.
 - (M)etadata read only signifies that thin pool encounters certain types of failures but it's still possible to do reads at least, but no metadata changes are allowed.
 - Related to Thin Logical Volumes: (F)ailed.
 - (F)ailed is set when related thin pool enters Failed state and no further I/O is permitted at all.
 - Related to writecache logical volumes: (E)rror.
 - (E)rror is set dm-writecache reports an error.
- 10 s(k)ip activation: this volume is flagged to be skipped during activation.

NAME

lvscan – List all logical volumes in all volume groups

SYNOPSIS

lvscan

[*option_args*]

DESCRIPTION

lvscan scans all VGs or all supported LVM block devices in the system for LVs. The output consists of one line for each LV indicating whether or not it is active, a snapshot or origin, the size of the device and its allocation policy. Use **lvs(8)** or **lvdisplay(8)** to obtain more comprehensive information about LVs.

USAGE

lvscan

[**-a|--all**]
[**-b|--blockdevice**]
[**--ignorelockingfailure**]
[**--readonly**]
[**--reportformat basic|json**]
[COMMON_OPTIONS]

Common options for lvm:

[**-d|--debug**]
[**-h|--help**]
[**-q|--quiet**]
[**-t|--test**]
[**-v|--verbose**]
[**-y|--yes**]
[**--commandprofile** *String*]
[**--config** *String*]
[**--driverloaded** **y|n**]
[**--lockopt** *String*]
[**--longhelp**]
[**--nolocking**]
[**--profile** *String*]
[**--version**]

OPTIONS

-a|--all

Show information about internal LVs. These are components of normal LVs, such as mirrors, which are not independently accessible, e.g. not mountable.

-b|--blockdevice

No longer used.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded **y|n**

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*String*

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

man – an interface to the system reference manuals

SYNOPSIS

```
man [ man options] [ [section] pa ge ...] ...
man -k [ apropos options] regexp ...
man -K [ man options] [section] term ...
man -f [ whatis options] pa ge ...
man -l [ man options] file ...
man -w|-W [ man options] pa ge ...
```

DESCRIPTION

man is the system's manual pager. Each *pa ge* argument given to **man** is normally the name of a program, utility or function. The *manual page* associated with each of these arguments is then found and displayed. A *section*, if provided, will direct **man** to look only in that *section* of the manual. The default action is to search in all of the available *sections* following a pre-defined order (see **DEFAULTS**), and to show only the first *page* found, even if *page* exists in several *sections*.

The table below shows the *section* numbers of the manual followed by the types of pages they contain.

1	Executable programs or shell commands
2	System calls (functions provided by the kernel)
3	Library calls (functions within program libraries)
4	Special files (usually found in <i>/dev</i>)
5	File formats and conventions, e.g. <i>/etc/passwd</i>
6	Games
7	Miscellaneous (including macro packages and conventions), e.g. man (7), groff (7), man-pages (7)
8	System administration commands (usually only for root)
9	Kernel routines [Non standard]

A manual *page* consists of several sections.

Conventional section names include **NAME**, **SYNOPSIS**, **CONFIGURATION**, **DESCRIPTION**, **OPTIONS**, **EXIT STATUS**, **RETURN VALUE**, **ERRORS**, **ENVIRONMENT**, **FILES**, **VERSIONS**, **CONFORMING TO**, **NOTES**, **BUGS**, **EXAMPLE**, **AUTHORS**, and **SEE ALSO**.

The following conventions apply to the **SYNOPSIS** section and can be used as a guide in other sections.

bold text	type exactly as shown.
<i>italic text</i>	replace with appropriate argument.
[-abc]	any or all arguments within [] are optional.
-a -b	options delimited by cannot be used together.
<i>argument</i> ...	<i>argument</i> is repeatable.
[<i>expression</i>] ...	entire <i>expression</i> within [] is repeatable.

Exact rendering may vary depending on the output device. For instance, man will usually not be able to render italics when running in a terminal, and will typically use underlined or coloured text instead.

The command or function illustration is a pattern that should match all possible invocations. In some cases it is advisable to illustrate several exclusive invocations as is shown in the **SYNOPSIS** section of this manual page.

EXAMPLES

man ls

Display the manual page for the *item* (program) *ls*.

man man.7

Display the manual page for macro package *man* from section 7. (This is an alternative spelling of "**man 7 man**".)

man 'man(7)'

Display the manual page for macro package *man* from section 7. (This is another alternative spelling of "**man 7 man**". It may be more convenient when copying and pasting cross-references to manual pages. Note that the parentheses must normally be quoted to protect them from the shell.)

man -a intro

Display, in succession, all of the available *intro* manual pages contained within the manual. It is possible to quit between successive displays or skip any of them.

man -t bash | lpr -Pps

Format the manual page for *bash* into the default **troff** or **groff** format and pipe it to the printer named *ps*. The default output for **groff** is usually PostScript. **man --help** should advise as to which processor is bound to the **-t** option.

man -l -Tdvi ./foo.1x.gz > ./foo.1x.dvi

This command will decompress and format the nroff source manual page *./foo.1x.gz* into a **device independent (dvi)** file. The redirection is necessary as the **-T** flag causes output to be directed to **stdout** with no pager. The output could be viewed with a program such as **xdvi** or further processed into PostScript using a program such as **dvips**.

man -k printf

Search the short descriptions and manual page names for the keyword *printf* as regular expression. Print out any matches. Equivalent to **apropos printf**.

man -f smail

Lookup the manual pages referenced by *smail* and print out the short descriptions of any found. Equivalent to **whatis smail**.

OVERVIEW

Many options are available to **man** in order to give as much flexibility as possible to the user. Changes can be made to the search path, section order, output processor, and other behaviours and operations detailed below.

If set, various environment variables are interrogated to determine the operation of **man**. It is possible to set the "catch-all" variable **\$MANOPT** to any string in command line format, with the exception that any spaces used as part of an option's argument must be escaped (preceded by a backslash). **man** will parse **\$MANOPT** prior to parsing its own command line. Those options requiring an argument will be overridden by the same options found on the command line. To reset all of the options set in **\$MANOPT**, **-D** can be specified as the initial command line option. This will allow man to "forget" about the options specified in **\$MANOPT**, although they must still have been valid.

Manual pages are normally stored in **nroff(1)** format under a directory such as */usr/share/man*. In some installations, there may also be preformatted *cat pages* to improve performance. See **manpath(5)** for details of where these files are stored.

This package supports manual pages in multiple languages, controlled by your *locale*. If your system did not set this up for you automatically, then you may need to set **\$LC_MESSAGES**, **\$LANG**, or another system-dependent environment variable to indicate your preferred locale, usually specified in the **POSIX** format:

<language>[_<territory>[.<character-set>[,<version>]]]

If the desired page is available in your *locale*, it will be displayed in lieu of the standard (usually American English) page.

If you find that the translations supplied with this package are not available in your native language and you would like to supply them, please contact the maintainer who will be coordinating such activity.

Individual manual pages are normally written and maintained by the maintainers of the program, function, or other topic that they document, and are not included with this package. If you find that a manual page is missing or inadequate, please report that to the maintainers of the package in question.

For information regarding other features and extensions available with this manual pager, please read the documents supplied with the package.

DEFUALTS

The order of sections to search may be overridden by the environment variable \$MANSECT or by the **SECTION** directive in */etc/manpath.config*. By default it is as follows:

```
1 n l 8 3 0 2 3posix 3pm 3perl 3am 5 4 9 6 7
```

The formatted manual page is displayed using a *pager*. This can be specified in a number of ways, or else will fall back to a default (see option **-P** for details).

The filters are deciphered by a number of means. Firstly, the command line option **-p** or the environment variable \$MANOFFSEQ is interrogated. If **-p** was not used and the environment variable was not set, the initial line of the nroff file is parsed for a preprocessor string. To contain a valid preprocessor string, the first line must resemble

```
'\" <string>
```

where **string** can be any combination of letters described by option **-p** below.

If none of the above methods provide any filter information, a default set is used.

A formatting pipeline is formed from the filters and the primary formatter (**nroff** or **[tg]roff** with **-t**) and executed. Alternatively, if an executable program *mandb_nfnt* (or *mandb_tfmt* with **-t**) exists in the man tree root, it is executed instead. It gets passed the manual source file, the preprocessor string, and optionally the device specified with **-T** or **-E** as arguments.

OPTIONS

Non-argument options that are duplicated either on the command line, in \$MANOPT, or both, are not harmful. For options that require an argument, each duplication will override the previous argument value.

General options

-C *file*, **--config-file**=*file*

Use this user configuration file rather than the default of *~/.manpath*.

-d, **--debug**

Print debugging information.

-D, **--default**

This option is normally issued as the very first option and resets **man**'s behaviour to its default. Its use is to reset those options that may have been set in \$MANOPT. Any options that follow **-D** will have their usual effect.

--warnings[=*warnings*]

Enable warnings from *groff*. This may be used to perform sanity checks on the source text of manual pages. *warnings* is a comma-separated list of warning names; if it is not supplied, the default is "mac". See the "Warnings" node in **inf o groff** for a list of available warning names.

Main modes of operation**-f, --whatis**

Equivalent to **whatis**. Display a short description from the manual page, if available. See **whatis(1)** for details.

-k, --apropos

Equivalent to **apropos**. Search the short manual page descriptions for keywords and display any matches. See **apropos(1)** for details.

-K, --global-apropos

Search for text in all manual pages. This is a brute-force search, and is likely to take some time; if you can, you should specify a section to reduce the number of pages that need to be searched. Search terms may be simple strings (the default), or regular expressions if the **--regex** option is used.

Note that this searches the *sources* of the manual pages, not the rendered text, and so may include false positives due to things like comments in source files. Searching the rendered text would be much slower.

-l, --local-file

Activate "local" mode. Format and display local manual files instead of searching through the system's manual collection. Each manual page argument will be interpreted as an nroff source file in the correct format. No cat file is produced. If '-' is listed as one of the arguments, input will be taken from stdin. When this option is not used, and man fails to find the page required, before displaying the error message, it attempts to act as if this option was supplied, using the name as a file-name and looking for an exact match.

-w, --where, --path, --location

Don't actually display the manual page, but do print the location of the source nroff file that would be formatted. If the **-a** option is also used, then print the locations of all source files that match the search criteria.

-W, --where-cat, --location-cat

Don't actually display the manual page, but do print the location of the preformatted cat file that would be displayed. If the **-a** option is also used, then print the locations of all preformatted cat files that match the search criteria.

If **-w** and **-W** are both used, then print both source file and cat file separated by a space. If all of **-w**, **-W**, and **-a** are used, then do this for each possible match.

-c, --catman

This option is not for general use and should only be used by the **catman** program.

-R encoding, --recode=encoding

Instead of formatting the manual page in the usual way, output its source converted to the specified *encoding*. If you already know the encoding of the source file, you can also use **manconv(1)** directly. However, this option allows you to convert several manual pages to a single encoding without having to explicitly state the encoding of each, provided that they were already installed in a structure similar to a manual page hierarchy.

Consider using **man-recode(1)** instead for converting multiple manual pages, since it has an interface designed for bulk conversion and so can be much faster.

Finding manual pages**-L locale, --locale=locale**

man will normally determine your current locale by a call to the C function **setlocale(3)** which interrogates various environment variables, possibly including **\$LC_MESSAGES** and **\$LANG**. To temporarily override the determined value, use this option to supply a *locale* string directly to **man**. Note that it will not take effect until the search for pages actually begins. Output such as the help message will always be displayed in the initially determined locale.

-m system [,...] , --systems=system [,...]

If this system has access to other operating systems' manual pages, they can be accessed using this option. To search for a manual page from NewOS's manual page collection, use the option **-m NewOS**.

The *system* specified can be a combination of comma delimited operating system names. To include a search of the native operating system's manual pages, include the system name **man** in the argument string. This option will override the **\$SYSTEM** environment variable.

-M path, --manpath=path

Specify an alternate manpath to use. By default, **man** uses **manpath** derived code to determine the path to search. This option overrides the **\$MANPATH** environment variable and causes option **-m** to be ignored.

A path specified as a manpath must be the root of a manual page hierarchy structured into sections as described in the man-db manual (under "The manual page system"). To view manual pages outside such hierarchies, see the **-l** option.

-S list, -s list, --sections=list

The given *list* is a colon- or comma-separated list of sections, used to determine which manual sections to search and in what order. This option overrides the **\$MANSECT** environment variable. (The **-s** spelling is for compatibility with System V.)

-e sub-extension, --extension=sub-extension

Some systems incorporate large packages of manual pages, such as those that accompany the **Tcl** package, into the main manual page hierarchy. To get around the problem of having two manual pages with the same name such as **exit(3)**, the **Tcl** pages were usually all assigned to section **I**. As this is unfortunate, it is now possible to put the pages in the correct section, and to assign a specific "extension" to them, in this case, **exit(3tcl)**. Under normal operation, **man** will display **exit(3)** in preference to **exit(3tcl)**. To negotiate this situation and to avoid having to know which section the page you require resides in, it is now possible to give **man** a *sub-extension* string indicating which package the page must belong to. Using the above example, supplying the option **-e tcl** to **man** will restrict the search to pages having an extension of ***tcl**.

-i, --ignore-case

Ignore case when searching for manual pages. This is the default.

-I, --match-case

Search for manual pages case-sensitively.

--regex

Show all pages with any part of either their names or their descriptions matching each *page* argument as a regular expression, as with **apropos(1)**. Since there is usually no reasonable way to pick a "best" page when searching for a regular expression, this option implies **-a**.

--wildcard

Show all pages with any part of either their names or their descriptions matching each *page* argument using shell-style wildcards, as with **apropos(1)** **--wildcard**. The *page* argument must match the entire name or description, or match on word boundaries in the description. Since there is usually no reasonable way to pick a "best" page when searching for a wildcard, this option implies **-a**.

--names-only

If the **--regex** or **--wildcard** option is used, match only page names, not page descriptions, as with **whatis(1)**. Otherwise, no effect.

-a, --all

By default, **man** will exit after displaying the most suitable manual page it finds. Using this option forces **man** to display all the manual pages with names that match the search criteria.

-u, --update

This option causes **man** to update its database caches of installed manual pages. This is only needed in rare situations, and it is normally better to run **mandb(8)** instead.

--no-subpages

By default, **man** will try to interpret pairs of manual page names given on the command line as equivalent to a single manual page name containing a hyphen or an underscore. This supports the common pattern of programs that implement a number of subcommands, allowing them to provide manual pages for each that can be accessed using similar syntax as would be used to invoke the subcommands themselves. For example:

```
$ man -aw git diff
/usr/share/man/man1/git-diff.1.gz
```

To disable this behaviour, use the **--no-subpages** option.

```
$ man -aw --no-subpages git diff
/usr/share/man/man1/git.1.gz
/usr/share/man/man3/Git.3pm.gz
/usr/share/man/man1/diff.1.gz
```

Controlling formatted output**-P pager, --pager=pager**

Specify which output pager to use. By default, **man** uses **pager**, falling back to **cat** if **pager** is not found or is not executable. This option overrides the **\$MANPAGER** environment variable, which in turn overrides the **\$PAGER** environment variable. It is not used in conjunction with **-f** or **-k**.

The value may be a simple command name or a command with arguments, and may use shell quoting (backslashes, single quotes, or double quotes). It may not use pipes to connect multiple commands; if you need that, use a wrapper script, which may take the file to display either as an argument or on standard input.

-r prompt, --prompt=prompt

If a recent version of **less** is used as the pager, **man** will attempt to set its prompt and some sensible options. The default prompt looks like

Manual page name(sec) line x

where *name* denotes the manual page name, *sec* denotes the section it was found under and *x* the current line number. This is achieved by using the **\$LESS** environment variable.

Supplying **-r** with a string will override this default. The string may contain the text **\$MAN_PN** which will be expanded to the name of the current manual page and its section name surrounded by "(" and ")". The string used to produce the default could be expressed as

```
\ Manual\ page\ $MAN_PN\ ?ltline\ %lt?L/%L.:
byte\ %bB?s/%s..?\ (END):?pB\ %pB\\%..
(press h for help or q to quit)
```

It is broken into three lines here for the sake of readability only. For its meaning see the **less(1)** manual page. The prompt string is first evaluated by the shell. All double quotes, back-quotes and backslashes in the prompt must be escaped by a preceding backslash. The prompt string may end in an escaped \$ which may be followed by further options for less. By default **man** sets the **-ix8** options.

The **\$MANLESS** environment variable described below may be used to set a default prompt

string if none is supplied on the command line.

-7, --ascii

When viewing a pure *ascii*(7) manual page on a 7 bit terminal or terminal emulator, some characters may not display correctly when using the *latin1*(7) device description with **GNU nroff**. This option allows pure *ascii* manual pages to be displayed in *ascii* with the *latin1* device. It will not translate any *latin1* text. The following table shows the translations performed: some parts of it may only be displayed properly when using **GNU nroff**'s *latin1*(7) device.

Description	Octal	latin1	ascii
continuation hyphen	255	-	-
bullet (middle dot)	267	•	o
acute accent	264	ˊ	,
multiplication sign	327	×	x

If the *latin1* column displays correctly, your terminal may be set up for *latin1* characters and this option is not necessary. If the *latin1* and *ascii* columns are identical, you are reading this page using this option or **man** did not format this page using the *latin1* device description. If the *latin1* column is missing or corrupt, you may need to view manual pages with this option.

This option is ignored when using options **-t**, **-H**, **-T**, or **-Z** and may be useless for **nroff** other than **GNU**'s.

-E encoding, --encoding=encoding

Generate output for a character encoding other than the default. For backward compatibility, *encoding* may be an **nroff** device such as **ascii**, **latin1**, or **utf8** as well as a true character encoding such as **UTF-8**.

--no-hyphenation, --nh

Normally, **nroff** will automatically hyphenate text at line breaks even in words that do not contain hyphens, if it is necessary to do so to lay out words on a line without excessive spacing. This option disables automatic hyphenation, so words will only be hyphenated if they already contain hyphens.

If you are writing a manual page and simply want to prevent **nroff** from hyphenating a word at an inappropriate point, do not use this option, but consult the **nroff** documentation instead; for instance, you can put "%\" inside a word to indicate that it may be hyphenated at that point, or put "%\" at the start of a word to prevent it from being hyphenated.

--no-justification, --nj

Normally, **nroff** will automatically justify text to both margins. This option disables full justification, leaving justified only to the left margin, sometimes called "ragged-right" text.

If you are writing a manual page and simply want to prevent **nroff** from justifying certain paragraphs, do not use this option, but consult the **nroff** documentation instead; for instance, you can use the ".na", ".nf", ".fi", and ".ad" requests to temporarily disable adjusting and filling.

-p string, --preprocessor=string

Specify the sequence of preprocessors to run before **nroff** or **troff/groff**. Not all installations will have a full set of preprocessors. Some of the preprocessors and the letters used to designate them are: **eqn** (**e**), **grap** (**g**), **pic** (**p**), **tbl** (**t**), **vgrind** (**v**), **refer** (**r**). This option overrides the **\$MAN-ROFFSEQ** environment variable. **zsoelim** is always run as the very first preprocessor.

-t, --troff

Use **groff -mandoc** to format the manual page to stdout. This option is not required in conjunction with **-H**, **-T**, or **-Z**.

-T[device], --troff-device[=device]

This option is used to change **groff** (or possibly **troff**'s) output to be suitable for a device other than the default. It implies **-t**. Examples (provided with Groff-1.17) include **dvi**, **latin1**, **ps**, **utf8**, **X75** and **X100**.

-H[browser], --html[=browser]

This option will cause **groff** to produce HTML output, and will display that output in a web browser. The choice of browser is determined by the optional *browser* argument if one is provided, by the **\$BROWSER** environment variable, or by a compile-time default if that is unset (usually **lynx**). This option implies **-t**, and will only work with GNU **troff**.

-X[dpi], --gxditview[=dpi]

This option displays the output of **groff** in a graphical window using the **gxditview** program. The *dpi* (dots per inch) may be 75, 75-12, 100, or 100-12, defaulting to 75; the -12 variants use a 12-point base font. This option implies **-T** with the X75, X75-12, X100, or X100-12 device respectively.

-Z, --ditroff

groff will run **troff** and then use an appropriate post-processor to produce output suitable for the chosen device. If *off -mandoc* is **groff**, this option is passed to **groff** and will suppress the use of a post-processor. It implies **-t**.

Getting help**-?, --help**

Print a help message and exit.

--usage

Print a short usage message and exit.

-V, --version

Display version information.

EXIT STATUS

- | | |
|-----------|--|
| 0 | Successful program execution. |
| 1 | Usage, syntax or configuration file error. |
| 2 | Operational error. |
| 3 | A child process returned a non-zero exit status. |
| 16 | At least one of the pages/files/keywords didn't exist or wasn't matched. |

ENVIRONMENT**MANPATH**

If **\$MANPATH** is set, its value is used as the path to search for manual pages.

See the **SEARCH PATH** section of **manpath(5)** for the default behaviour and details of how this environment variable is handled.

MANROFOPT

Every time **man** invokes the formatter (**nroff**, **troff**, or **groff**), it adds the contents of **\$MANROFOPT** to the formatter's command line.

MANOFFSEQ

If **\$MANOFFSEQ** is set, its value is used to determine the set of preprocessors to pass each manual page through. The default preprocessor list is system dependent.

MANSECT

If **\$MANSECT** is set, its value is a colon-delimited list of sections and it is used to determine which manual sections to search and in what order. The default is "1 n 1 8 3 0 2 3posix 3pm 3perl 3am 5 4 9 6 7", unless overridden by the **SECTION** directive in */etc/manpath.config*.

MANPAGER, PAGER

If **\$MANPAGER** or **\$PAGER** is set (**\$MANPAGER** is used in preference), its value is used as the name of the program used to display the manual page. By default, **pager** is used, falling back to **cat** if **pager** is not found or is not executable.

The value may be a simple command name or a command with arguments, and may use shell quoting (backslashes, single quotes, or double quotes). It may not use pipes to connect multiple commands; if you need that, use a wrapper script, which may take the file to display either as an argument or on standard input.

MANLESS

If **\$MANLESS** is set, its value will be used as the default prompt string for the **less** pager, as if it had been passed using the **-r** option (so any occurrences of the text **\$MAN_PN** will be expanded in the same way). For example, if you want to set the prompt string unconditionally to “my prompt string”, set **\$MANLESS** to ‘**-P***my prompt string*’. Using the **-r** option overrides this environment variable.

BROWSER

If **\$BROWSER** is set, its value is a colon-delimited list of commands, each of which in turn is used to try to start a web browser for **man --html**. In each command, **%s** is replaced by a file-name containing the HTML output from **groff**, **%%** is replaced by a single percent sign (%), and **%c** is replaced by a colon (:).

SYSTEM

If **\$SYSTEM** is set, it will have the same effect as if it had been specified as the argument to the **-m** option.

MANOPT

If **\$MANOPT** is set, it will be parsed prior to **man**’s command line and is expected to be in a similar format. As all of the other **man** specific environment variables can be expressed as command line options, and are thus candidates for being included in **\$MANOPT** it is expected that they will become obsolete. N.B. All spaces that should be interpreted as part of an option’s argument must be escaped.

MANWIDTH

If **\$MANWIDTH** is set, its value is used as the line length for which manual pages should be formatted. If it is not set, manual pages will be formatted with a line length appropriate to the current terminal (using the value of **\$COLUMNS**, and **ioctl(2)** if available, or falling back to 80 characters if neither is available). Cat pages will only be saved when the default formatting can be used, that is when the terminal line length is between 66 and 80 characters.

MAN_KEEP_FORMATTING

Normally, when output is not being directed to a terminal (such as to a file or a pipe), formatting characters are discarded to make it easier to read the result without special tools. However, if **\$MAN_KEEP_FORMATTING** is set to any non-empty value, these formatting characters are retained. This may be useful for wrappers around **man** that can interpret formatting characters.

MAN_KEEP_STDERR

Normally, when output is being directed to a terminal (usually to a pager), any error output from the command used to produce formatted versions of manual pages is discarded to avoid interfering with the pager’s display. Programs such as **gr off** often produce relatively minor error messages about typographical problems such as poor alignment, which are unsightly and generally confusing when displayed along with the manual page. However, some users want to see them anyway, so, if **\$MAN_KEEP_STDERR** is set to any non-empty value, error output will be displayed as usual.

MAN_DISABLE_SECCOMP

On Linux, **man** normally confines subprocesses that handle untrusted data using a **seccomp(2)** sandbox. This makes it safer to run complex parsing code over arbitrary manual pages. If this

goes wrong for some reason unrelated to the content of the page being displayed, you can set **\$MAN_DISABLE_SECCOMP** to any non-empty value to disable the sandbox.

PIPELINE_DEBUG

If the **\$PIPELINE_DEBUG** environment variable is set to "1", then **man** will print debugging messages to standard error describing each subprocess it runs.

LANG, LC_MESSAGES

Depending on system and implementation, either or both of **\$LANG** and **\$LC_MESSAGES** will be interrogated for the current message locale. **man** will display its messages in that locale (if available). See **setlocale(3)** for precise details.

FILES

/etc/manpath.config
man-db configuration file.

/usr/share/man
A global manual page hierarchy.

<https://savannah.nongnu.org/bugs/?group=man-db>

NAME

man – macros to format man pages

SYNOPSIS

```
groff -Tascii -man file ...
groff -Tp -man file ...
man [section] title
```

DESCRIPTION

This manual page explains the **groff an.tmac** macro package (often called the **man** macro package). This macro package should be used by developers when writing or porting man pages for Linux. It is fairly compatible with other versions of this macro package, so porting man pages should not be a major problem (exceptions include the NET-2 BSD release, which uses a totally different macro package called mdoc; see **mdoc(7)**).

Note that NET-2 BSD mdoc man pages can be used with **groff** simply by specifying the **-mdoc** option instead of the **-man** option. Using the **-mandoc** option is, however, recommended, since this will automatically detect which macro package is in use.

For conventions that should be employed when writing man pages for the Linux *man-pages* package, see **man-pages(7)**.

Title line

The first command in a man page (after comment lines, that is, lines that start with .\") should be

```
.TH title section date source manual
```

For details of the arguments that should be supplied to the **TH** command, see **man-pages(7)**.

Note that BSD mdoc-formatted pages begin with the **Dd** command, not the **TH** command.

Sections

Sections are started with **.SH** followed by the heading name.

The only mandatory heading is NAME, which should be the first section and be followed on the next line by a one-line description of the program:

```
.SH NAME
item \- description
```

It is extremely important that this format is followed, and that there is a backslash before the single dash which follows the item name. This syntax is used by the **mandb(8)** program to create a database of short descriptions for the **whatis(1)** and **apropos(1)** commands. (See **lexgrog(1)** for further details on the syntax of the NAME section.)

For a list of other sections that might appear in a manual page, see **man-pages(7)**.

Fonts

The commands to select the type face are:

.B Bold

.BI Bold alternating with italics (especially useful for function specifications)

.BR

Bold alternating with Roman (especially useful for referring to other manual pages)

.I Italics

.IB Italics alternating with bold

.IR Italics alternating with Roman

.RB

Roman alternating with bold

- .RI Roman alternating with italics
- .SB Small alternating with bold
- .SM
 - Small (useful for acronyms)

Traditionally, each command can have up to six arguments, but the GNU implementation removes this limitation (you might still want to limit yourself to 6 arguments for portability's sake). Arguments are delimited by spaces. Double quotes can be used to specify an argument which contains spaces. For the macros that produce alternating type faces, the arguments will be printed next to each other without intervening spaces, so that the .BR command can be used to specify a word in bold followed by a mark of punctuation in Roman. If no arguments are given, the command is applied to the following line of text.

Other macros and strings

Below are other relevant macros and predefined strings. Unless noted otherwise, all macros cause a break (end the current line of text). Many of these macros set or use the "prevailing indent". The "prevailing indent" value is set by any macro with the parameter *i* below; macros may omit *i* in which case the current prevailing indent will be used. As a result, successive indented paragraphs can use the same indent without respecifying the indent value. A normal (nonindented) paragraph resets the prevailing indent value to its default value (0.5 inches). By default, a given indent is measured in ens; try to use ens or ems as units for indents, since these will automatically adjust to font size changes. The other key macro definitions are:

Normal paragraphs

- .LP Same as .PP (begin a new paragraph).
- .P Same as .PP (begin a new paragraph).
- .PP Begin a new paragraph and reset prevailing indent.

Relative margin indent

- .RS *i* Start relative margin indent: moves the left margin *i* to the right (if *i* is omitted, the prevailing indent value is used). A new prevailing indent is set to 0.5 inches. As a result, all following paragraph(s) will be indented until the corresponding .RE.
- .RE End relative margin indent and restores the previous value of the prevailing indent.

Indented paragraph macros

- .HP *i* Begin paragraph with a hanging indent (the first line of the paragraph is at the left margin of normal paragraphs, and the rest of the paragraph's lines are indented).
- .IP *x i* Indented paragraph with optional hanging tag. If the tag *x* is omitted, the entire following paragraph is indented by *i*. If the tag *x* is provided, it is hung at the left margin before the following indented paragraph (this is just like .TP except the tag is included with the command instead of being on the following line). If the tag is too long, the text after the tag will be moved down to the next line (text will not be lost or garbled). For bulleted lists, use this macro with \bu (bullet) or \em (em dash) as the tag, and for numbered lists, use the number or letter followed by a period as the tag; this simplifies translation to other formats.
- .TP *i* Begin paragraph with hanging tag. The tag is given on the next line, but its results are like those of the .IP command.

Hypertext link macros

- .UR *url* Insert a hypertext link to the URI (URL) *url*, with all text up to the following .UE macro as the link text.
- .UE [*trailer*] Terminate the link text of the preceding .UR macro, with the optional *trailer* (if present, usually a closing parenthesis and/or end-of-sentence punctuation) immediately following. For non-HTML output devices (e.g., man -Tutf8), the link text is followed by the URL in angle brackets; if there is no link text, the URL is printed as its own link text, surrounded by angle brackets. (Angle

brackets may not be available on all output devices.) For the HTML output device, the link text is hyperlinked to the URL; if there is no link text, the URL is printed as its own link text.

These macros have been supported since GNU Troff 1.20 (2009-01-05) and Heirloom DocTools Troff since 160217 (2016-02-17).

Miscellaneous macros

.DT	Reset tabs to default tab values (every 0.5 inches); does not cause a break.
.PD <i>d</i>	Set inter-paragraph vertical distance to <i>d</i> (if omitted, <i>d</i> =0.4v); does not cause a break.
.SS <i>t</i>	Subheading <i>t</i> (like .SH , but used for a subsection inside a section).

Predefined strings

The **man** package has the following predefined strings:

*R	Registration Symbol: ®
*S	Change to default font size
*(Tm	Trademark Symbol: ™

Safe subset

Although technically **man** is a troff macro package, in reality a large number of other tools process man page files that don't implement all of troff's abilities. Thus, it's best to avoid some of troff's more exotic abilities where possible to permit these other tools to work correctly. Avoid using the various troff preprocessors (if you must, go ahead and use **tbl**(1), but try to use the **IP** and **TP** commands instead for two-column tables). Avoid using computations; most other tools can't process them. Use simple commands that are easy to translate to other formats. The following troff macros are believed to be safe (though in many cases they will be ignored by translators): **\", ., ad, bp, br, ce, de, ds, el, ie, if, fi, ft, hy, ig, in, na, ne, nf, nh, ps, so, sp, ti, tr**.

You may also use many troff escape sequences (those sequences beginning with \). When you need to include the backslash character as normal text, use \e. Other sequences you may use, where x or xx are any characters and N is any digit, include: \', \`, \-, \., \", \%, *x, *(xx, \xx, \\$N, \nx, \n(xx, \fx, and \f(xx. Avoid using the escape sequences for drawing graphics.

Do not use the optional parameter for **bp** (break page). Use only positive values for **sp** (vertical space). Don't define a macro (**de**) with the same name as a macro in this or the mdoc macro package with a different meaning; it's likely that such redefinitions will be ignored. Every positive indent (**in**) should be paired with a matching negative indent (although you should be using the **RS** and **RE** macros instead). The condition test (**if,ie**) should only have 't' or 'n' as the condition. Only translations (**tr**) that can be ignored should be used. Font changes (**ft** and the **\f** escape sequence) should only have the values 1, 2, 3, 4, R, I, B, P, or CW (the **ft** command may also have no parameters).

If you use capabilities beyond these, check the results carefully on several tools. Once you've confirmed that the additional capability is safe, let the maintainer of this document know about the safe command or sequence that should be added to this list.

FILES

/usr/share/groff/*/]tmac/an.tmac
/usr/man/whatis

NOTES

By all means include full URLs (or URIs) in the text itself; some tools such as **man2html**(1) can automatically turn them into hypertext links. You can also use the **UR** and **UE** macros to identify links to related information. If you include URLs, use the full URL (e.g.,<http://www.kernel.org>) to ensure that tools can automatically find the URLs.

Tools processing these files should open the file and examine the first nonwhitespace character. A period (.) or single quote (') at the beginning of a line indicates a troff-based file (such as man or mdoc). A left angle

bracket (<) indicates an SGML/XML-based file (such as HTML or Docbook). Anything else suggests simple ASCII text (e.g., a "catman" result).

Many man pages begin with '\>' followed by a space and a list of characters, indicating how the page is to be preprocessed. For portability's sake to non-troff translators we recommend that you avoid using anything other than **tbl**(1), and Linux can detect that automatically. However, you might want to include this information so your man page can be handled by other (less capable) systems. Here are the definitions of the preprocessors invoked by these characters:

- e** eqn(1)
- g** grap(1)
- p** pic(1)
- r** refer(1)
- t** tbl(1)
- v** vgrind(1)

BUGS

Most of the macros describe formatting (e.g., font type and spacing) instead of marking semantic content (e.g., this text is a reference to another page), compared to formats like mdoc and DocBook (even HTML has more semantic markings). This situation makes it harder to vary the **man** format for different media, to make the formatting consistent for a given media, and to automatically insert cross-references. By sticking to the safe subset described above, it should be easier to automate transitioning to a different reference page format in the future.

The Sun macro **TX** is not implemented.

NAME

mandb – create or update the manual page index caches

SYNOPSIS

```
mandb [ -dqsupt?V ] [-C file] [manpath]
mandb [ -dqsut ] [-C file] -f filename ...
```

DESCRIPTION

mandb is used to initialise or manually update **index** database caches. The caches contain information relevant to the current state of the manual page system and the information stored within them is used by the man-db utilities to enhance their speed and functionality.

When creating or updating an **index**, **mandb** will warn of bad ROFF .so requests, bogus manual page file-names and manual pages from which the **whatis** cannot be parsed.

Supplying **mandb** with an optional colon-delimited path will override the internal system manual page hierarchy search path, determined from information found within the man-db configuration file.

DATABASE CACHES

mandb can be compiled with support for any one of the following database types.

Name	Async	Filename
Berkeley db	Yes	<i>index.bt</i>
GNU gdbm	Yes	<i>index.db</i>
UNIX ndbm	No	<i>index.(dir/pag)</i>

Those database types that support asynchronous updates provide enhanced speed at the cost of possible corruption in the event of unusual termination. In an unusual case where this has occurred, it may be necessary to rerun **mandb** with the **-c** option to re-create the databases from scratch.

OPTIONS**-d, --debug**

Print debugging information.

-q, --quiet

Produce no warnings.

-s, --no-straycats

Do not spend time looking for or adding information to the databases regarding stray cats.

-p, --no-purge

Do not spend time checking for deleted manual pages and purging them from the databases.

-c, --create

By default, **mandb** will try to update any previously created databases. If a database does not exist, it will create it. This option forces **mandb** to delete previous databases and re-create them from scratch, and implies **--no-purge**. This may be necessary if a database becomes corrupt or if a new database storage scheme is introduced in the future.

-u, --user-db

Create user databases only, even with write permissions necessary to create system databases.

-t, --test

Perform correctness checks on manual pages in the hierarchy search path. With this option, **mandb** will not alter existing databases.

-f, --filename

Update only the entries for the given filename. This option is not for general use; it is used internally by **man** when it has been compiled with the **MAN_DB_UPDATES** option and finds that a page is out of date. It implies **-p** and disables **-c** and **-s**.

-C file, --config-file=file

Use this user configuration file rather than the default of `~/.manpath`.

-?, --help

Show the usage message, then exit.

--usage

Print a short usage message and exit.

-V, --version

Show the version, then exit.

EXIT STATUS

0 Successful program execution.

1 Usage, syntax, or configuration file error.

2 Operational error.

3 A child process failed.

DIAGNOSTICS

The following warning messages can be emitted during database building.

<filename>: whatis parse for page(sec) failed

An attempt to extract whatis line(s) from the given `<filename>` failed. This is usually due to a poorly written manual page, but if many such messages are emitted it is likely that the system contains non-standard manual pages which are incompatible with the man-db whatis parser. See the **WHATIS PARSING** section in **lexgrog(1)** for more information.

<filename>: is a dangling symlink

`<filename>` does not exist but is referenced by a symbolic link. Further diagnostics are usually emitted to identify the `<filename>` of the offending link.

<filename>: bad symlink or ROFF ‘.so’ request

`<filename>` is either a symbolic link to, or contains a ROFF include request to, a non-existent file.

<filename>: ignoring bogus filename

The `<filename>` may or may not be a valid manual page but its name is invalid. This is usually due to a manual page with sectional extension `<x>` being put in manual page section `<y>`.

<filename_mask>: competing extensions

The wildcard `<filename_mask>` is not unique. This is usually caused by the existence of both a compressed and uncompressed version of the same manual page. All but the most recent are ignored.

FILES

`/etc/manpath.config`

man-db configuration file.

`/var/cache/man/index.(bt/db/dir/pag)`

An FHS compliant global *index* database cache.

Older locations for the database cache included:

`/usr/man/index.(bt/db/dir/pag)`

A traditional global *index* database cache.

`/var/catman/index.(bt/db/dir/pag)`

An alternate or FSSTND compliant global *index* database cache.

md(4) - Linux man page

Name

md - Multiple Device driver aka Linux Software RAID

Synopsis

`/dev/mdn`
`/dev/md/n`
`/dev/md/name`

Description

The **md** driver provides virtual devices that are created from one or more independent underlying devices. This array of devices often contains redundancy and the devices are often disk drives, hence the acronym RAID which stands for a Redundant Array of Independent Disks.

md supports RAID levels 1 (mirroring), 4 (striped array with parity device), 5 (striped array with distributed parity information), 6 (striped array with distributed dual redundancy information), and 10 (striped and mirrored). If some number of underlying devices fails while using one of these levels, the array will continue to function; this number is one for RAID levels 4 and 5, two for RAID level 6, and all but one ($N-1$) for RAID level 1, and dependent on configuration for level 10.

md also supports a number of pseudo RAID (non-redundant) configurations including RAID0 (striped array), LINEAR (catenated array), MULTIPATH (a set of different interfaces to the same device), and FAULTY (a layer over a single device into which errors can be injected).

Md Metadata

Each device in an array may have some *metadata* stored in the device. This metadata is sometimes called a **superblock**. The metadata records information about the structure and state of the array. This allows the array to be reliably re-assembled after a shutdown.

From Linux kernel version 2.6.10, **md** provides support for two different formats of metadata, and other formats can be added. Prior to this release, only one format is supported.

The common format -- known as version 0.90 -- has a superblock that is 4K long and is written into a 64K aligned block that starts at least 64K and less than 128K from the end of the device (i.e. to get the address of the superblock round the size of the device down to a multiple of 64K and then subtract 64K). The available size of each device is the amount of

space before the super block, so between 64K and 128K is lost when a device is incorporated into an MD array. This superblock stores multi-byte fields in a processor-dependent manner, so arrays cannot easily be moved between computers with different processors.

The new format -- known as version 1 -- has a superblock that is normally 1K long, but can be longer. It is normally stored between 8K and 12K from the end of the device, on a 4K boundary, though variations can be stored at the start of the device (version 1.1) or 4K from the start of the device (version 1.2). This metadata format stores multibyte data in a processor-independent format and supports up to hundreds of component devices (version 0.90 only supports 28).

The metadata contains, among other things:

LEVEL

The manner in which the devices are arranged into the array (linear, raid0, raid1, raid4, raid5, raid10, multipath).

UUID

a 128 bit Universally Unique Identifier that identifies the array that contains this device.

When a version 0.90 array is being reshaped (e.g. adding extra devices to a RAID5), the version number is temporarily set to 0.91. This ensures that if the reshape process is stopped in the middle (e.g. by a system crash) and the machine boots into an older kernel that does not support reshaping, then the array will not be assembled (which would cause data corruption) but will be left untouched until a kernel that can complete the reshape processes is used.

Arrays Without Metadata

While it is usually best to create arrays with superblocks so that they can be assembled reliably, there are some circumstances when an array without superblocks is preferred. These include:

LEGACY ARRAYS

Early versions of the **md** driver only supported Linear and Raid0 configurations and did not use a superblock (which is less critical with these configurations). While such arrays should be rebuilt with superblocks if possible, **md** continues to support them.

FAULTY

Being a largely transparent layer over a different device, the FAULTY personality doesn't gain anything from having a superblock.

MULTIPATH

It is often possible to detect devices which are different paths to the same storage directly rather than having a distinctive superblock written to the device and searched for on all paths. In this case, a MULTIPATH array with no superblock makes sense.

RAID1

In some configurations it might be desired to create a raid1 configuration that does not use a superblock, and to maintain the state of the array elsewhere. While not encouraged for general use, it does have special-purpose uses and is supported.

Arrays with External Metadata

From release 2.6.28, the *md* driver supports arrays with externally managed metadata. That is, the metadata is not managed by the kernel but rather by a user-space program which is external to the kernel. This allows support for a variety of metadata formats without cluttering the kernel with lots of details.

md is able to communicate with the user-space program through various sysfs attributes so that it can make appropriate changes to the metadata - for example to mark a device as faulty. When necessary, *md* will wait for the program to acknowledge the event by writing to a sysfs attribute. The manual page for [*mdmon*\(8\)](#) contains more detail about this interaction.

Containers

Many metadata formats use a single block of metadata to describe a number of different arrays which all use the same set of devices. In this case it is helpful for the kernel to know about the full set of devices as a whole. This set is known to *md* as a *container*. A container is an *md* array with externally managed metadata and with device offset and size so that it just covers the metadata part of the devices. The remainder of each device is available to be incorporated into various arrays.

Linear

A linear array simply catenates the available space on each drive to form one large virtual drive.

One advantage of this arrangement over the more common RAID0 arrangement is that the array may be reconfigured at a later time with an extra drive, so the array is made bigger without disturbing the data that is on the array. This can even be done on a live array.

If a chunksize is given with a LINEAR array, the usable space on each device is rounded down to a multiple of this chunksize.

Raid0

A RAID0 array (which has zero redundancy) is also known as a striped array. A RAID0 array is configured at creation with a **Chunk Size** which must be a power of two (prior to Linux 2.6.31), and at least 4 kibibytes.

The RAID0 driver assigns the first chunk of the array to the first device, the second chunk to the second device, and so on until all drives have been assigned one chunk. This collection of chunks forms a **stripe**. Further chunks are gathered into stripes in the same way, and are assigned to the remaining space in the drives.

If devices in the array are not all the same size, then once the smallest device has been exhausted, the RAID0 driver starts collecting chunks into smaller stripes that only span the drives which still have remaining space.

Raid1

A RAID1 array is also known as a mirrored set (though mirrors tend to provide reflected images, which RAID1 does not) or a plex.

Once initialised, each device in a RAID1 array contains exactly the same data. Changes are written to all devices in parallel. Data is read from any one device. The driver attempts to distribute read requests across all devices to maximise performance.

All devices in a RAID1 array should be the same size. If they are not, then only the amount of space available on the smallest device is used (any extra space on other devices is wasted).

Note that the read balancing done by the driver does not make the RAID1 performance profile be the same as for RAID0; a single stream of sequential input will not be accelerated (e.g. a single dd), but multiple sequential streams or a random workload will use more than one spindle. In theory, having an N-disk RAID1 will allow N sequential threads to read from all disks.

Individual devices in a RAID1 can be marked as "write-mostly". These drives are excluded from the normal read balancing and will only be read from when there is no other option. This can be useful for devices connected over a slow link.

Raid4

A RAID4 array is like a RAID0 array with an extra device for storing parity. This device is the last of the active devices in the array. Unlike RAID0, RAID4 also requires that all stripes span all drives, so extra space on devices that are larger than the smallest is wasted.

When any block in a RAID4 array is modified, the parity block for that stripe (i.e. the block in the parity device at the same device offset as the stripe) is also modified so that the parity block always contains the "parity" for the whole stripe. I.e. its content is equivalent to the result of performing an exclusive-or operation between all the data blocks in the stripe.

This allows the array to continue to function if one device fails. The data that was on that device can be calculated as needed from the parity block and the other data blocks.

Raid5

RAID5 is very similar to RAID4. The difference is that the parity blocks for each stripe, instead of being on a single device, are distributed across all devices. This allows more parallelism when writing, as two different block updates will quite possibly affect parity blocks on different devices so there is less contention.

This also allows more parallelism when reading, as read requests are distributed over all the devices in the array instead of all but one.

Raid6

RAID6 is similar to RAID5, but can handle the loss of any *two* devices without data loss. Accordingly, it requires N+2 drives to store N drives worth of data.

The performance for RAID6 is slightly lower but comparable to RAID5 in normal mode and single disk failure mode. It is very slow in dual disk failure mode, however.

Raid10

RAID10 provides a combination of RAID1 and RAID0, and is sometimes known as RAID1+0. Every datablock is duplicated some number of times, and the resulting collection of datablocks are distributed over multiple drives.

When configuring a RAID10 array, it is necessary to specify the number of replicas of each data block that are required (this will normally be 2) and whether the replicas should be 'near', 'offset' or 'far'. (Note that the 'offset' layout is only available from 2.6.18).

When 'near' replicas are chosen, the multiple copies of a given chunk are laid out consecutively across the stripes of the array, so the two copies of a datablock will likely be at the same offset on two adjacent devices.

When 'far' replicas are chosen, the multiple copies of a given chunk are laid out quite distant from each other. The first copy of all data blocks will be striped across the early part of all drives in RAID0 fashion, and then the next copy of all blocks will be striped across a later section of all drives, always ensuring that all copies of any given block are on different drives.

The 'far' arrangement can give sequential read performance equal to that of a RAID0 array, but at the cost of reduced write performance.

When 'offset' replicas are chosen, the multiple copies of a given chunk are laid out on consecutive drives and at consecutive offsets. Effectively each stripe is duplicated and the copies are offset by one device. This should give similar read characteristics to 'far' if a suitably large chunk size is used, but without as much seeking for writes.

It should be noted that the number of devices in a RAID10 array need not be a multiple of the number of replica of each data block; however, there must be at least as many devices as replicas.

If, for example, an array is created with 5 devices and 2 replicas, then space equivalent to 2.5 of the devices will be available, and every block will be stored on two different devices.

Finally, it is possible to have an array with both 'near' and 'far' copies. If an array is configured with 2 near copies and 2 far copies, then there will be a total of 4 copies of each block, each on a different drive. This is an artifact of the implementation and is unlikely to be of real value.

Multipath

MULTIPATH is not really a RAID at all as there is only one real device in a MULTIPATH md array. However there are multiple access points (paths) to this device, and one of these paths might fail, so there are some similarities.

A MULTIPATH array is composed of a number of logically different devices, often fibre channel interfaces, that all refer to the same real device. If one of these interfaces fails (e.g. due to cable problems), the multipath driver will attempt to redirect requests to another interface.

The MULTIPATH drive is not receiving any ongoing development and should be considered a legacy driver. The device-mapper based multipath drivers should be preferred for new installations.

Faulty

The FAULTY md module is provided for testing purposes. A faulty array has exactly one component device and is normally assembled without a superblock, so the md array created provides direct access to all of the data in the component device.

The FAULTY module may be requested to simulate faults to allow testing of other md levels or of filesystems. Faults can be chosen to trigger on read requests or write requests, and can be transient (a subsequent read/write at the address will probably succeed) or persistent (subsequent read/write of the same address will fail). Further, read faults can be "fixable" meaning that they persist until a write request at the same address.

Fault types can be requested with a period. In this case, the fault will recur repeatedly after the given number of requests of the relevant type. For example if persistent read faults have a period of 100, then every 100th read request would generate a fault, and the faulty sector would be recorded so that subsequent reads on that sector would also fail.

There is a limit to the number of faulty sectors that are remembered. Faults generated after this limit is exhausted are treated as transient.

The list of faulty sectors can be flushed, and the active list of failure modes can be cleared.

Unclean Shutdown

When changes are made to a RAID1, RAID4, RAID5, RAID6, or RAID10 array there is a possibility of inconsistency for short periods of time as each update requires at least two block to be written to different devices, and these writes probably won't happen at exactly the same time. Thus if a system with one of these arrays is shutdown in the middle of a write operation (e.g. due to power failure), the array may not be consistent.

To handle this situation, the md driver marks an array as "dirty" before writing any data to it, and marks it as "clean" when the array is being disabled, e.g. at shutdown. If the md driver finds an array to be dirty at startup, it proceeds to correct any possibly inconsistency. For RAID1, this involves copying the contents of the first drive onto all other drives. For RAID4, RAID5 and RAID6 this involves recalculating the parity for each stripe and making sure that the parity block has the correct data. For RAID10 it involves copying one of the replicas of each block onto all the others. This process, known as "resynchronising" or "resync" is performed in the background. The array can still be used, though possibly with reduced performance.

If a RAID4, RAID5 or RAID6 array is degraded (missing at least one drive, two for RAID6) when it is restarted after an unclean shutdown, it cannot recalculate parity, and so it is possible that data might be undetectably corrupted. The 2.4 md driver **does not** alert the operator to this condition. The 2.6 md driver will fail to start an array in this condition without manual intervention, though this behaviour can be overridden by a kernel parameter.

Recovery

If the md driver detects a write error on a device in a RAID1, RAID4, RAID5, RAID6, or RAID10 array, it immediately disables that device (marking it as faulty) and continues operation on the remaining devices. If there are spare drives, the driver will start recreating on one of the spare drives the data which was on that failed drive, either by copying a working drive in a RAID1 configuration, or by doing calculations with the parity block on RAID4, RAID5 or RAID6, or by finding and copying originals for RAID10.

In kernels prior to about 2.6.15, a read error would cause the same effect as a write error. In later kernels, a read-error will instead cause md to attempt a recovery by overwriting the bad block. i.e. it will find the correct data from elsewhere, write it over the block that failed, and then try to read it back again. If either the write or the re-read fail, md will treat the error the same way that a write error is treated, and will fail the whole device.

While this recovery process is happening, the md driver will monitor accesses to the array and will slow down the rate of recovery if other activity is happening, so that normal access to the array will not be unduly affected. When no other activity is happening, the recovery

process proceeds at full speed. The actual speed targets for the two different situations can be controlled by the **speed_limit_min** and **speed_limit_max** control files mentioned below.

Scrubbing and Mismatches

As storage devices can develop bad blocks at any time it is valuable to regularly read all blocks on all devices in an array so as to catch such bad blocks early. This process is called *scrubbing*.

md arrays can be scrubbed by writing either *check* or *repair* to the file *md/sync_action* in the *sysfs* directory for the device.

Requesting a scrub will cause *md* to read every block on every device in the array, and check that the data is consistent. For RAID1 and RAID10, this means checking that the copies are identical. For RAID4, RAID5, RAID6 this means checking that the parity block is (or blocks are) correct.

If a read error is detected during this process, the normal read-error handling causes correct data to be found from other devices and to be written back to the faulty device. In many case this will effectively *fix* the bad block.

If all blocks read successfully but are found to not be consistent, then this is regarded as a *mismatch*.

If *check* was used, then no action is taken to handle the mismatch, it is simply recorded. If *repair* was used, then a mismatch will be repaired in the same way that *resync* repairs arrays. For RAID5/RAID6 new parity blocks are written. For RAID1/RAID10, all but one block are overwritten with the content of that one block.

A count of mismatches is recorded in the *sysfs* file *md/mismatch_cnt*. This is set to zero when a scrub starts and is incremented whenever a sector is found that is a mismatch. *md* normally works in units much larger than a single sector and when it finds a mismatch, it does not determine exactly how many actual sectors were affected but simply adds the number of sectors in the IO unit that was used. So a value of 128 could simply mean that a single 64KB check found an error ($128 \times 512\text{bytes} = 64\text{KB}$).

If an array is created by *mdadm* with *--assume-clean* then a subsequent check could be expected to find some mismatches.

On a truly clean RAID5 or RAID6 array, any mismatches should indicate a hardware problem at some level - software issues should never cause such a mismatch.

However on RAID1 and RAID10 it is possible for software issues to cause a mismatch to be reported. This does not necessarily mean that the data on the array is corrupted. It could

simply be that the system does not care what is stored on that part of the array - it is unused space.

The most likely cause for an unexpected mismatch on RAID1 or RAID10 occurs if a swap partition or swap file is stored on the array.

When the swap subsystem wants to write a page of memory out, it flags the page as 'clean' in the memory manager and requests the swap device to write it out. It is quite possible that the memory will be changed while the write-out is happening. In that case the 'clean' flag will be found to be clear when the write completes and so the swap subsystem will simply forget that the swapout had been attempted, and will possibly choose a different page to write out.

If the swap device was on RAID1 (or RAID10), then the data is sent from memory to a device twice (or more depending on the number of devices in the array). Thus it is possible that the memory gets changed between the times it is sent, so different data can be written to the different devices in the array. This will be detected by *check* as a mismatch. However it does not reflect any corruption as the block where this mismatch occurs is being treated by the swap system as being empty, and the data will never be read from that block.

It is conceivable for a similar situation to occur on non-swap files, though it is less likely.

Thus the *mismatch_cnt* value can not be interpreted very reliably on RAID1 or RAID10, especially when the device is used for swap.

Bitmap Write-intent Logging

From Linux 2.6.13, *md* supports a bitmap based write-intent log. If configured, the bitmap is used to record which blocks of the array may be out of sync. Before any write request is honoured, *md* will make sure that the corresponding bit in the log is set. After a period of time with no writes to an area of the array, the corresponding bit will be cleared.

This bitmap is used for two optimisations.

Firstly, after an unclean shutdown, the resync process will consult the bitmap and only resync those blocks that correspond to bits in the bitmap that are set. This can dramatically reduce resync time.

Secondly, when a drive fails and is removed from the array, *md* stops clearing bits in the intent log. If that same drive is re-added to the array, *md* will notice and will only recover the sections of the drive that are covered by bits in the intent log that are set. This can allow a device to be temporarily removed and reinserted without causing an enormous recovery cost.

The intent log can be stored in a file on a separate device, or it can be stored near the superblocks of an array which has superblocks.

It is possible to add an intent log to an active array, or remove an intent log if one is present.

In 2.6.13, intent bitmaps are only supported with RAID1. Other levels with redundancy are supported from 2.6.15.

Write-behind

From Linux 2.6.14, *md* supports WRITE-BEHIND on RAID1 arrays.

This allows certain devices in the array to be flagged as *write-mostly*. MD will only read from such devices if there is no other option.

If a write-intent bitmap is also provided, write requests to write-mostly devices will be treated as write-behind requests and md will not wait for writes to those requests to complete before reporting the write as complete to the filesystem.

This allows for a RAID1 with WRITE-BEHIND to be used to mirror data over a slow link to a remote computer (providing the link isn't too slow). The extra latency of the remote link will not slow down normal operations, but the remote system will still have a reasonably up-to-date copy of all data.

Restriping

Restriping, also known as *Reshaping*, is the processes of re-arranging the data stored in each stripe into a new layout. This might involve changing the number of devices in the array (so the stripes are wider), changing the chunk size (so stripes are deeper or shallower), or changing the arrangement of data and parity (possibly changing the raid level, e.g. 1 to 5 or 5 to 6).

As of Linux 2.6.35, *md* can reshape a RAID4, RAID5, or RAID6 array to have a different number of devices (more or fewer) and to have a different layout or chunk size. It can also convert between these different RAID levels. It can also convert between RAID0 and RAID10, and between RAID0 and RAID4 or RAID5. Other possibilities may follow in future kernels.

During any stripe process there is a 'critical section' during which live data is being overwritten on disk. For the operation of increasing the number of drives in a raid5, this critical section covers the first few stripes (the number being the product of the old and new number of devices). After this critical section is passed, data is only written to areas of the array which no longer hold live data -- the live data has already been located away.

For a reshape which reduces the number of devices, the 'critical section' is at the end of the reshape process.

md is not able to ensure data preservation if there is a crash (e.g. power failure) during the critical section. If md is asked to start an array which failed during a critical section of restriping, it will fail to start the array.

To deal with this possibility, a user-space program must

- Disable writes to that section of the array (using the **sysfs** interface),
- take a copy of the data somewhere (i.e. make a backup),
- allow the process to continue and invalidate the backup and restore write access once the critical section is passed, and
- provide for restoring the critical data before restarting the array after a system crash.

mdadm versions from 2.4 do this for growing a RAID5 array.

For operations that do not change the size of the array, like simply increasing chunk size, or converting RAID5 to RAID6 with one extra device, the entire process is the critical section. In this case, the stripe will need to progress in stages, as a section is suspended, backed up, restriped, and released.

Sysfs Interface

Each block device appears as a directory in *sysfs* (which is usually mounted at **/sys**). For MD devices, this directory will contain a subdirectory called **md** which contains various files for providing access to information about the array.

This interface is documented more fully in the file **Documentation/md.txt** which is distributed with the kernel sources. That file should be consulted for full documentation. The following are just a selection of attribute files that are available.

md/sync_speed_min

This value, if set, overrides the system-wide setting in **/proc/sys/dev/raid/speed_limit_min** for this array only. Writing the value **system** to this file will cause the system-wide setting to have effect.

md/sync_speed_max

This is the partner of **md/sync_speed_min** and overrides **/proc/sys/dev/raid/speed_limit_max** described below.

md/sync_action

This can be used to monitor and control the resync/recovery process of MD. In particular, writing "check" here will cause the array to read all data block and check that they are consistent (e.g. parity is correct, or all mirror replicas are the same). Any discrepancies found are **NOT** corrected.

A count of problems found will be stored in **md/mismatch_count**.

Alternately, "repair" can be written which will cause the same check to be performed, but any errors will be corrected.

Finally, "idle" can be written to stop the check/repair process.

md/stripe_cache_size

This is only available on RAID5 and RAID6. It records the size (in pages per device) of the stripe cache which is used for synchronising all write operations to the array and all read operations if the array is degraded. The default is 256. Valid values are 17 to 32768. Increasing this number can increase performance in some situations, at some cost in system memory. Note, setting this value too high can result in an "out of memory" condition for the system.

`memory_consumed = system_page_size * nr_disks * stripe_cache_size`

md/preread_bypass_threshold

This is only available on RAID5 and RAID6. This variable sets the number of times MD will service a full-stripe-write before servicing a stripe that requires some "prereading". For fairness this defaults to 1. Valid values are 0 to `stripe_cache_size`. Setting this to 0 maximizes sequential-write throughput at the cost of fairness to threads doing small or random writes.

Kernel Parameters

The md driver recognised several different kernel parameters.

raid=noautodetect

This will disable the normal detection of md arrays that happens at boot time. If a drive is partitioned with MS-DOS style partitions, then if any of the 4 main partitions has a partition type of 0xFD, then that partition will normally be inspected to see if it is part of an MD array, and if any full arrays are found, they are started. This kernel parameter disables this behaviour.

raid=partitionable

raid=part

These are available in 2.6 and later kernels only. They indicate that autodetected MD arrays should be created as partitionable arrays, with a different major device number to the original non-partitionable md arrays. The device number is listed as `mdp` in `/proc/devices`.

md_mod.start_ro=1

/sys/module/md_mod/parameters/start_ro

This tells md to start all arrays in read-only mode. This is a soft read-only that will automatically switch to read-write on the first write request. However until that write request, nothing is written to any device by md, and in particular, no resync or recovery operation is started.

md_mod.start_dirty_degraded=1

/sys/module/md_mod/parameters/start_dirty_degraded

As mentioned above, md will not normally start a RAID4, RAID5, or RAID6 that is both dirty and degraded as this situation can imply hidden data loss. This can be awkward if the root filesystem is affected. Using this module parameter allows such arrays to be started at boot time. It should be understood that there is a real (though small) risk of data corruption in this situation.

md=n,dev,dev,...

md=dn,dev,dev,...

This tells the md driver to assemble **/dev/md n** from the listed devices. It is only necessary to start the device holding the root filesystem this way. Other arrays are best started once the system is booted.

In 2.6 kernels, the **d** immediately after the **=** indicates that a partitionable device (e.g. **/dev/md/d0**) should be created rather than the original non-partitionable device.

md=n,l,c,i,dev...

This tells the md driver to assemble a legacy RAID0 or LINEAR array without a superblock. *n* gives the md device number, *l* gives the level, 0 for RAID0 or -1 for LINEAR, *c* gives the chunk size as a base-2 logarithm offset by twelve, so 0 means 4K, 1 means 8K. *i* is ignored (legacy support).

Files

/proc/mdstat

Contains information about the status of currently running array.

/proc/sys/dev/raid/speed_limit_min

A readable and writable file that reflects the current "goal" rebuild speed for times when non-rebuild activity is current on an array. The speed is in Kibibytes per second, and is a per-device rate, not a per-array rate (which means that an array with more disks will shuffle more data for a given speed). The default is 1000.

/proc/sys/dev/raid/speed_limit_max

A readable and writable file that reflects the current "goal" rebuild speed for times when no non-rebuild activity is current on an array. The default is 200,000.

NAME

md5sum – compute and check MD5 message digest

SYNOPSIS

md5sum [*OPTION*]... [*FILE*]...

DESCRIPTION

Print or check MD5 (128-bit) checksums.

With no FILE, or when FILE is `-`, read standard input.

-b, --binary

read in binary mode

-c, --check

read MD5 sums from the FILEs and check them

--tag create a BSD-style checksum

-t, --text

read in text mode (default)

-z, --zero

end each output line with NUL, not newline, and disable file name escaping

The following five options are useful only when verifying checksums:

--ignore-missing

don't fail or report status for missing files

--quiet

don't print OK for each successfully verified file

--status

don't output anything, status code shows success

--strict

exit non-zero for improperly formatted checksum lines

-w, --warn

warn about improperly formatted checksum lines

--help display this help and exit

--version

output version information and exit

The sums are computed as described in RFC 1321. When checking, the input should be a former output of this program. The default mode is to print a line with checksum, a space, a character indicating input mode ('*' for binary, ' ' for text or where binary is insignificant), and name for each FILE.

Note: There is no difference between binary mode and text mode on GNU systems.

BUGS

Do not use the MD5 algorithm for security related purposes. Instead, use an SHA-2 algorithm, implemented in the programs sha224sum(1), sha256sum(1), sha384sum(1), sha512sum(1), or the BLAKE2 algorithm, implemented in b2sum(1)

NAME

`mdadm` – manage MD devices *aka* Linux Software RAID

SYNOPSIS

`mdadm [mode] <raiddevice> [options] <component-devices>`

DESCRIPTION

RAID devices are virtual devices created from two or more real block devices. This allows multiple devices (typically disk drives or partitions thereof) to be combined into a single device to hold (for example) a single filesystem. Some RAID levels include redundancy and so can survive some degree of device failure.

Linux Software RAID devices are implemented through the md (Multiple Devices) device driver.

Currently, Linux supports **LINEAR** md devices, **RAID0** (striping), **RAID1** (mirroring), **RAID4**, **RAID5**, **RAID6**, **RAID10**, **MULTIPATH**, **FAULTY**, and **CONTAINER**.

MULTIPATH is not a Software RAID mechanism, but does involve multiple devices: each device is a path to one common physical storage device. New installations should not use md/multipath as it is not well supported and has no ongoing development. Use the Device Mapper based multipath-tools instead.

FAULTY is also not true RAID, and it only involves one device. It provides a layer over a true device that can be used to inject faults.

CONTAINER is different again. **ACONTAINER** is a collection of devices that are managed as a set. This is similar to the set of devices connected to a hardware RAID controller. The set of devices may contain a number of different RAID arrays each utilising some (or all) of the blocks from a number of the devices in the set. For example, two devices in a 5-device set might form a RAID1 using the whole devices. The remaining three might have a RAID5 over the first half of each device, and a RAID0 over the second half.

With a **CONTAINER**, there is one set of metadata that describes all of the arrays in the container. So when `mdadm` creates a **CONTAINER** device, the device just represents the metadata. Other normal arrays (RAID1 etc) can be created inside the container.

MODES

`mdadm` has several major modes of operation:

Assemble

Assemble the components of a previously created array into an active array. Components can be explicitly given or can be searched for. `mdadm` checks that the components do form a bona fide array, and can, on request, fiddle superblock information so as to assemble a faulty array.

Build Build an array that doesn't have per-device metadata (superblocks). For these sorts of arrays, `mdadm` cannot differentiate between initial creation and subsequent assembly of an array. It also cannot perform any checks that appropriate components have been requested. Because of this, the **Build** mode should only be used together with a complete understanding of what you are doing.

Create Create a new array with per-device metadata (superblocks). Appropriate metadata is written to each device, and then the array comprising those devices is activated. A 'resync' process is started to make sure that the array is consistent (e.g. both sides of a mirror contain the same data) but the content of the device is left otherwise untouched. The array can be used as soon as it has been created. There is no need to wait for the initial resync to finish.

Follow or Monitor

Monitor one or more md devices and act on any state changes. This is only meaningful for RAID1, 4, 5, 6, 10 or multipath arrays, as only these have interesting state. RAID0 or Linear never have missing, spare, or failed drives, so there is nothing to monitor.

- Grow** Grow (or shrink) an array, or otherwise reshape it in some way. Currently supported growth options including changing the active size of component devices and changing the number of active devices in Linear and RAID levels 0/1/4/5/6, changing the RAID level between 0, 1, 5, and 6, and between 0 and 10, changing the chunk size and layout for RAID 0,4,5,6,10 as well as adding or removing a write-intent bitmap and changing the array's consistency policy.

Incremental Assembly

Add a single device to an appropriate array. If the addition of the device makes the array runnable, the array will be started. This provides a convenient interface to a *hot-plug* system. As each device is detected, *mdadm* has a chance to include it in some array as appropriate. Optionally, when the *--fail* flag is passed in we will remove the device from any active array instead of adding it.

If a **CONTAINER** is passed to *mdadm* in this mode, then any arrays within that container will be assembled and started.

Manage

This is for doing things to specific components of an array such as adding new spares and removing faulty devices.

- Misc** This is an 'everything else' mode that supports operations on active arrays, operations on component devices such as erasing old superblocks, and information gathering operations.

Auto-detect

This mode does not act on a specific device or array, but rather it requests the Linux Kernel to activate any auto-detected arrays.

OPTIONS**Options for selecting a mode are:****-A, --assemble**

Assemble a pre-existing array.

-B, --build

Build a legacy array without superblocks.

-C, --create

Create a new array.

-F, --follow, --monitor

Select **Monitor** mode.

-G, --grow

Change the size or shape of an active array.

-I, --incremental

Add/remove a single device to/from an appropriate array, and possibly start the array.

--auto-detect

Request that the kernel starts any auto-detected arrays. This can only work if *md* is compiled into the kernel — not if it is a module. Arrays can be auto-detected by the kernel if all the components are in primary MS-DOS partitions with partition type **FD**, and all use v0.90 metadata. In-kernel autodetect is not recommended for new installations. Using *mdadm* to detect and assemble arrays — possibly in *aninitrd* — is substantially more flexible and should be preferred.

If a device is given before any options, or if the first option is one of **--add**, **--re-add**, **--add-spare**, **--fail**, **--remove**, or **--replace**, then the **MANAGE** mode is assumed. Anything other than these will cause the **Misc** mode to be assumed.

Options that are not mode-specific are:**-h, --help**

Display general help message or, after one of the above options, a mode-specific help message.

--help-options

Display more detailed help about command line parsing and some commonly used options.

-V, --version

Print version information for *mdadm*.

-v, --verbose

Be more verbose about what is happening. This can be used twice to be extra-verbose. The extra verbosity currently only affects **--detail** **--scan** and **--examine** **--scan**.

-q, --quiet

Avoid printing purely informative messages. With this, *mdadm* will be silent unless there is something really important to report.

-f, --force

Be more forceful about certain operations. See the various modes for the exact meaning of this option in different contexts.

-c, --config=

Specify the config file or directory. Default is to use **/etc/mdadm/mdadm.conf** and **/etc/mdadm/mdadm.conf.d**, or if those are missing then **/etc/mdadm.conf** and **/etc/mdadm.conf.d**. If the config file given is **partitions** then nothing will be read, but *mdadm* will act as though the config file contained exactly

DEVICE partitions containers

and will read **/proc/partitions** to find a list of devices to scan, and **/proc/mdstat** to find a list of containers to examine. If the word **none** is given for the config file, then *mdadm* will act as though the config file were empty.

If the name given is of a directory, then *mdadm* will collect all the files contained in the directory with a name ending in **.conf**, sort them lexically, and process all of those files as config files.

-s, --scan

Scan config file or **/proc/mdstat** for missing information. In general, this option gives *mdadm* permission to get any missing information (like component devices, array devices, array identities, and alert destination) from the configuration file (see previous option); one exception is MISC

mode when using **--detail** or **--stop**, in which case **--scan** says to get a list of array devices from **/proc/mdstat**.

-e, --metadata=

Declare the style of RAID metadata (superblock) to be used. The default is 1.2 for **--create**, and to guess for other operations. The default can be overridden by setting the **metadata** value for the **CREATE** keyword in **mdadm.conf**.

Options are:

0, 0.90 Use the original 0.90 format superblock. This format limits arrays to 28 component devices and limits component devices of levels 1 and greater to 2 terabytes. It is also possible for there to be confusion about whether the superblock applies to a whole device or just the last partition, if that partition starts on a 64K boundary.

1, 1.0, 1.1, 1.2 default

Use the new version-1 format superblock. This has fewer restrictions. It can easily be moved between hosts with different endian-ness, and a recovery operation can be check-pointed and restarted. The different sub-versions store the superblock at different locations on the device, either at the end (for 1.0), at the start (for 1.1) or 4K from the start (for 1.2). "1" is equivalent to "1.2" (the commonly preferred 1.x format). "default" is equivalent to "1.2".

ddf Use the "Industry Standard" DDF (Disk Data Format) format defined by SNIA. When creating a DDF array a **CONTAINER** will be created, and normal arrays can be created in that container.

imsm Use the Intel(R) Matrix Storage Manager metadata format. This creates a **CONTAINER** which is managed in a similar manner to DDF, and is supported by an option-rom on some platforms:

<https://www.intel.com/content/www/us/en/support/products/122484/memory-and-storage/ssd-software/intel-virtual-raid-on-cpu-intel-vroc.html>

--homehost=

This will override any **HOMEHOST** setting in the config file and provides the identity of the host which should be considered the home for any arrays.

When creating an array, the **homehost** will be recorded in the metadata. For version-1 superblocks, it will be prefixed to the array name. For version-0.90 superblocks, part of the SHA1 hash of the hostname will be stored in the later half of the UUID.

When reporting information about an array, any array which is tagged for the given homehost will be reported as such.

When using Auto-Assemble, only arrays tagged for the given homehost will be allowed to use 'local' names (i.e. not ending in '_' followed by a digit string). See below under **Auto Assembly**.

The special name "**any**" can be used as a wild card. If an array is created with **--homehost=any** then the name "**any**" will be stored in the array and it can be assembled in the same way on any host. If an array is assembled with this option, then the homehost recorded on the array will be ignored.

--prefer=

When *mdadm* needs to print the name for a device it normally finds the name in */dev* which refers to the device and is shortest. When a path component is given with **--prefer** *mdadm* will prefer a longer name if it contains that component. For example **--prefer=by-uuid** will prefer a name in a subdirectory of */dev* called **by-uuid**.

This functionality is currently only provided by **--detail** and **--monitor**.

--home-cluster=

specifies the cluster name for the md device. The md device can be assembled only on the cluster which matches the name specified. If this option is not provided, *mdadm* tries to detect the cluster name automatically.

For create, build, or grow:**-n, --raid-devices=**

Specify the number of active devices in the array. This, plus the number of spare devices (see below) must equal the number of *component-devices* (including "missing" devices) that are listed on the command line for **--create**. Setting a value of 1 is probably a mistake and so requires that **--force** be specified first. A value of 1 will then be allowed for linear, multipath, RAID0 and RAID1. It is never allowed for RAID4, RAID5 or RAID6.

This number can only be changed using **--grow** for RAID1, RAID4, RAID5 and RAID6 arrays, and only on kernels which provide the necessary support.

-x, --spare-devices=

Specify the number of spare (eXtra) devices in the initial array. Spares can also be added and removed later. The number of component devices listed on the command line must equal the number of RAID devices plus the number of spare devices.

-z, --size=

Amount (in Kilobytes) of space to use from each drive in RAID levels 1/4/5/6. This must be a multiple of the chunk size, and must leave about 128Kb of space at the end of the drive for the RAID superblock. When specified as *max*, (as it often is) the smallest drive (or partition) sets the size. In that case, a warning will follow if the drives, as a group, have sizes that differ by more than one percent.

A suffix of 'K', 'M', 'G' or 'T' can be given to indicate Kilobytes, Megabytes, Gigabytes or Terabytes respectively.

Sometimes a replacement drive can be a little smaller than the original drives though this should be minimised by IDEMA standards. Such a replacement drive will be rejected by *md*. To guard against this it can be useful to set the initial size slightly smaller than the smaller device with the aim that it will still be larger than any replacement.

This value can be set with **--grow** for RAID level 1/4/5/6 though DDF arrays may not be able to support this. If the array was created with a size smaller than the currently active drives, the extra space can be accessed using **--grow**. The size can be given as **max** which means to choose the largest size that fits on all current drives.

Before reducing the size of the array (with **--grow --size=**) you should make sure that space isn't needed. If the device holds a filesystem, you would need to resize the filesystem to use less space.

After reducing the array size you should check that the data stored in the device is still available. If the device holds a filesystem, then an 'fsck' of the filesystem is a minimum requirement. If

there are problems the array can be made bigger again with no loss with another **--grow --size=** command.

This value cannot be used when creating a **CONTAINER** such as with DDF and IMSM metadata, though it perfectly valid when creating an array inside a container.

-Z, --array-size=

This is only meaningful with **--grow** and its effect is not persistent: when the array is stopped and restarted the default array size will be restored.

Setting the array-size causes the array to appear smaller to programs that access the data. This is particularly needed before reshaping an array so that it will be smaller. As the reshape is not reversible, but setting the size with **--array-size** is, it is required that the array size is reduced as appropriate before the number of devices in the array is reduced.

Before reducing the size of the array you should make sure that space isn't needed. If the device holds a filesystem, you would need to resize the filesystem to use less space.

After reducing the array size you should check that the data stored in the device is still available. If the device holds a filesystem, then an 'fsck' of the filesystem is a minimum requirement. If there are problems the array can be made bigger again with no loss with another **--grow --array-size=** command.

A suffix of 'K', 'M', 'G' or 'T' can be given to indicate Kilobytes, Megabytes, Gigabytes or Terabytes respectively. A value of **max** restores the apparent size of the array to be whatever the real amount of available space is.

Clustered arrays do not support this parameter yet.

-c, --chunk=

Specify chunk size of kilobytes. The default when creating an array is 512KB. To ensure compatibility with earlier versions, the default when building an array with no persistent metadata is 64KB. This is only meaningful for RAID0, RAID4, RAID5, RAID6, and RAID10.

RAID4, RAID5, RAID6, and RAID10 require the chunk size to be a power of 2. In any case it must be a multiple of 4KB.

A suffix of 'K', 'M', 'G' or 'T' can be given to indicate Kilobytes, Megabytes, Gigabytes or Terabytes respectively.

--rounding=

Specify rounding factor for a Linear array. The size of each component will be rounded down to a multiple of this size. This is a synonym for **--chunk** but highlights the different meaning for Linear as compared to other RAID levels. The default is 64K if a kernel earlier than 2.6.16 is in use, and is 0K (i.e. no rounding) in later kernels.

-l, --level=

Set RAID level. When used with **--create**, options are: linear, raid0, 0, stripe, raid1, 1, mirror, raid4, 4, raid5, 5, raid6, 6, raid10, 10, multipath, mp, faulty, container. Obviously some of these are synonymous.

When a **CONTAINER** metadata type is requested, only the **container** level is permitted, and it does not need to be explicitly given.

When used with **--build**, only linear, stripe, raid0, 0, raid1, multipath, mp, and faulty are valid.

Can be used with **--grow** to change the RAID level in some cases. See LEVEL CHANGES below.

-p, --layout=

This option configures the fine details of data layout for RAID5, RAID6, and RAID10 arrays, and controls the failure modes for *faulty*. It can also be used for working around a kernel bug with RAID0, but generally doesn't need to be used explicitly.

The layout of the RAID5 parity block can be one of **left-asymmetric**, **left-symmetric**, **right-asymmetric**, **right-symmetric**, **la**, **ra**, **ls**, **rs**. The default is **left-symmetric**.

It is also possible to cause RAID5 to use a RAID4-like layout by choosing **parity-first**, or **parity-last**.

Finally for RAID5 there are DDF-compatible layouts, **ddf-zero-restart**, **ddf-N-restart**, and **ddf-N-continue**.

These same layouts are available for RAID6. There are also 4 layouts that will provide an intermediate stage for converting between RAID5 and RAID6. These provide a layout which is identical to the corresponding RAID5 layout on the first N-1 devices, and has the 'Q' syndrome (the second 'parity' block used by RAID6) on the last device. These layouts are:**left-symmetric-6**, **right-symmetric-6**, **left-asymmetric-6**, **right-asymmetric-6**, and **parity-first-6**.

When setting the failure mode for level *faulty*, the options are: **write-transient**, **wt**, **read-transient**, **rt**, **write-persistent**, **wp**, **read-persistent**, **rp**, **write-all**, **read-fixable**, **rf**, **clear**, **flush**, **none**.

Each failure mode can be followed by a number, which is used as a period between fault generation. Without a number, the fault is generated once on the first relevant request. With a number, the fault will be generated after that many requests, and will continue to be generated every time the period elapses.

Multiple failure modes can be current simultaneously by using the **--grow** option to set subsequent failure modes.

"clear" or "none" will remove any pending or periodic failure modes, and "flush" will clear any persistent faults.

The layout options for RAID10 are one of 'n', 'o' or 'f' followed by a small number. The default is 'n2'. The supported options are:

'n' signals 'near' copies. Multiple copies of one data block are at similar offsets in different devices.

'o' signals 'offset' copies. Rather than the chunks being duplicated within a stripe, whole stripes are duplicated but are rotated by one device so duplicate blocks are on different devices. Thus subsequent copies of a block are in the next drive, and are one chunk further down.

'f' signals 'far' copies (multiple copies have very different offsets). See md(4) for more detail about 'near', 'offset', and 'far'.

The number is the number of copies of each datablock. 2 is normal, 3 can be useful. This number

can be at most equal to the number of devices in the array. It does not need to divide evenly into that number (e.g. it is perfectly legal to have an 'n2' layout for an array with an odd number of devices).

A bug introduced in Linux 3.14 means that RAID0 arrays **with devices of differing sizes** started using a different layout. This could lead to data corruption. Since Linux 5.4 (and various stable releases that received backports), the kernel will not accept such an array unless a layout is explicitly set. It can be set to '**original**' or '**alternate**'. When creating a new array, *mdadm* will select '**original**' by default, so the layout does not normally need to be set. An array created for either '**original**' or '**alternate**' will not be recognized by an (unpatched) kernel prior to 5.4. To create a RAID0 array with devices of differing sizes that can be used on an older kernel, you can set the layout to '**dangerous**'. This will use whichever layout the running kernel supports, so the data on the array may become corrupt when changing kernel from pre-3.14 to a later kernel.

When an array is converted between RAID5 and RAID6 an intermediate RAID6 layout is used in which the second parity block (Q) is always on the last device. To convert a RAID5 to RAID6 and leave it in this new layout (which does not require re-striping) use **--layout=preserve**. This will try to avoid any restriping.

The converse of this is **--layout=normalise** which will change a non-standard RAID6 layout into a more standard arrangement.

--parity=

same as **--layout** (thus explaining the p of **-p**).

-b, --bitmap=

Specify a file to store a write-intent bitmap in. The file should not exist unless **--force** is also given. The same file should be provided when assembling the array. If the word **internal** is given, then the bitmap is stored with the metadata on the array, and so is replicated on all devices. If the word **none** is given with **--grow** mode, then any bitmap that is present is removed. If the word **clustered** is given, the array is created for a clustered environment. One bitmap is created for each node as defined by the **--nodes** parameter and are stored internally.

To help catch typing errors, the filename must contain at least one slash ('/') if it is a real file (not 'internal' or 'none').

Note: external bitmaps are only known to work on ext2 and ext3. Storing bitmap files on other filesystems may result in serious problems.

When creating an array on devices which are 100G or larger, *mdadm* automatically adds an internal bitmap as it will usually be beneficial. This can be suppressed with **--bitmap=none** or by selecting a different consistency policy with **--consistency-policy**.

--bitmap-chunk=

Set the chunksize of the bitmap. Each bit corresponds to that many Kilobytes of storage. When using a file based bitmap, the default is to use the smallest size that is at-least 4 and requires no more than 2^{21} chunks. When using an **internal** bitmap, the chunksize defaults to 64Meg, or larger if necessary to fit the bitmap into the available space.

A suffix of 'K', 'M', 'G' or 'T' can be given to indicate Kilobytes, Megabytes, Gigabytes or Terabytes respectively.

-W, --write-mostly

subsequent devices listed in a **--build**, **--create**, or **--add** command will be flagged as 'write-mostly'. This is valid for RAID1 only and means that the 'md' driver will avoid reading from these devices if at all possible. This can be useful if mirroring over a slow link.

--write-behind=

Specify that write-behind mode should be enabled (valid for RAID1 only). If an argument is specified, it will set the maximum number of outstanding writes allowed. The default value is 256. A write-intent bitmap is required in order to use write-behind mode, and write-behind is only attempted on drives marked as *write-mostly*.

--failfast

subsequent devices listed in a **--create** or **--add** command will be flagged as 'failfast'. This is valid for RAID1 and RAID10 only. IO requests to these devices will be encouraged to fail quickly rather than cause long delays due to error handling. Also no attempt is made to repair a read error on these devices.

If an array becomes degraded so that the 'failfast' device is the only usable device, the 'failfast' flag will then be ignored and extended delays will be preferred to complete failure.

The 'failfast' flag is appropriate for storage arrays which have a low probability of true failure, but which may sometimes cause unacceptable delays due to internal maintenance functions.

--assume-clean

Tell *mdadm* that the array pre-existed and is known to be clean. It can be useful when trying to recover from a major failure as you can be sure that no data will be affected unless you actually write to the array. It can also be used when creating a RAID1 or RAID10 if you want to avoid the initial resync, however this practice — while normally safe — is not recommended. Use this only if you really know what you are doing.

When the devices that will be part of a new array were filled with zeros before creation the operator knows the array is actually clean. If that is the case, such as after running badblocks, this argument can be used to tell *mdadm* the facts the operator knows.

When an array is resized to a larger size with **--grow --size=** the new space is normally resynced in that same way that the whole array is resynced at creation. From Linux version 3.0, **--assume-clean** can be used with that command to avoid the automatic resync.

--backup-file=

This is needed when **--grow** is used to increase the number of raid-devices in a RAID5 or RAID6 if there are no spare devices available, or to shrink, change RAID level or layout. See the GROW MODE section below on RAID-DEVICES CHANGES. The file must be stored on a separate device, not on the RAID array being reshaped.

--data-offset=

Arrays with 1.x metadata can leave a gap between the start of the device and the start of array data. This gap can be used for various metadata. The start of data is known as the *data-offset*. Normally an appropriate data offset is computed automatically. However it can be useful to set it explicitly such as when re-creating an array which was originally created using a different version of *mdadm* which computed a different offset.

Setting the offset explicitly over-rides the default. The value given is in Kilobytes unless a suffix of 'K', 'M', 'G' or 'T' is used to explicitly indicate Kilobytes, Megabytes, Gigabytes or Terabytes respectively.

Since Linux 3.4, **--data-offset** can also be used with **--grow** for some RAID levels (initially on RAID10). This allows the data-offset to be changed as part of the reshape process. When the data offset is changed, no backup file is required as the difference in offsets is used to provide the same functionality.

When the new offset is earlier than the old offset, the number of devices in the array cannot shrink. When it is after the old offset, the number of devices in the array cannot increase.

When creating an array, **--data-offset** can be specified as **variable**. In the case each member device is expected to have a offset appended to the name, separated by a colon. This makes it possible to recreate exactly an array which has varying data offsets (as can happen when different versions of *mdadm* are used to add different devices).

--continue

This option is complementary to the **--freeze-reshape** option for assembly. It is needed when **--grow** operation is interrupted and it is not restarted automatically due to **--freeze-reshape** usage during array assembly. This option is used together with **-G** , (**--gr ow**) command and device for a pending reshape to be continued. All parameters required for reshape continuation will be read from array metadata. If initial **--grow** command had required **--backup-file=** option to be set, continuation option will require to have exactly the same backup file given as well.

Any other parameter passed together with **--continue** option will be ignored.

-N, --name=

Set a **name** for the array. This is currently only effective when creating an array with a version-1 superblock, or an array in a DDF container. The name is a simple textual string that can be used to identify array components when assembling. If name is needed but not specified, it is taken from the basename of the device that is being created. e.g. when creating */dev/md/home* the **name** will default to *home*. (Does not work in Grow mode.)

-R, --run

Insist that *mdadm* run the array, even if some of the components appear to be active in another array or filesystem. Normally *mdadm* will ask for confirmation before including such components in an array. This option causes that question to be suppressed.

-f, --force

Insist that *mdadm* accept the geometry and layout specified without question. Normally *mdadm* will not allow creation of an array with only one device, and will try to create a RAID5 array with one missing drive (as this makes the initial resync work faster). With **--force**, *mdadm* will not try to be so clever.

-o, --readonly

Start the array **read only** rather than read-write as normal. No writes will be allowed to the array, and no resync, recovery, or reshape will be started. It works with Create, Assemble, Manage and Misc mode.

-a, --auto{=yes,md,mdp,part,p}{NN}

Instruct *mdadm* how to create the device file if needed, possibly allocating an unused minor number. "md" causes a non-partitionable array to be used (though since Linux 2.6.28, these array devices are in fact partitionable). "mdp", "part" or "p" causes a partitionable array (2.6 and later) to be used. "yes" requires the named md device to have a 'standard' format, and the type and minor number will be determined from this. With *mdadm* 3.0, device creation is normally left up to *udev* so this option is unlikely to be needed. See DEVICE NAMES below.

The argument can also come immediately after "**-a**". e.g. "**-ap**".

If **--auto** is not given on the command line or in the config file, then the default will be **--auto=yes**.

If **--scan** is also given, then any *auto=* entries in the config file will override the **--auto** instruction given on the command line.

For partitionable arrays, *mdadm* will create the device file for the whole array and for the first 4 partitions. A different number of partitions can be specified at the end of this option (e.g. **--auto=p7**). If the device name ends with a digit, the partition names add a 'p', and a number, e.g. */dev/md/home1p3*. If there is no trailing digit, then the partition names just have a number added, e.g. */dev/md/scratch3*.

If the md device name is in a 'standard' format as described in DEVICE NAMES, then it will be created, if necessary, with the appropriate device number based on that name. If the device name is not in one of these formats, then a unused device number will be allocated. The device number will be considered unused if there is no active array for that number, and there is no entry in /dev for that number and with a non-standard name. Names that are not in 'standard' format are only allowed in "/dev/md/".

This is meaningful with **--create** or **--build**.

-a, --add

This option can be used in Grow mode in two cases.

If the target array is a Linear array, then **--add** can be used to add one or more devices to the array. They are simply catenated on to the end of the array. Once added, the devices cannot be removed.

If the **--raid-disks** option is being used to increase the number of devices in an array, then **--add** can be used to add some extra devices to be included in the array. In most cases this is not needed as the extra devices can be added as spares first, and then the number of raid-disks can be changed. However for RAID0, it is not possible to add spares. So to increase the number of devices in a RAID0, it is necessary to set the new number of devices, and to add the new devices, in the same command.

--nodes

Only works when the array is for clustered environment. It specifies the maximum number of nodes in the cluster that will use this device simultaneously. If not specified, this defaults to 4.

--write-journal

Specify journal device for the RAID-4/5/6 array. The journal device should be a SSD with reasonable lifetime.

--symlinks

Auto creation of symlinks in /dev to /dev/md, option **--symlinks** must be 'no' or 'yes' and work with **--create** and **--build**.

-k, --consistency-policy=

Specify how the array maintains consistency in case of unexpected shutdown. Only relevant for RAID levels with redundancy. Currently supported options are:

resync Full resync is performed and all redundancy is regenerated when the array is started after unclean shutdown.

bitmap Resync assisted by a write-intent bitmap. Implicitly selected when using **--bitmap**.

journal

For RAID levels 4/5/6, journal device is used to log transactions and replay after unclean shutdown. Implicitly selected when using **--write-journal**.

ppl For RAID5 only, Partial Parity Log is used to close the write hole and eliminate resync. PPL is stored in the metadata region of RAID member drives, no additional journal drive is needed.

Can be used with **--grow** to change the consistency policy of an active array in some cases. See CONSISTENCY POLICY CHANGES below.

For assemble:

-u, --uuid=

uuid of array to assemble. Devices which don't have this uuid are excluded

-m, --super-minor=

Minor number of device that array was created for. Devices which don't have this minor number are excluded. If you create an array as /dev/md1, then all superblocks will contain the minor number 1, even if the array is later assembled as /dev/md2.

Giving the literal word "dev" for **--super-minor** will cause *mdadm* to use the minor number of the md device that is being assembled. e.g. when assembling **/dev/md0, --super-minor=dev** will look for super blocks with a minor number of 0.

--super-minor is only relevant for v0.90 metadata, and should not normally be used. Using **--uuid** is much safer.

-N, --name=

Specify the name of the array to assemble. This must be the name that was specified when creating the array. It must either match the name stored in the superblock exactly, or it must match with the current *hostname* prefixed to the start of the given name.

-f, --force

Assemble the array even if the metadata on some devices appears to be out-of-date. If *mdadm* cannot find enough working devices to start the array, but can find some devices that are recorded as having failed, then it will mark those devices as working so that the array can be started. This works only for native. For external metadata it allows to start dirty degraded RAID 4, 5, 6. An array which requires **--force** to be started may contain data corruption. Use it carefully.

-R, --run

Attempt to start the array even if fewer drives were given than were present last time the array was active. Normally if not all the expected drives are found and **--scan** is not used, then the array will be assembled but not started. With **--run** an attempt will be made to start it anyway.

--no-degraded

This is the reverse of **--run** in that it inhibits the startup of array unless all expected drives are present. This is only needed with **--scan**, and can be used if the physical connections to devices are not as reliable as you would like.

-a, --auto{=no,yes,md,mdp,part}

See this option under Create and Build options.

-b, --bitmap=

Specify the bitmap file that was given when the array was created. If an array has an **internal** bitmap, there is no need to specify this when assembling the array.

--backup-file=

If **--backup-file** was used while reshaping an array (e.g. changing number of devices or chunk size) and the system crashed during the critical section, then the same **--backup-file** must be presented to **--assemble** to allow possibly corrupted data to be restored, and the reshape to be completed.

--invalid-backup

If the file needed for the above option is not available for any reason an empty file can be given together with this option to indicate that the backup file is invalid. In this case the data that was being rearranged at the time of the crash could be irrecoverably lost, but the rest of the array may still be recoverable. This option should only be used as a last resort if there is no way to recover the backup file.

-U, --update=

Update the superblock on each device while assembling the array. The argument given to this flag can be one of **sparc2.2**, **summaries**, **uuid**, **name**, **nodes**, **homehost**, **home-cluster**, **resync**, **byte-order**, **devicesize**, **no-bitmap**, **bbl**, **no-bbl**, **ppl**, **no-ppl**, **layout-original**, **layout-alternate**, **layout-unspecified**, **metadata**, or **super-minor**.

The **sparc2.2** option will adjust the superblock of an array what was created on a Sparc machine running a patched 2.2 Linux kernel. This kernel got the alignment of part of the superblock wrong. You can use the **--examine --sparc2.2** option to *mdadm* to see what effect this would have.

The **super-minor** option will update the **preferred minor** field on each superblock to match the minor number of the array being assembled. This can be useful if **--examine** reports a different "Preferred Minor" to **--detail**. In some cases this update will be performed automatically by the kernel driver. In particular the update happens automatically at the first write to an array with redundancy (RAID level 1 or greater) on a 2.6 (or later) kernel.

The **uuid** option will change the uuid of the array. If a UUID is given with the **--uuid** option that UUID will be used as a new UUID and will **NOT** be used to help identify the devices in the array. If no **--uuid** is given, a random UUID is chosen.

The **name** option will change the *name* of the array as stored in the superblock. This is only supported for version-1 superblocks.

The **nodes** option will change the *nodes* of the array as stored in the bitmap superblock. This option only works for a clustered environment.

The **homehost** option will change the *homehost* as recorded in the superblock. For version-0 superblocks, this is the same as updating the UUID. For version-1 superblocks, this involves updating the name.

The **home-cluster** option will change the cluster name as recorded in the superblock and bitmap. This option only works for clustered environment.

The **resync** option will cause the array to be marked *dirty* meaning that any redundancy in the array (e.g. parity for RAID5, copies for RAID1) may be incorrect. This will cause the RAID system to perform a "resync" pass to make sure that all redundant information is correct.

The **byteorder** option allows arrays to be moved between machines with different byte-order, such as from a big-endian machine like a Sparc or some MIPS machines, to a little-endian x86_64 machine. When assembling such an array for the first time after a move, giving **--update=byteorder** will cause *mdadm* to expect superblocks to have their byteorder reversed, and will correct that order before assembling the array. This is only valid with original (Version 0.90) superblocks.

The **summaries** option will correct the summaries in the superblock. That is the counts of total, working, active, failed, and spare devices.

The **devicesize** option will rarely be of use. It applies to version 1.1 and 1.2 metadata only (where the metadata is at the start of the device) and is only useful when the component device has changed size (typically become larger). The version 1 metadata records the amount of the device that can be used to store data, so if a device in a version 1.1 or 1.2 array becomes larger, the metadata will still be visible, but the extra space will not. In this case it might be useful to assemble the array with **--update=devicesize**. This will cause *mdadm* to determine the maximum usable amount of space on each device and update the relevant field in the metadata.

The **metadata** option only works on v0.90 metadata arrays and will convert them to v1.0 metadata. The array must not be dirty (i.e. it must not need a sync) and it must not have a write-intent bitmap.

The old metadata will remain on the devices, but will appear older than the new metadata and so will usually be ignored. The old metadata (or indeed the new metadata) can be removed by giving the appropriate **--metadata=** option to **--zero-superblock**.

The **no-bitmap** option can be used when an array has an internal bitmap which is corrupt in some way so that assembling the array normally fails. It will cause any internal bitmap to be ignored.

The **bbl** option will reserve space in each device for a bad block list. This will be 4K in size and positioned near the end of any free space between the superblock and the data.

The **no-bbl** option will cause any reservation of space for a bad block list to be removed. If the bad block list contains entries, this will fail, as removing the list could cause data corruption.

The **ppl** option will enable PPL for a RAID5 array and reserve space for PPL on each device. There must be enough free space between the data and superblock and a write-intent bitmap or journal must not be used.

The **no-ppl** option will disable PPL in the superblock.

The **layout-original** and **layout-alternate** options are for RAID0 arrays with non-uniform devices size that were in use before Linux 5.4. If the array was being used with Linux 3.13 or earlier, then to assemble the array on a new kernel, **--update=layout-original** must be given. If the

array was created and used with a kernel from Linux 3.14 to Linux 5.3, then **--update=layout-alternate** must be given. This only needs to be given once. Subsequent assembly of the array will happen normally. For more information, see *md(4)*.

The **layout-unspecified** option reverts the effect of **layout-original** or **layout-alternate** and allows the array to be again used on a kernel prior to Linux 5.3. This option should be used with great caution.

--freeze-reshape

Option is intended to be used in start-up scripts during initrd boot phase. When array under reshape is assembled during initrd phase, this option stops reshape after reshape critical section is being restored. This happens before file system pivot operation and avoids loss of file system context. Losing file system context would cause reshape to be broken.

Reshape can be continued later using the **--continue** option for the grow command.

--symlinks

See this option under Create and Build options.

For Manage mode:

-t, --test

Unless a more serious error occurred, *mdadm* will exit with a status of 2 if no changes were made to the array and 0 if at least one change was made. This can be useful when an indirect specifier such as **missing**, **detached** or **faulty** is used in requesting an operation on the array. **--test** will report failure if these specifiers didn't find any match.

-a, --add

hot-add listed devices. If a device appears to have recently been part of the array (possibly it failed or was removed) the device is re-added as described in the next point. If that fails or the device was never part of the array, the device is added as a hot-spare. If the array is degraded, it will immediately start to rebuild data onto that spare.

Note that this and the following options are only meaningful on array with redundancy. They don't apply to RAID0 or Linear.

--re-add

re-add a device that was previously removed from an array. If the metadata on the device reports that it is a member of the array, and the slot that it used is still vacant, then the device will be added back to the array in the same position. This will normally cause the data for that device to be recovered. However based on the event count on the device, the recovery may only require sections that are flagged by a write-intent bitmap to be recovered or may not require any recovery at all.

When used on an array that has no metadata (i.e. it was built with **--build**) it will be assumed that bitmap-based recovery is enough to make the device fully consistent with the array.

When used with v1.x metadata, **--re-add** can be accompanied by **--update=devicesize**, **--update=bbl**, or **--update=no-bbl**. See the description of these option when used in Assemble mode for an explanation of their use.

If the device name given is **missing** then *mdadm* will try to find any device that looks like it should be part of the array but isn't and will try to re-add all such devices.

If the device name given is **faulty** then *mdadm* will find all devices in the array that are marked **faulty**, remove them and attempt to immediately re-add them. This can be useful if you are certain that the reason for failure has been resolved.

--add--spare

Add a device as a spare. This is similar to **--add** except that it does not attempt **--re-add** first. The device will be added as a spare even if it looks like it could be a recent member of the array.

-r, --remove

remove listed devices. They must not be active. i.e. they should be failed or spare devices.

As well as the name of a device file (e.g. **/dev/v/sda1**) the words **failed**, **detached** and names like **set-A** can be given to **--remove**. The first causes all failed device to be removed. The second causes any device which is no longer connected to the system (i.e an 'open' returns **ENXIO**) to be removed. The third will remove a set as described below under **--fail**.

-f, --fail

Mark listed devices as faulty. As well as the name of a device file, the word **detached** or a set name like **set-A** can be given. The former will cause any device that has been detached from the system to be marked as failed. It can then be removed.

For RAID10 arrays where the number of copies evenly divides the number of devices, the devices can be conceptually divided into sets where each set contains a single complete copy of the data on the array. Sometimes a RAID10 array will be configured so that these sets are on separate controllers. In this case all the devices in one set can be failed by giving a name like **set-A** or **set-B** to **--fail**. The appropriate set names are reported by **--detail**.

--set-faulty

same as **--fail**.

--replace

Mark listed devices as requiring replacement. As soon as a spare is available, it will be rebuilt and will replace the marked device. This is similar to marking a device as faulty, but the device remains in service during the recovery process to increase resilience against multiple failures. When the replacement process finishes, the replaced device will be marked as faulty.

--with This can follow a list of **--replace** devices. The devices listed after **--with** will be preferentially used to replace the devices listed after **--replace**. These devices must already be spare devices in the array.

--write-mostly

Subsequent devices that are added or re-added will have the 'write-mostly' flag set. This is only valid for RAID1 and means that the 'md' driver will avoid reading from these devices if possible.

--readwrite

Subsequent devices that are added or re-added will have the 'write-mostly' flag cleared.

--cluster-confirm

Confirm the existence of the device. This is issued in response to an **--add** request by a node in a cluster. When a node adds a device it sends a message to all nodes in the cluster to look for a device with a UUID. This translates to a udev notification with the UUID of the device to be added and the slot number. The receiving node must acknowledge this message with **--cluster-confirm**. Valid arguments are <slot>:<devicename> in case the device is found or <slot>:missing in case the

device is not found.

--add-journal

Add journal to an existing array, or recreate journal for RAID-4/5/6 array that lost a journal device. To avoid interrupting on-going write operations, **--add-journal** only works for array in Read-Only state.

--failfast

Subsequent devices that are added or re-added will have the 'failfast' flag set. This is only valid for RAID1 and RAID10 and means that the 'md' driver will avoid long timeouts on error handling where possible.

--nofailfast

Subsequent devices that are re-added will be re-added without the 'failfast' flag set.

Each of these options requires that the first device listed is the array to be acted upon, and the remainder are component devices to be added, removed, marked as faulty, etc. Several different operations can be specified for different devices, e.g.

```
mdadm /dev/md0 --add /dev/sda1 --fail /dev/sdb1 --remove /dev/sdb1
```

Each operation applies to all devices listed until the next operation.

If an array is using a write-intent bitmap, then devices which have been removed can be re-added in a way that avoids a full reconstruction but instead just updates the blocks that have changed since the device was removed. For arrays with persistent metadata (superblocks) this is done automatically. For arrays created with **--build** mdadm needs to be told that this device was removed recently with **--re-add**.

Devices can only be removed from an array if they are not in active use, i.e. that must be spares or failed devices. To remove an active device, it must first be marked as **faulty**.

For Misc mode:

-Q, --query

Examine a device to see (1) if it is an md device and (2) if it is a component of an md array. Information about what is discovered is presented.

-D, --detail

Print details of one or more md devices.

--detail-platform

Print details of the platform's RAID capabilities (firmware / hardware topology) for a given metadata format. If used without argument, mdadm will scan all controllers looking for their capabilities. Otherwise, mdadm will only look at the controller specified by the argument in form of an absolute filepath or a link, e.g. */sys/devices/pci0000:00/0000:00:If.2*.

-Y, --export

When used with **--detail**, **--detail-platform**, **--examine**, or **--incremental** output will be formatted as **key=value** pairs for easy import into the environment.

With **--incremental** The value **MD_STARTED** indicates whether an array was started (**yes**) or not, which may include a reason (**unsafe**, **nothing**, **no**). Also the value **MD_FOREIGN** indicates if the array is expected on this host (**no**), or seems to be from elsewhere (**yes**).

-E, --examine

Print contents of the metadata stored on the named device(s). Note the contrast between **--examine** and **--detail**. **--examine** applies to devices which are components of an array, while **--detail** applies to a whole array which is currently active.

--sparc2.2

If an array was created on a SPARC machine with a 2.2 Linux kernel patched with RAID support, the superblock will have been created incorrectly, or at least incompatibly with 2.4 and later kernels. Using the **--sparc2.2** flag with **--examine** will fix the superblock before displaying it. If this appears to do the right thing, then the array can be successfully assembled using **--assemble --update=sparc2.2**.

-X, --examine-bitmap

Report information about a bitmap file. The argument is either an external bitmap file or an array component in case of an internal bitmap. Note that running this on an array device (e.g. **/dev/md0**) does not report the bitmap for that array.

--examine-badblocks

List the bad-blocks recorded for the device, if a bad-blocks list has been configured. Currently only **1.x** and **IMSM** metadata support bad-blocks lists.

--dump=directory**--restore=directory**

Save metadata from listed devices, or restore metadata to listed devices.

-R, --run

start a partially assembled array. If **--assemble** did not find enough devices to fully start the array, it might leave it partially assembled. If you wish, you can then use **--run** to start the array in degraded mode.

-S, --stop

deactivate array, releasing all resources.

-o, --readonly

mark array as readonly.

-w, --readwrite

mark array as readwrite.

--zero-superblock

If the device contains a valid md superblock, the block is overwritten with zeros. With **--force** the block where the superblock would be is overwritten even if it doesn't appear to be valid.

Note: Be careful to call **--zero-superblock** with clustered raid, make sure array isn't used or assembled in other cluster node before execute it.

--kill-subarray=

If the device is a container and the argument to **--kill-subarray** specifies an inactive subarray in the container, then the subarray is deleted. Deleting all subarrays will leave an 'empty-container' or spare superblock on the drives. See **--zero-superblock** for completely removing a superblock. Note that some formats depend on the subarray index for generating a UUID, this

command will fail if it would change the UUID of an active subarray.

--update–subarray=

If the device is a container and the argument to **--update–subarray** specifies a subarray in the container, then attempt to update the given superblock field in the subarray. See below in **MISC MODE** for details.

-t, --test

When used with **--detail**, the exit status of *mdadm* is set to reflect the status of the device. See below in **MISC MODE** for details.

-W, --wait

For each md device given, wait for any resync, recovery, or reshape activity to finish before returning. *mdadm* will return with success if it actually waited for every device listed, otherwise it will return failure.

--wait–clean

For each md device given, or each device in /proc/mdstat if **--scan** is given, arrange for the array to be marked clean as soon as possible. *mdadm* will return with success if the array uses external metadata and we successfully waited. For native arrays this returns immediately as the kernel handles dirty-clean transitions at shutdown. No action is taken if safe-mode handling is disabled.

--action=

Set the "sync_action" for all md devices given to one of **idle**, **frozen**, **check**, **repair**. Setting to **idle** will abort any currently running action though some actions will automatically restart. Setting to **frozen** will abort any current action and ensure no other action starts automatically.

Details of **check** and **repair** can be found in *md(4)* under **SCRUBBING AND MISMATCHES**.

For Incremental Assembly mode:

--rebuild–map, -r

Rebuild the map file (**/run/mdadm/map**) that *mdadm* uses to help track which arrays are currently being assembled.

--run, -R

Run any array assembled as soon as a minimal number of devices are available, rather than waiting until all expected devices are present.

--scan, -s

Only meaningful with **-R** this will scan the **map** file for arrays that are being incrementally assembled and will try to start any that are not already started. If any such array is listed in **mdadm.conf** as requiring an external bitmap, that bitmap will be attached first.

--fail, -f

This allows the hot-plug system to remove devices that have fully disappeared from the kernel. It will first fail and then remove the device from any array it belongs to. The device name given should be a kernel device name such as "sda", not a name in **/dev**.

--path=

Only used with --fail. The 'path' given will be recorded so that if a new device appears at the same location it can be automatically added to the same array. This allows the failed device to be automatically replaced by a new device without metadata if it appears at specified path. This option is normally only set by a *udev* script.

For Monitor mode:**-m, --mail**

Give a mail address to send alerts to.

-p, --program, --alert

Give a program to be run whenever an event is detected.

-y, --syslog

Cause all events to be reported through 'syslog'. The messages have facility of 'daemon' and varying priorities.

-d, --delay

Give a delay in seconds. *mdadm* polls the md arrays and then waits this many seconds before polling again. The default is 60 seconds. Since 2.6.16, there is no need to reduce this as the kernel alerts *mdadm* immediately when there is any change.

-r, --increment

Give a percentage increment. *mdadm* will generate RebuildNN events with the given percentage increment.

-f, --daemonic

Tell *mdadm* to run as a background daemon if it decides to monitor anything. This causes it to fork and run in the child, and to disconnect from the terminal. The process id of the child is written to stdout. This is useful with --scan which will only continue monitoring if a mail address or alert program is found in the config file.

-i, --pid-file

When *mdadm* is running in daemon mode, write the pid of the daemon process to the specified file, instead of printing it on standard output.

-1, --oneshot

Check arrays only once. This will generate **NewArray** events and more significantly **DegradedArray** and **SparesMissing** events. Running

mdadm --monitor --scan -1

from a cron script will ensure regular notification of any degraded arrays.

-t, --test

Generate a **TestMessage** alert for every array found at startup. This alert gets mailed and passed to the alert program. This can be used for testing that alert message do get through successfully.

--no-sharing

This inhibits the functionality for moving spares between arrays. Only one monitoring process started with --scan but without this flag is allowed, otherwise the two could interfere with each other.

ASSEMBLE MODE

Usage: **mdadm** **--assemble** *md-device options-and-component-devices...*

Usage: **mdadm** **--assemble** **--scan** *md-devices-and-options...*

Usage: **mdadm** **--assemble** **--scan** *options...*

This usage assembles one or more RAID arrays from pre-existing components. For each array, mdadm needs to know the md device, the identity of the array, and a number of component-devices. These can be found in a number of ways.

In the first usage example (without the **--scan**) the first device given is the md device. In the second usage example, all devices listed are treated as md devices and assembly is attempted. In the third (where no devices are listed) all md devices that are listed in the configuration file are assembled. If no arrays are described by the configuration file, then any arrays that can be found on unused devices will be assembled.

If precisely one device is listed, but **--scan** is not given, then *mdadm* acts as though **--scan** was given and identity information is extracted from the configuration file.

The identity can be given with the **--uuid** option, the **--name** option, or the **--super-minor** option, will be taken from the md-device record in the config file, or will be taken from the super block of the first component-device listed on the command line.

Devices can be given on the **--assemble** command line or in the config file. Only devices which have an md superblock which contains the right identity will be considered for any array.

The config file is only used if explicitly named with **--config** or requested with (a possibly implicit) **--scan**. In the later case, **/etc/mdadm/mdadm.conf** or **/etc/mdadm.conf** is used.

If **--scan** is not given, then the config file will only be used to find the identity of md arrays.

Normally the array will be started after it is assembled. However if **--scan** is not given and not all expected drives were listed, then the array is not started (to guard against usage errors). To insist that the array be started in this case (as may work for RAID1, 4, 5, 6, or 10), give the **--run** flag.

If *udev* is active, *mdadm* does not create any entries in **/dev** but leaves that to *udev*. It does record information in **/run/mdadm/map** which will allow *udev* to choose the correct name.

If *mdadm* detects that *udev* is not configured, it will create the devices in **/dev** itself.

In Linux kernels prior to version 2.6.28 there were two distinctly different types of md devices that could be created: one that could be partitioned using standard partitioning tools and one that could not. Since 2.6.28 that distinction is no longer relevant as both type of devices can be partitioned. *mdadm* will normally create the type that originally could not be partitioned as it has a well defined major number (9).

Prior to 2.6.28, it is important that *mdadm* chooses the correct type of array device to use. This can be controlled with the **--auto** option. In particular, a value of "mdp" or "part" or "p" tells *mdadm* to use a partitionable device rather than the default.

In the no-*udev* case, the value given to **--auto** can be suffixed by a number. This tells *mdadm* to create that number of partition devices rather than the default of 4.

The value given to **--auto** can also be given in the configuration file as a word starting **auto=** on the ARRAY line for the relevant array.

Auto Assembly

When **--assemble** is used with **--scan** and no devices are listed, *mdadm* will first attempt to assemble all the arrays listed in the config file.

If no arrays are listed in the config (other than those marked <ignore>) it will look through the available devices for possible arrays and will try to assemble anything that it finds. Arrays which are tagged as belonging to the given homehost will be assembled and started normally. Arrays which do not obviously belong to this host are given names that are expected not to conflict with anything local, and are started "read-auto" so that nothing is written to any device until the array is written to. i.e. automatic resync etc is delayed.

If *mdadm* finds a consistent set of devices that look like they should comprise an array, and if the superblock is tagged as belonging to the given home host, it will automatically choose a device name and try to assemble the array. If the array uses version-0.90 metadata, then the **minor** number as recorded in the superblock is used to create a name in **/dev/md/** so for example **/dev/md/3**. If the array uses version-1 metadata, then the **name** from the superblock is used to similarly create a name in **/dev/md/** (the name will have any 'host' prefix stripped first).

This behaviour can be modified by the **AUTO** line in the *mdadm.conf* configuration file. This line can indicate that specific metadata type should, or should not, be automatically assembled. If an array is found which is not listed in *mdadm.conf* and has a metadata format that is denied by the **AUTO** line, then it will not be assembled. The **AUTO** line can also request that all arrays identified as being for this homehost should be assembled regardless of their metadata type. See *mdadm.conf*(5) for further details.

Note: Auto assembly cannot be used for assembling and activating some arrays which are undergoing reshape. In particular as the**backup-file** cannot be given, any reshape which requires a backup-file to continue cannot be started by auto assembly. An array which is growing to more devices and has passed the critical section can be assembled using auto-assembly.

BUILD MODE

Usage: **mdadm --build** *md-device* **--chunk=X** **--level=Y** **--raid-devices=Z** *devices*

This usage is similar to **--create**. The difference is that it creates an array without a superblock. With these arrays there is no difference between initially creating the array and subsequently assembling the array, except that hopefully there is useful data there in the second case.

The level may raid0, linear, raid1, raid10, multipath, or faulty, or one of their synonyms. All devices must be listed and the array will be started once complete. It will often be appropriate to use **--assume-clean** with levels raid1 or raid10.

CREATE MODE

Usage: **mdadm --create** *md-device* **--chunk=X** **--level=Y**
--raid-devices=Z *devices*

This usage will initialise a new md array, associate some devices with it, and activate the array.

The named device will normally not exist when *mdadm --create* is run, but will be created by *udev* once the array becomes active.

The max length md-device name is limited to 32 characters. Different metadata types have more strict limitation (like IMSM where only 16 characters are allowed). For that reason, long name could be truncated or rejected, it depends on metadata policy.

As devices are added, they are checked to see if they contain RAID superblocks or filesystems. They are

also checked to see if the variance in device size exceeds 1%.

If any discrepancy is found, the array will not automatically be run, though the presence of a **--run** can override this caution.

To create a "degraded" array in which some devices are missing, simply give the word "**missing**" in place of a device name. This will cause *mdadm* to leave the corresponding slot in the array empty. For a RAID4 or RAID5 array at most one slot can be "**missing**"; for a RAID6 array at most two slots. For a RAID1 array, only one real device needs to be given. All of the others can be "**missing**".

When creating a RAID5 array, *mdadm* will automatically create a degraded array with an extra spare drive. This is because building the spare into a degraded array is in general faster than resyncing the parity on a non-degraded, but not clean, array. This feature can be overridden with the **--force** option.

When creating an array with version-1 metadata a name for the array is required. If this is not given with the **--name** option, *mdadm* will choose a name based on the last component of the name of the device being created. So if **/dev/md3** is being created, then the name **3** will be chosen. If **/dev/md/home** is being created, then the name **home** will be used.

When creating a partition based array, using *mdadm* with version-1.x metadata, the partition type should be set to **0xDA** (non fs-data). This type selection allows for greater precision since using any other [RAID auto-detect (0xFD) or a GNU/Linux partition (0x83)], might create problems in the event of array recovery through a live cdrom.

A new array will normally get a randomly assigned 128bit UUID which is very likely to be unique. If you have a specific need, you can choose a UUID for the array by giving the **--uuid=** option. Be warned that creating two arrays with the same UUID is a recipe for disaster. Also, using **--uuid=** when creating a v0.90 array will silently override any **--homehost=** setting.

If the array type supports a write-intent bitmap, and if the devices in the array exceed 100G in size, an internal write-intent bitmap will automatically be added unless some other option is explicitly requested with the **--bitmap** option or a different consistency policy is selected with the **--consistency-policy** option. In any case space for a bitmap will be reserved so that one can be added later with **--grow --bitmap=internal**.

If the metadata type supports it (currently only 1.x and IMSM metadata), space will be allocated to store a bad block list. This allows a modest number of bad blocks to be recorded, allowing the drive to remain in service while only partially functional.

When creating an array within a **CONTAINER** *mdadm* can be given either the list of devices to use, or simply the name of the container. The former case gives control over which devices in the container will be used for the array. The latter case allows *mdadm* to automatically choose which devices to use based on how much spare space is available.

The General Management options that are valid with **--create** are:

--run insist on running the array even if some devices look like they might be in use.

--readonly

start the array in readonly mode.

MANAGE MODE

Usage: **mdadm device options... devices...**

This usage will allow individual devices in an array to be failed, removed or added. It is possible to

perform multiple operations with one command. For example:

mdadm /dev/md0 -f /dev/hda1 -r /dev/hda1 -a /dev/hda1

will firstly mark **/dev/hda1** as faulty in **/dev/md0** and will then remove it from the array and finally add it back in as a spare. However only one md array can be affected by a single command.

When a device is added to an active array, mdadm checks to see if it has metadata on it which suggests that it was recently a member of the array. If it does, it tries to "re-add" the device. If there have been no changes since the device was removed, or if the array has a write-intent bitmap which has recorded whatever changes there were, then the device will immediately become a full member of the array and those differences recorded in the bitmap will be resolved.

MISC MODE

Usage: **mdadm options ... devices ...**

MISC mode includes a number of distinct operations that operate on distinct devices. The operations are:

--query

The device is examined to see if it is (1) an active md array, or (2) a component of an md array.
The information discovered is reported.

--detail

The device should be an active md device. **mdadm** will display a detailed description of the array. **--brief** or **--scan** will cause the output to be less detailed and the format to be suitable for inclusion in **mdadm.conf**. The exit status of *mdadm* will normally be 0 unless *mdadm* failed to get useful information about the device(s); however, if the **--test** option is given, then the exit status will be:

- 0 The array is functioning normally.
- 1 The array has at least one failed device.
- 2 The array has multiple failed devices such that it is unusable.
- 4 There was an error while trying to get information about the device.

--detail-platform

Print detail of the platform's RAID capabilities (firmware / hardware topology). If the metadata is specified with **-e** or **--metadata=** then the return status will be:

- 0 metadata successfully enumerated its platform components on this system
- 1 metadata is platform independent
- 2 metadata failed to find its platform components on this system

--update-subarray=

If the device is a container and the argument to **--update-subarray** specifies a subarray in the container, then attempt to update the given superblock field in the subarray. Similar to updating an array in "assemble" mode, the field to update is selected by **-U** or **--update=** option. The supported options are **name**, **ppl**, **no-ppl**, **bitmap** and **no-bitmap**.

The **name** option updates the subarray name in the metadata, it may not affect the device node name or the device node symlink until the subarray is re-assembled. If updating **name** would change the UUID of an active subarray this operation is blocked, and the command will end in an error.

The **ppl** and **no-ppl** options enable and disable PPL in the metadata. Currently supported only for IMSM subarrays.

The **bitmap** and **no-bitmap** options enable and disable write-intent bitmap in the metadata. Currently supported only for IMSM subarrays.

--examine

The device should be a component of an md array. *mdadm* will read the md superblock of the device and display the contents. If **--brief** or **--scan** is given, then multiple devices that are components of the one array are grouped together and reported in a single entry suitable for inclusion in **mdadm.conf**.

Having **--scan** without listing any devices will cause all devices listed in the config file to be examined.

--dump=directory

If the device contains RAID metadata, a file will be created in the *directory* and the metadata will be written to it. The file will be the same size as the device and have the metadata written in the file at the same locate that it exists in the device. However the file will be "sparse" so that only those blocks containing metadata will be allocated. The total space used will be small.

The file name used in the *directory* will be the base name of the device. Further if any links appear in */dev/disk/by-id* which point to the device, then hard links to the file will be created in *directory* based on these *by-id* names.

Multiple devices can be listed and their metadata will all be stored in the one directory.

--restore=directory

This is the reverse of **--dump**. *mdadm* will locate a file in the directory that has a name appropriate for the given device and will restore metadata from it. Names that match */dev/disk/by-id* names are preferred, however if two of those refer to different files, *mdadm* will not choose between them but will abort the operation.

If a file name is given instead of a *directory* then *mdadm* will restore from that file to a single device, always provided the size of the file matches that of the device, and the file contains valid metadata.

--stop The devices should be active md arrays which will be deactivated, as long as they are not currently in use.

--run This will fully activate a partially assembled md array.

--readonly

This will mark an active array as read-only, providing that it is not currently being used.

--readwrite

This will change a **readonly** array back to being read/write.

--scan For all operations except **--examine**, **--scan** will cause the operation to be applied to all arrays listed in */proc/mdstat*. For **--examine**, **--scan** causes all devices listed in the config file to be examined.

-b, --brief

Be less verbose. This is used with **--detail** and **--examine**. Using **--brief** with **--verbose** gives an intermediate level of verbosity.

MONITOR MODE

Usage: **mdadm --monitor** *options... devices...*

This usage causes *mdadm* to periodically poll a number of md arrays and to report on any events noticed. *mdadm* will never exit once it decides that there are arrays to be checked, so it should normally be run in the background.

As well as reporting events, *mdadm* may move a spare drive from one array to another if they are in the same **spare-group** or **domain** and if the destination array has a failed drive but no spares.

If any devices are listed on the command line, *mdadm* will only monitor those devices. Otherwise all arrays listed in the configuration file will be monitored. Further, if **--scan** is given, then any other md devices that appear in **/proc/mdstat** will also be monitored.

The result of monitoring the arrays is the generation of events. These events are passed to a separate program (if specified) and may be mailed to a given E-mail address.

When passing events to a program, the program is run once for each event, and is given 2 or 3 command-line arguments: the first is the name of the event (see below), the second is the name of the md device which is affected, and the third is the name of a related device if relevant (such as a component device that has failed).

If **--scan** is given, then a program or an E-mail address must be specified on the command line or in the config file. If neither are available, then *mdadm* will not monitor anything. Without **--scan**, *mdadm* will continue monitoring as long as something was found to monitor. If no program or email is given, then each event is reported to **stdout**.

The different events are:

DeviceDisappeared

An md array which previously was configured appears to no longer be configured. (syslog priority: Critical)

If *mdadm* was told to monitor an array which is RAID0 or Linear, then it will report **DeviceDisappeared** with the extra information **Wrong-Level**. This is because RAID0 and Linear do not support the device-failed, hot-spare and resync operations which are monitored.

RebuildStarted

An md array started reconstruction (e.g. recovery, resync, reshape, check, repair). (syslog priority: Warning)

RebuildNN

Where *NN* is a two-digit number (ie. 05, 48). This indicates that rebuild has passed that many percent of the total. The events are generated with fixed increment since 0. Increment size may be specified with a commandline option (default is 20). (syslog priority: Warning)

RebuildFinished

An md array that was rebuilding, isn't any more, either because it finished normally or was aborted. (syslog priority: Warning)

Fail

An active component device of an array has been marked as faulty. (syslog priority: Critical)

FailSpare

A spare component device which was being rebuilt to replace a faulty device has failed. (syslog priority: Critical)

SpareActive

A spare component device which was being rebuilt to replace a faulty device has been successfully rebuilt and has been made active. (syslog priority: Info)

NewArray

A new md array has been detected in the **/proc/mdstat** file. (syslog priority: Info)

DegradedArray

A newly noticed array appears to be degraded. This message is not generated when *mdadm* notices a drive failure which causes degradation, but only when *mdadm* notices that an array is degraded when it first sees the array. (syslog priority: Critical)

MoveSpare

A spare drive has been moved from one array in a **spare-group** or **domain** to another to allow a failed drive to be replaced. (syslog priority: Info)

SparesMissing

If *mdadm* has been told, via the config file, that an array should have a certain number of spare devices, and *mdadm* detects that it has fewer than this number when it first sees the array, it will report a **SparesMissing** message. (syslog priority: Warning)

TestMessage

An array was found at startup, and the **--test** flag was given. (syslog priority: Info)

Only **Fail**, **FailSpare**, **DegradedArray**, **SparesMissing** and **TestMessage** cause Email to be sent. All events cause the program to be run. The program is run with two or three arguments: the event name, the array device and possibly a second device.

Each event has an associated array device (e.g. **/de v/***md1*) and possibly a second device. For **Fail**, **FailSpare**, and **SpareActive** the second device is the relevant component device. For **MoveSpare** the second device is the array that the spare was moved from.

For *mdadm* to move spares from one array to another, the different arrays need to be labeled with the same **spare-group** or the spares must be allowed to migrate through matching POLICY domains in the configuration file. The **spare-group** name can be any string; it is only necessary that different spare groups use different names.

When *mdadm* detects that an array in a spare group has fewer active devices than necessary for the complete array, and has no spare devices, it will look for another array in the same spare group that has a full complement of working drive and a spare. It will then attempt to remove the spare from the second drive and add it to the first. If the removal succeeds but the adding fails, then it is added back to the original array.

If the spare group for a degraded array is not defined, *mdadm* will look at the rules of spare migration specified by POLICY lines in **mdadm.conf** and then follow similar steps as above if a matching spare is found.

GROW MODE

The GROW mode is used for changing the size or shape of an active array. For this to work, the kernel must support the necessary change. Various types of growth are being added during 2.6 development.

Currently the supported changes include

- change the "size" attribute for RAID1, RAID4, RAID5 and RAID6.
- increase or decrease the "raid-devices" attribute of RAID0, RAID1, RAID4, RAID5, and RAID6.
- change the chunk-size and layout of RAID0, RAID4, RAID5, RAID6 and RAID10.
- convert between RAID1 and RAID5, between RAID5 and RAID6, between RAID0, RAID4, and RAID5, and between RAID0 and RAID10 (in the near-2 mode).
- add a write-intent bitmap to any array which supports these bitmaps, or remove a write-intent bitmap from such an array.
- change the array's consistency policy.

Using GROW on containers is currently supported only for Intel's IMSM container format. The number of devices in a container can be increased - which affects all arrays in the container - or an array in a container can be converted between levels where those levels are supported by the container, and the conversion is one of those listed above.

Notes:

- Intel's native checkpointing doesn't use **--backup-file** option and it is transparent for assembly feature.
- Roaming between Windows(R) and Linux systems for IMSM metadata is not supported during grow process.
- When growing a raid0 device, the new component disk size (or external backup size) should be larger than $\text{LCM}(\text{old}, \text{new}) * \text{chunk-size} * 2$, where $\text{LCM}()$ is the least common multiple of the old and new count of component disks, and " $* 2$ " comes from the fact that mdadm refuses to use more than half of a spare device for backup space.

SIZE CHANGES

Normally when an array is built the "size" is taken from the smallest of the drives. If all the small drives in an array are, one at a time, removed and replaced with larger drives, then you could have an array of large drives with only a small amount used. In this situation, changing the "size" with "GROW" mode will allow the extra space to start being used. If the size is increased in this way, a "resync" process will start to make sure the new parts of the array are synchronised.

Note that when an array changes size, any filesystem that may be stored in the array will not automatically grow or shrink to use or vacate the space. The filesystem will need to be explicitly told to use the extra space after growing, or to reduce its size **prior** to shrinking the array.

Also the size of an array cannot be changed while it has an active bitmap. If an array has a bitmap, it must be removed before the size can be changed. Once the change is complete a new bitmap can be created.

Note: **--grow --size** is not yet supported for external file bitmap.

RAID-DEVICES CHANGES

A RAID1 array can work with any number of devices from 1 upwards (though 1 is not very useful). There may be times which you want to increase or decrease the number of active devices. Note that this is different to hot-add or hot-remove which changes the number of inactive devices.

When reducing the number of devices in a RAID1 array, the slots which are to be removed from the array

must already be vacant. That is, the devices which were in those slots must be failed and removed.

When the number of devices is increased, any hot spares that are present will be activated immediately.

Changing the number of active devices in a RAID5 or RAID6 is much more effort. Every block in the array will need to be read and written back to a new location. From 2.6.17, the Linux Kernel is able to increase the number of devices in a RAID5 safely, including restarting an interrupted "reshape". From 2.6.31, the Linux Kernel is able to increase or decrease the number of devices in a RAID5 or RAID6.

From 2.6.35, the Linux Kernel is able to convert a RAID0 in to a RAID4 or RAID5. *mdadm* uses this functionality and the ability to add devices to a RAID4 to allow devices to be added to a RAID0. When requested to do this, *mdadm* will convert the RAID0 to a RAID4, add the necessary disks and make the reshape happen, and then convert the RAID4 back to RAID0.

When decreasing the number of devices, the size of the array will also decrease. If there was data in the array, it could get destroyed and this is not reversible, so you should firstly shrink the filesystem on the array to fit within the new size. To help prevent accidents, *mdadm* requires that the size of the array be decreased first with **mdadm --grow --array-size**. This is a reversible change which simply makes the end of the array inaccessible. The integrity of any data can then be checked before the non-reversible reduction in the number of devices is requested.

When relocating the first few stripes on a RAID5 or RAID6, it is not possible to keep the data on disk completely consistent and crash-proof. To provide the required safety, *mdadm* disables writes to the array while this "critical section" is reshaped, and takes a backup of the data that is in that section. For grows, this backup may be stored in any spare devices that the array has, however it can also be stored in a separate file specified with the **--backup-file** option, and is required to be specified for shrinks, RAID level changes and layout changes. If this option is used, and the system does crash during the critical period, the same file must be passed to **--assemble** to restore the backup and reassemble the array. When shrinking rather than growing the array, the reshape is done from the end towards the beginning, so the "critical section" is at the end of the reshape.

LEVEL CHANGES

Changing the RAID level of any array happens instantaneously. However in the RAID5 to RAID6 case this requires a non-standard layout of the RAID6 data, and in the RAID6 to RAID5 case that non-standard layout is required before the change can be accomplished. So while the level change is instant, the accompanying layout change can take quite a long time. A **--backup-file** is required. If the array is not simultaneously being grown or shrunk, so that the array size will remain the same - for example, reshaping a 3-drive RAID5 into a 4-drive RAID6 - the backup file will be used not just for a "critical section" but throughout the reshape operation, as described below under LAYOUT CHANGES.

CHUNK-SIZE AND LAYOUT CHANGES

Changing the chunk-size or layout without also changing the number of devices as the same time will involve re-writing all blocks in-place. To ensure against data loss in the case of a crash, a **--backup-file** must be provided for these changes. Small sections of the array will be copied to the backup file while they are being rearranged. This means that all the data is copied twice, once to the backup and once to the new layout on the array, so this type of reshape will go very slowly.

If the reshape is interrupted for any reason, this backup file must be made available to **mdadm --assemble** so the array can be reassembled. Consequently the file cannot be stored on the device being reshaped.

BITMAP CHANGES

A write-intent bitmap can be added to, or removed from, an active array. Either internal bitmaps, or bitmaps stored in a separate file, can be added. Note that if you add a bitmap stored in a file which is in a filesystem that is on the RAID array being affected, the system will deadlock. The bitmap must be on a separate filesystem.

CONSISTENCY POLICY CHANGES

The consistency policy of an active array can be changed by using the **--consistency-policy** option in Grow mode. Currently this works only for the **ppl** and **resync** policies and allows one to enable or disable the RAID5 Partial Parity Log (PPL).

INCREMENTAL MODE

Usage: **mdadm --incremental** [**--run**] [**--quiet**] *component-device* [*optional-aliases-for-device*]

Usage: **mdadm --incremental --fail** *component-device*

Usage: **mdadm --incremental --rebuild-map**

Usage: **mdadm --incremental --run --scan**

This mode is designed to be used in conjunction with a device discovery system. As devices are found in a system, they can be passed to **mdadm --incremental** to be conditionally added to an appropriate array.

Conversely, it can also be used with the **--fail** flag to do just the opposite and find whatever array a particular device is part of and remove the device from that array.

If the device passed is a **CONTAINER** device created by a previous call to *mdadm*, then rather than trying to add that device to an array, all the arrays described by the metadata of the container will be started.

mdadm performs a number of tests to determine if the device is part of an array, and which array it should be part of. If an appropriate array is found, or can be created, *mdadm* adds the device to the array and conditionally starts the array.

Note that *mdadm* will normally only add devices to an array which were previously working (active or spare) parts of that array. The support for automatic inclusion of a new drive as a spare in some array requires a configuration through POLICY in config file.

The tests that *mdadm* makes are as follow:

- + Is the device permitted by **mdadm.conf**? That is, is it listed in a**DEVICES** line in that file. If **DEVICES** is absent then the default it to allow any device. Similarly if**DEVICES** contains the special word **partitions** then any device is allowed. Otherwise the device name given to *mdadm*, or one of the aliases given, or an alias found in the filesystem, must match one of the names or patterns in a **DEVICES** line.

This is the only context where the aliases are used. They are usually provided by a *udev* rules mentioning **\$env{DEVLINKS}**.

- + Does the device have a valid md superblock? If a specific metadata version is requested with **--metadata** or **-e** then only that style of metadata is accepted, otherwise *mdadm* finds any known version of metadata. If no *md* metadata is found, the device may be still added to an array as a spare if POLICY allows.

mdadm keeps a list of arrays that it has partially assembled in **/run/mdadm/map**. If no array exists which

matches the metadata on the new device, *mdadm* must choose a device name and unit number. It does this based on any name given in **mdadm.conf** or any name information stored in the metadata. If this name suggests a unit number, that number will be used, otherwise a free unit number will be chosen. Normally *mdadm* will prefer to create a partitionable array, however if the **CREATE** line in **mdadm.conf** suggests that a non-partitionable array is preferred, that will be honoured.

If the array is not found in the config file and its metadata does not identify it as belonging to the "home-host", then *mdadm* will choose a name for the array which is certain not to conflict with any array which does belong to this host. It does this by adding an underscore and a small number to the name preferred by the metadata.

Once an appropriate array is found or created and the device is added, *mdadm* must decide if the array is ready to be started. It will normally compare the number of available (non-spare) devices to the number of devices that the metadata suggests need to be active. If there are at least that many, the array will be started. This means that if any devices are missing the array will not be restarted.

As an alternative, **--run** may be passed to *mdadm* in which case the array will be run as soon as there are enough devices present for the data to be accessible. For a RAID1, that means one device will start the array. For a clean RAID5, the array will be started as soon as all but one drive is present.

Note that neither of these approaches is really ideal. If it can be known that all device discovery has completed, then

mdadm -IRs

can be run which will try to start all arrays that are being incrementally assembled. They are started in "read-auto" mode in which they are read-only until the first write request. This means that no metadata updates are made and no attempt at resync or recovery happens. Further devices that are found before the first write can still be added safely.

ENVIRONMENT

This section describes environment variables that affect how *mdadm* operates.

MDADM_NO_MDMON

Setting this value to 1 will prevent *mdadm* from automatically launching *mdmon*. This variable is intended primarily for debugging *mdadm*/*mdmon*.

MDADM_NO_UDEV

Normally, *mdadm* does not create any device nodes in /dev, but leaves that task to *udev*. If *udev* v appears not to be configured, or if this environment variable is set to '1', the *mdadm* will create and devices that are needed.

MDADM_NO_SYSTEMCTL

If *mdadm* detects that *systemd* is in use it will normally request *systemd* to start various background tasks (particularly *mdmon*) rather than forking and running them in the background. This can be suppressed by setting **MDADM_NO_SYSTEMCTL=1**.

IMSM_NO_PLATFORM

A key value of IMSM metadata is that it allows interoperability with boot ROMs on Intel platforms, and with other major operating systems. Consequently, *mdadm* will only allow an IMSM array to be created or modified if detects that it is running on an Intel platform which supports IMSM, and supports the particular configuration of IMSM that is being requested (some functionality requires newer OROM support).

These checks can be suppressed by setting `IMSM_NO_PLATFORM=1` in the environment. This can be useful for testing or for disaster recovery. You should be aware that interoperability may be compromised by setting this value.

MDADM_GROW_ALLOW_OLD

If an array is stopped while it is performing a reshape and that reshape was making use of a backup file, then when the array is re-assembled `mdadm` will sometimes complain that the backup file is too old. If this happens and you are certain it is the right backup file, you can over-ride this check by setting `MDADM_GROW_ALLOW_OLD=1` in the environment.

MDADM_CONF_AUTO

Any string given in this variable is added to the start of the **AUTO** line in the config file, or treated as the whole **AUTO** line if none is given. It can be used to disable certain metadata types when `mdadm` is called from a boot script. For example

```
export MDADM_CONF_AUTO=-ddf -imsm
```

will make sure that `mdadm` does not automatically assemble any DDF or IMSM arrays that are found. This can be useful on systems configured to manage such arrays with **dmraid**.

EXAMPLES

mdadm --query /dev/name-of-device

This will find out if a given device is a RAID array, or is part of one, and will provide brief information about the device.

mdadm --assemble --scan

This will assemble and start all arrays listed in the standard config file. This command will typically go in a system startup file.

mdadm --stop --scan

This will shut down all arrays that can be shut down (i.e. are not currently in use). This will typically go in a system shutdown script.

mdadm --follow --scan --delay=120

If (and only if) there is an Email address or program given in the standard config file, then monitor the status of all arrays listed in that file by polling them ever 2 minutes.

mdadm --create /dev/md0 --level=1 --raid-devices=2 /dev/hd[ac]1

Create `/dev/md0` as a RAID1 array consisting of `/dev/hda1` and `/dev/hdc1`.

echo 'DEVICE /dev/hd*[0-9] /dev/sd*[0-9]' > mdadm.conf

mdadm --detail --scan >> mdadm.conf

This will create a prototype config file that describes currently active arrays that are known to be made from partitions of IDE or SCSI drives. This file should be reviewed before being used as it may contain unwanted detail.

echo 'DEVICE /dev/hd[a-z] /dev/sd*[a-z]' > mdadm.conf

mdadm --examine --scan --config=mdadm.conf >> mdadm.conf

This will find arrays which could be assembled from existing IDE and SCSI whole drives (not partitions), and store the information in the format of a config file. This file is very likely to contain unwanted detail, particularly the `devices=` entries. It should be reviewed and edited before being used as an actual config file.

mdadm --examine --brief --scan --config=partitions

mdadm -Ebsc partitions

Create a list of devices by reading **/proc/partitions**, scan these for RAID superblocks, and printout a brief listing of all that were found.

mdadm -Ac partitions -m 0 /dev/md0

Scan all partitions and devices listed in **/proc/partitions** and assemble **/dev/md0** out of all such devices with a RAID superblock with a minor number of 0.

mdadm --monitor --scan --daemonise > /run/mdadm/mon.pid

If config file contains a mail address or alert program, run mdadm in the background in monitor mode monitoring all md devices. Also write pid of mdadm daemon to **/run/mdadm/mon.pid**.

mdadm -Iq /dev/somedevice

Try to incorporate newly discovered device into some array as appropriate.

mdadm --incremental --rebuild-map --run --scan

Rebuild the array map from any current arrays, and then start any that can be started.

mdadm /dev/md4 --fail detached --remove detached

Any devices which are components of /dev/md4 will be marked as faulty and then remove from the array.

mdadm --grow /dev/md4 --level=6 --backup-file=/root/backup-md4

The array **/dev/md4** which is currently a RAID5 array will be converted to RAID6. There should normally already be a spare drive attached to the array as a RAID6 needs one more drive than a matching RAID5.

mdadm --create /dev/md/ddf --metadata=ddf --raid-disks 6 /dev/sd[a-f]

Create a DDF array over 6 devices.

mdadm --create /dev/md/home -n3 -l5 -z 30000000 /dev/md/ddf

Create a RAID5 array over any 3 devices in the given DDF set. Use only 30 gigabytes of each device.

mdadm -A /dev/md/ddf1 /dev/sd[a-f]

Assemble a pre-exist ddf array.

mdadm -I /dev/md/ddf1

Assemble all arrays contained in the ddf array, assigning names as appropriate.

mdadm --create --help

Provide help about the Create mode.

mdadm --config --help

Provide help about the format of the config file.

mdadm --help

Provide general help.

FILES

/proc/mdstat

If you're using the **/proc** filesystem, **/proc/mdstat** lists all active md devices with information about them. *mdadm* uses this to find arrays when **--scan** is given in Misc mode, and to monitor array reconstruction on Monitor mode.

/etc/mdadm/mdadm.conf (or /etc/mdadm.conf)

The config file lists which devices may be scanned to see if they contain MD super block, and gives identifying information (e.g. UUID) about known MD arrays. See **mdadm.conf(5)** for more details.

/etc/mdadm/mdadm.conf.d (or /etc/mdadm.conf.d)

A directory containing configuration files which are read in lexical order.

/run/mdadm/map

When **--incremental** mode is used, this file gets a list of arrays currently being created.

DEVICE NAMES

mdadm understand two sorts of names for array devices.

The first is the so-called 'standard' format name, which matches the names used by the kernel and which appear in */proc/mdstat*.

The second sort can be freely chosen, but must reside in */dev/md/*. When giving a device name to *mdadm* to create or assemble an array, either full path name such as */dev/md0* or */dev/md/home* can be given, or just the suffix of the second sort of name, such as *home* can be given.

When *mdadm* chooses device names during auto-assembly or incremental assembly, it will sometimes add a small sequence number to the end of the name to avoid conflicted between multiple arrays that have the same name. If *mdadm* can reasonably determine that the array really is meant for this host, either by a hostname in the metadata, or by the presence of the array in **mdadm.conf**, then it will leave off the suffix if possible. Also if the homehost is specified as<ignore> *mdadm* will only use a suffix if a different array of the same name already exists or is listed in the config file.

The standard names for non-partitioned arrays (the only sort of md array available in 2.4 and earlier) are of the form

/dev/mdNN

where NN is a number. The standard names for partitionable arrays (as available from 2.6 onwards) are of the form:

/dev/md_dNN

Partition numbers should be indicated by adding "pMM" to these, thus "*/dev/md/d1p2*".

From kernel version 2.6.28 the "non-partitioned array" can actually be partitioned. So the "md_dNN" names are no longer needed, and partitions such as "*/dev/mdNNpXX*" are possible.

From kernel version 2.6.29 standard names can be non-numeric following the form:

/dev/md_XXX

where **XXX** is any string. These names are supported by *mdadm* since version 3.3 provided they are enabled in *mdadm.conf*.

NOTE

mdadm was previously known as *mdctl*.

NAME

`mdadm.conf` – configuration for management of Software RAID with `mdadm`

SYNOPSIS

`/etc/mdadm/mdadm.conf`

DESCRIPTION

`mdadm` is a tool for creating, managing, and monitoring RAID devices using the **md** driver in Linux.

Some common tasks, such as assembling all arrays, can be simplified by describing the devices and arrays in this configuration file.

SYNTAX

The file should be seen as a collection of words separated by white space (space, tab, or newline). Any word that begins with a hash sign (#) starts a comment and that word together with the remainder of the line is ignored.

Spaces can be included in a word using quotation characters. Either single quotes ('') or double quotes ("") may be used. All the characters from one quotation character to next identical character are protected and will not be used to separate words to start new quoted strings. To include a single quote it must be between double quotes. To include a double quote it must be between single quotes.

Any line that starts with white space (space or tab) is treated as though it were a continuation of the previous line.

Empty lines are ignored, but otherwise each (non continuation) line must start with a keyword as listed below. The keywords are case insensitive and can be abbreviated to 3 characters.

The keywords are:

DEVICE

A **device** line lists the devices (whole devices or partitions) that might contain a component of an MD array. When looking for the components of an array, `mdadm` will scan these devices (or any devices listed on the command line).

The **device** line may contain a number of different devices (separated by spaces) and each device name can contain wild cards as defined by **glob(7)**.

Also, there may be several device lines present in the file.

Alternatively, a **device** line can contain either or both of the words **containers** and **partitions**. The word **containers** will cause `mdadm` to look for assembled CONTAINER arrays and include them as a source for assembling further arrays.

The word **partitions** will cause `mdadm` to read `/proc/partitions` and include all devices and partitions found therein. `mdadm` does not use the names from `/proc/partitions` but only the major and minor device numbers. It scans `/dev` to find the name that matches the numbers.

If no DEVICE line is present, then "DEVICE partitions containers" is assumed.

For example:

```
DEVICE /dev/hda* /dev/hdc*
DEV  /dev/sd*
DEVICE /dev/disk/by-path/pci*
DEVICE partitions
```

ARRAY

The ARRAY lines identify actual arrays. The second word on the line may be the name of the device where the array is normally assembled, such as **/dev/md1** or **/dev/md/backup**. If the name does not start with a slash ('/'), it is treated as being in **/dev/md/**. Alternately the word **<ignore>** (complete with angle brackets) can be given in which case any array which matches the rest of the line will never be automatically assembled. If no device name is given, *mdadm* will use various heuristics to determine an appropriate name.

Subsequent words identify the array, or identify the array as a member of a group. If multiple identities are given, then a component device must match ALL identities to be considered a match. Each identity word has a tag, and equals sign, and some value. The tags are:

uuid= The value should be a 128 bit uuid in hexadecimal, with punctuation interspersed if desired. This must match the uuid stored in the superblock.

name= The value should be a simple textual name as was given to *mdadm* when the array was created. This must match the name stored in the superblock on a device for that device to be included in the array. Not all superblock formats support names.

super-minor=

The value is an integer which indicates the minor number that was stored in the superblock when the array was created. When an array is created as **/dev/mdX**, then the minor number X is stored.

devices=

The value is a comma separated list of device names or device name patterns. Only devices with names which match one entry in the list will be used to assemble the array. Note that the devices listed there must also be listed on a DEVICE line.

level= The value is a RAID level. This is not normally used to identify an array, but is supported so that the output of

mdadm --examine --scan

can be used directly in the configuration file.

num-devices=

The value is the number of devices in a complete active array. As with **level** **vel=** this is mainly for compatibility with the output of

mdadm --examine --scan.

spares=

The value is a number of spare devices to expect the array to have. The sole use of this keyword and value is as follows: **mdadm --monitor** will report an array if it is found to have fewer than this number of spares when **--monitor** starts or when **--oneshot** is used.

spare-group=

The value is a textual name for a group of arrays. All arrays with the same **spare-group** name are considered to be part of the same group. The significance of a group of arrays is that *mdadm* will, when monitoring the arrays, move a spare drive from one array in a group to another array in that group if the first array had a failed or missing drive but no spare.

auto= This option is rarely needed with *mdadm*-3.0, particularly if use with the Linux kernel v2.6.28 or later. It tells *mdadm* whether to use partitionable array or non-partitionable arrays and, in the absence of *udev*, how many partition devices to create. From 2.6.28 all md array devices are partitionable, hence this option is not needed.

The value of this option can be "yes" or "md" to indicate that a traditional, non-partitionable md array should be created, or "mdp", "part" or "partition" to indicate that a partitionable md array (only available in linux 2.6 and later) should be used. This later set can also have a number appended to indicate how many partitions to create device files for, e.g. **auto=mdp5**. The default is 4.

bitmap=

The option specifies a file in which a write-intent bitmap should be found. When assembling the array, *mdadm* will provide this file to the **md** driver as the bitmap file. This has the same function as the **--bitmap-file** option to **--assemble**.

metadata=

Specify the metadata format that the array has. This is mainly recognised for comparability with the output of **mdadm -Es**.

container=

Specify that this array is a member array of some container. The value given can be either a path name in /dev, or a UUID of the container array.

member=

Specify that this array is a member array of some container. Each type of container has some way to enumerate member arrays, often a simple sequence number. The value identifies which member of a container the array is. It will usually accompany a "container=" word.

MAILADDR

The **mailaddr** line gives an E-mail address that alerts should be sent to when *mdadm* is running in **--monitor** mode (and was given the **--scan** option). There should only be one **MAILADDR** line and it should have only one address. Any subsequent addresses are silently ignored.

MAILFROM

The **mailfrom** line (which can only be abbreviated to at least 5 characters) gives an address to appear in the "From" address for alert mails. This can be useful if you want to explicitly set a domain, as the default from address is "root" with no domain. All words on this line are catenated with spaces to form the address.

Note that this value cannot be set via the *mdadm* commandline. It is only settable via the config file.

PROGRAM

The **program** line gives the name of a program to be run when **mdadm --monitor** detects potentially interesting events on any of the arrays that it is monitoring. This program gets run with two or three arguments, they being the Event, the md device, and possibly the related component device.

There should only be one **program** line and it should give only one program.

CREATE

The **create** line gives default values to be used when creating arrays, new members of arrays, and device entries for arrays. These include:

owner=**group=**

These can give user/group ids or names to use instead of system defaults (root/wheel or root/disk).

mode= An octal file mode such as 0660 can be given to override the default of 0600.

auto= This corresponds to the **--auto** flag to mdadm. Give **yes**, **md**, **mdp**, **part** — possibly followed by a number of partitions — to indicate how missing device entries should be created.

metadata=

The name of the metadata format to use if none is explicitly given. This can be useful to impose a system-wide default of version-1 superblocks.

symlinks=no

Normally when creating devices in **/dev/md/** *mdadm* will create a matching symlink from **/dev/** with a name starting **md** or **md_**. Give **symlinks=no** to suppress this symlink creation.

names=yes

Since Linux 2.6.29 it has been possible to create **md** devices with a name like **md_home** rather than just a number, like **md3**. *mdadm* will use the numeric alternative by default as other tools that interact with md arrays may expect only numbers. If **names=yes** is given in *mdadm.conf* then *mdadm* will use a name when appropriate. If **names=no** is given, then non-numeric *md* device names will not be used even if the default changes in a future release of *mdadm*.

bbl=no By default, *mdadm* will reserve space for a bad block list (bbl) on all devices included in or added to any array that supports them. Setting **bbl=no** will prevent this, so newly added devices will not have a bad block log.

HOMEHOST

The **homehost** line gives a default value for the **--homehost=** option to *mdadm*. There should normally be only one other word on the line. It should either be a host name, or one of the special words **<system>**, **<none>** and **<ignore>**. If **<system>** is given, then the **gethostname(2)** system-call is used to get the host name. This is the default.

If **<ignore>** is given, then a flag is set so that when arrays are being auto-assembled the checking of the recorded *homehost* is disabled. If **<ignore>** is given it is also possible to give an explicit name which will be used when creating arrays. This is the only case when there can be more than one other word on the **HOMEHOST** line. If there are other words, or other **HOMEHOST** lines, they are silently ignored.

If **<none>** is given, then the default of using **gethostname(2)** is over-ridden and no *homehost* name is assumed.

When arrays are created, this host name will be stored in the metadata. When arrays are assembled using auto-assembly, arrays which do not record the correct *homehost* name in their metadata will be assembled using a "foreign" name. A "foreign" name always ends with a digit string preceded by an underscore to differentiate it from any possible local name. e.g. **/dev/md/1_1** or **/dev/md/home_0**.

AUTO A list of names of metadata format can be given, each preceded by a plus or minus sign. Also the word *homehost* is allowed as is *all* preceded by plus or minus sign. *all* is usually last.

When *mdadm* is auto-assembling an array, either via *--assemble* or *--incremental* and it finds metadata of a given type, it checks that metadata type against those listed in this line. The first match wins, where *all* matches anything. If a match is found that was preceded by a plus sign, the auto assembly is allowed. If the match was preceded by a minus sign, the auto assembly is disallowed. If no match is found, the auto assembly is allowed.

If the metadata indicates that the array was created for *this* host, and the word *homehost* appears before any other match, then the array is treated as a valid candidate for auto-assembly.

This can be used to disable all auto-assembly (so that only arrays explicitly listed in mdadm.conf or on the command line are assembled), or to disable assembly of certain metadata types which might be handled by other software. It can also be used to disable assembly of all foreign arrays - normally such arrays are assembled but given a non-deterministic name in **/dev/md/**.

The known metadata types are **0.90**, **1.x**, **ddf**, **imsm**.

AUTO should be given at most once. Subsequent lines are silently ignored. Thus an earlier config file in a config directory will over-ride the setting in a later config file.

POLICY

This is used to specify what automatic behavior is allowed on devices newly appearing in the system and provides a way of marking spares that can be moved to other arrays as well as the migration domains. *Domain* can be defined through *policy* line by specifying a domain name for a number of paths from **/dev/disk/by-path/**. A device may belong to several domains. The domain of an array is a union of domains of all devices in that array. A spare can be automatically moved from one array to another if the set of the destination array's *domains* contains all the *domains* of the new disk or if both arrays have the same *spare-group*.

To update hot plug configuration it is necessary to execute **mdadm --udev-rules** command after changing the config file

Keywords used in the *POLICY* line and supported values are:

domain=

any arbitrary string

metadata=

0.9 1.x ddf or imsm

path= file glob matching anything from **/dev/disk/by-path**

type= either **disk** or **part**.

action=

include, re-add, spare, spare-same-slot, or force-spare

auto= yes, no, or homehost.

The *action* item determines the automatic behavior allowed for devices matching the *path* and *type* in the same line. If a device matches several lines with different *actions* then the most permissive will apply. The ordering of policy lines is irrelevant to the end result.

include

allows adding a disk to an array if metadata on that disk matches that array

re-add will include the device in the array if it appears to be a current member or a member that was recently removed and the array has a write-intent-bitmap to allow the **re-add** functionality.

spare as above and additionally: if the device is bare it can become a spare if there is any array that it is a candidate for based on domains and metadata.

spare=same-slot

as above and additionally if given slot was used by an array that went degraded recently and the device plugged in has no metadata then it will be automatically added to that array (or it's container)

force-spare

as above and the disk will become a spare in remaining cases

PART-POLICY

This is similar to **POLICY** and accepts the same keyword assignments. It allows a consistent set of policies to be applied to each of the partitions of a device.

A **PART-POLICY** line should set *type=disk* and identify the path to one or more disk devices. Each partition on these disks will be treated according to the *action=* setting from this line. If a *domain* is set in the line, then the domain associated with each partition will be based on the domain, but with "**-partN**" appended, when N is the partition number for the partition that was found.

SYSFS The **SYSFS** line lists custom values of MD device's sysfs attributes which will be stored in sysfs after the array is assembled. Multiple lines are allowed and each line has to contain the uid or the name of the device to which it relates.

uuid= hexadecimal identifier of MD device. This has to match the uuid stored in the superblock.

name= name of the MD device as was given to *mdadm* when the array was created. It will be ignored if **uuid** is not empty.

MONITORDELAY

The **monitordelay** line gives a delay in seconds *mdadm* shall wait before pooling md arrays when *mdadm* is running in **--monitor** mode. **-d**/**--delay** command line argument takes precedence over the config file

EXAMPLE

```
DEVICE /dev/sd[bcdjkl]1
DEVICE /dev/hda1 /dev/hdb1

# /dev/md0 is known by its UUID.
ARRAY /dev/md0 UUID=3aaa0122:29827cf:a5331ad66:ca767371
# /dev/md1 contains all devices with a minor number of
# 1 in the superblock.
ARRAY /dev/md1 superminor=1
# /dev/md2 is made from precisely these two devices
ARRAY /dev/md2 devices=/dev/hda1,/dev/hdb1

# /dev/md4 and /dev/md5 are a spare-group and spares
# can be moved between them
ARRAY /dev/md4 uuid=b23f3c6d:aec43a9f:fd65db85:369432df
    spare-group=group1
ARRAY /dev/md5 uuid=19464854:03f71b1b:e0df2edd:246cc977
    spare-group=group1
# /dev/md/home is created if need to be a partitionable md array
# any spare device number is allocated.
```

```
ARRAY /dev/md/home UUID=9187a482:5dde19d9:eea3cc4a:d646ab8b
    auto=part
# The name of this array contains a space.
ARRAY /dev/md9 name='Data Storage'

POLICY domain=domain1 metadata=imsm path=pci-0000:00:1f.2-scsi-*
    action=spare
POLICY domain=domain1 metadata=imsm path=pci-0000:04:00.0-scsi-[01]*
    action=include
# One domain comprising of devices attached to specified paths is defined.
# Bare device matching first path will be made an imsm spare on hot plug.
# If more than one array is created on devices belonging to domain1 and
# one of them becomes degraded, then any imsm spare matching any path for
# given domain name can be migrated.
MAILADDR root@mydomain.tld
PROGRAM /usr/sbin/handle-mdadm-events
CREATE group=system mode=0640 auto=part-8
HOMEHOST <system>

NAME

mesg – display (or do not display) messages from other users

SYNOPSIS

mesg [option] [n|y]

DESCRIPTION

The **mesg** utility is invoked by a user to control write access others have to the terminal device associated with standard error output. If write access is allowed, then programs such as **talk(1)** and **write(1)** may display messages on the terminal.

Traditionally, write access is allowed by default. However, as users become more conscious of various security risks, there is a trend to remove write access by default, at least for the primary login shell. To make sure your ttys are set the way you want them to be set, **mesg** should be executed in your login scripts.

The **mesg** utility silently exits with error status 2 if not executed on terminal. In this case execute **mesg** is pointless. The command line option **--verbose** forces mesg to print a warning in this situation. This behaviour has been introduced in version 2.33.

ARGUMENTS

n

Disallow messages.

y

Allow messages to be displayed.

If no arguments are given, **mesg** shows the current message status on standard error output.

OPTIONS

-v, --verbose

Explain what is being done.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

EXIT STATUS

The **mesg** utility exits with one of the following values:

0

Messages are allowed.

1

Messages are not allowed.

>1

An error has occurred.

FILES

/dev/[pt]ty[pq]?

HISTORY

A **mesg** command appeared in Version 6 AT&T UNIX.

SEE ALSO

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **mesg** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

`mkdir` – make directories

SYNOPSIS

`mkdir [OPTION]... DIRECTORY...`

DESCRIPTION

Create the DIRECTORY(ies), if they do not already exist.

Mandatory arguments to long options are mandatory for short options too.

`-m, --mode=MODE`

set file mode (as in `chmod`), not a=rwx – umask

`-p, --parents`

no error if existing, make parent directories as needed

`-v, --verbose`

print a message for each created directory

`-Z` set SELinux security context of each created directory to the default type

`--context[=CTX]`

like `-Z`, or if CTX is specified then set the SELinux or SMACK security context to CTX

`--help` display this help and exit

`--version`

output version information and exit

NAME

mkdir, mkdirat – create a directory

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/stat.h>
int mkdir(const char *pathname, mode_t mode);
#include <fcntl.h>      /* Definition of AT_* constants */
#include <sys/stat.h>
int mkdirat(int dirfd, const char *pathname, mode_t mode);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
mkdirat():
Since glibc 2.10:
    _POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
    _ATFILE_SOURCE
```

DESCRIPTION

mkdir() attempts to create a directory named *pathname*.

The argument *mode* specifies the mode for the new directory (see **inode(7)**). It is modified by the process's *umask* in the usual way: in the absence of a default ACL, the mode of the created directory is (*mode* & $\sim\text{umask}$ & 0777). Whether other *mode* bits are honored for the created directory depends on the operating system. For Linux, see NOTES below.

The newly created directory will be owned by the effective user ID of the process. If the directory containing the file has the set-group-ID bit set, or if the filesystem is mounted with BSD group semantics (*mount -o bsdgroups* or, synonymously *mount -o grpid*), the new directory will inherit the group ownership from its parent; otherwise it will be owned by the effective group ID of the process.

If the parent directory has the set-group-ID bit set, then so will the newly created directory.

mkdirat()

The **mkdirat()** system call operates in exactly the same way as **mkdir()**, except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **mkdir()** for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like **mkdir()**).

If *pathname* is absolute, then *dirfd* is ignored.

See **openat(2)** for an explanation of the need for **mkdirat()**.

RETURN VALUE

mkdir() and **mkdirat()** return zero on success. On error, -1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES

The parent directory does not allow write permission to the process, or one of the directories in *pathname* did not allow search permission. (See also **path_resolution(7)**.)

EBADF

(**mkdirat()**) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EDQUOT

The user's quota of disk blocks or inodes on the filesystem has been exhausted.

EEXIST

pathname already exists (not necessarily as a directory). This includes the case where *pathname* is a symbolic link, dangling or not.

EFAULT

pathname points outside your accessible address space.

EINVAL

The final component ("basename") of the new directory's *pathname* is invalid (e.g., it contains characters not permitted by the underlying filesystem).

ELOOP

Too many symbolic links were encountered in resolving *pathname*.

EMLINK

The number of links to the parent directory would exceed **LINK_MAX**.

ENAMETOOLONG

pathname was too long.

ENOENT

A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOMEM

Insufficient kernel memory was available.

ENOSPC

The device containing *pathname* has no room for the new directory.

ENOSPC

The new directory cannot be created because the user's disk quota is exhausted.

ENOTDIR

A component used as a directory in *pathname* is not, in fact, a directory.

ENOTDIR

(**mkdirat()**) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM

The filesystem containing *pathname* does not support the creation of directories.

EROFS

pathname refers to a file on a read-only filesystem.

VERSIONS

mkdirat() was added in Linux 2.6.16; library support was added in glibc 2.4.

STANDARDS

mkdir(): SVr4, BSD, POSIX.1-2001, POSIX.1-2008.

mkdirat(): POSIX.1-2008.

NOTES

Under Linux, apart from the permission bits, the **S_ISVTX mode** bit is also honored.

There are many infelicities in the protocol underlying NFS. Some of these affect **mkdir()**.

glibc notes

On older kernels where **mkdirat()** is unavailable, the glibc wrapper function falls back to the use of **mkdir()**. When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

NAME

mkfs – build a Linux filesystem

SYNOPSIS

mkfs [options] [**-t** *type*] [*fs-options*] *device* [*size*]

DESCRIPTION

This **mkfs** frontend is deprecated in favour of filesystem specific **mkfs.<type>** utils.

mkfs is used to build a Linux filesystem on a device, usually a hard disk partition. The *device* argument is either the device name (e.g., */dev/hda1*, */dev/sdb2*), or a regular file that shall contain the filesystem. The *size* argument is the number of blocks to be used for the filesystem.

The exit status returned by **mkfs** is 0 on success and 1 on failure.

In actuality, **mkfs** is simply a front-end for the various filesystem builders (**mkfs.fstype**) available under Linux. The filesystem-specific builder is searched for via your **PATH** environment setting only. Please see the filesystem-specific builder manual pages for further details.

OPTIONS

-t, --type *type*

Specify the *type* of filesystem to be built. If not specified, the default filesystem type (currently ext2) is used.

fs-options

Filesystem-specific options to be passed to the real filesystem builder.

-V, --verbose

Produce verbose output, including all filesystem-specific commands that are executed. Specifying this option more than once inhibits execution of any filesystem-specific commands. This is really only useful for testing.

-h, --help

Display help text and exit.

-V, --version

Print version and exit. (Option **-V** will display version information only when it is the only parameter, otherwise it will work as **--verbose**.)

BUGS

All generic options must precede and not be combined with filesystem-specific options. Some filesystem-specific programs do not automatically detect the device size and require the *size* parameter to be specified.

AUTHORS

David Engel <david@ods.com>, Fred N. van Kempen <waltje@uwalt.nl.mugnet.org>, Ron Sommeling <sommel@sci.kun.nl>.

The manual page was shamelessly adapted from Remy Card's version for the ext2 filesystem.

NAME

mkfs.bfs – make an SCO bfs filesystem

SYNOPSIS

mkfs.bfs [options] *device* [*block-count*]

DESCRIPTION

mkfs.bfs creates an SCO bfs filesystem on a block device (usually a disk partition or a file accessed via the loop device).

The *block-count* parameter is the desired size of the filesystem, in blocks. If nothing is specified, the entire partition will be used.

OPTIONS

-N, --inodes *number*

Specify the desired *number* of inodes (at most 512). If nothing is specified, some default number in the range 48–512 is picked depending on the size of the partition.

-V, --vname *label*

Specify the volume *label*. I have no idea if/where this is used.

-F, --fname *name*

Specify the filesystem *name*. I have no idea if/where this is used.

-v, --verbose

Explain what is being done.

-c

This option is silently ignored.

-l

This option is silently ignored.

-h, --help

Display help text and exit.

-V, --version

Print version and exit. Option **-V** only works as **--version** when it is the only option.

EXIT STATUS

The exit status returned by **mkfs.bfs** is 0 when all went well, and 1 when something went wrong.

NAME

`mkfs.btrfs` – create a btrfs filesystem

SYNOPSIS

mkfs.btrfs [options] <*device*> [<*device*>...]

DESCRIPTION

mkfs.btrfs is used to create the btrfs filesystem on a single or multiple devices. <*device*> is typically a block device but can be a file-backed image as well. Multiple devices are grouped by UUID of the filesystem.

Before mounting such filesystem, the kernel module must know all the devices either via preceding execution of **btrfs device scan** or using the **device** mount option. See section **MULTIPLE DEVICES** for more details.

The default block group profiles for data and metadata depend on number of devices and possibly other factors. It's recommended to use specific profiles but the defaults should be OK and allowing future conversions to other profiles. Please see options **-d** and **-m** for further details and **btrfs-balance(8)** for the profile conversion post mkfs.

OPTIONS

-b|--byte-count <*size*>

Specify the size of the filesystem. If this option is not used, then `mkfs.btrfs` uses the entire device space for the filesystem.

--csum <*type*>, **--checksum** <*type*>

Specify the checksum algorithm. Default is *crc32c*. Valid values are *crc32c*, *xxhash*, *sha256* or *blake2*. To mount such filesystem kernel must support the checksums as well. See *CHECKSUM ALGORITHMS* in **btrfs(5)**.

-d|--data <*profile*>

Specify the profile for the data block groups. Valid values are *raid0*, *raid1*, *raid1c3*, *raid1c4*, *raid5*, *raid6*, *raid10* or *single* or *dup* (case does not matter).

See *DUP PROFILES ON A SINGLE DEVICE* for more details.

On multiple devices, the default was *raid0* until version 5.7, while it is *single* since version 5.8. You can still select *raid0* manually, but it was not suitable as default.

-m|--metadata <*profile*>

Specify the profile for the metadata block groups. Valid values are *raid0*, *raid1*, *raid1c3*, *raid1c4*, *raid5*, *raid6*, *raid10*, *single* or *dup* (case does not matter).

Default on a single device filesystem is *DUP* and is recommended for metadata in general. The duplication might not be necessary in some use cases and it's up to the user to change that at mkfs time or later. This depends on hardware that could potentially deduplicate the blocks again but this cannot be detected at mkfs time.

NOTE

Up to version 5.14 there was a detection of a SSD device (more precisely if it's a rotational device, determined by the contents of file `/sys/block/DEV/queue/rotational`) that used to select *single*. This has changed in version 5.15 to be always *dup*.

Note that the rotational status can be arbitrarily set by the underlying block device driver and may not reflect the true status (network block device, memory-backed SCSI devices, real block device behind some additional device mapper layer, etc). It's recommended to always set the options **--data**/**--metadata** to avoid confusion and unexpected results.

See *DUP PROFILES ON A SINGLE DEVICE* for more details.

On multiple devices the default is *raid1*.

-M|--mixed

Normally the data and metadata block groups are isolated. The *mixed* mode will remove the isolation and store both types in the same block group type. This helps to utilize the free space regardless of the purpose and is suitable for small devices. The separate allocation of block groups leads to a situation where the space is reserved for the other block group type, is not available for allocation and can lead to ENOSPC state.

The recommended size for the mixed mode is for filesystems less than 1GiB. The soft recommendation is to use it for filesystems smaller than 5GiB. The mixed mode may lead to degraded performance on larger filesystems, but is otherwise usable, even on multiple devices.

The *nodesize* and *sectorsize* must be equal, and the block group types must match.

Note

versions up to 4.2.x forced the mixed mode for devices smaller than 1GiB. This has been removed in 4.3+ as it caused some usability issues.

-l|--leafsize <size>

Alias for *--nodesize*. Deprecated.

-n|--nodesize <size>

Specify the *nodesize*, the tree block size in which btrfs stores metadata. The default value is 16KiB (16384) or the page size, whichever is bigger. Must be a multiple of the *sectorsize* and a power of 2, but not larger than 64KiB (65536). Leafsize always equals *nodesize* and the options are aliases.

Smaller node size increases fragmentation but leads to taller b-trees which in turn leads to lower locking contention. Higher node sizes give better packing and less fragmentation at the cost of more expensive memory operations while updating the metadata blocks.

Note

versions up to 3.11 set the *nodesize* to 4k.

-s|--sectorsize <size>

Specify the *sectorsize*, the minimum data block allocation unit.

The default value is the page size and is autodetected. If the *sectorsize* differs from the page size, the created filesystem may not be mountable by the running kernel. Therefore it is not recommended to use this option unless you are going to mount it on a system with the appropriate page size.

-L|--label <string>

Specify a label for the filesystem. The *string* should be less than 256 bytes and must not contain newline characters.

-K|--nodiscard

Do not perform whole device TRIM operation on devices that are capable of that. This does not affect discard/trim operation when the filesystem is mounted. Please see the mount option *discard* for that in **btrfs(5)**.

-r|--rootdir <rootdir>

Populate the toplevel subvolume with files from *rootdir*. This does not require root permissions to write the new files or to mount the filesystem.

Note

This option may enlarge the image or file to ensure it's big enough to contain the files from *rootdir*. Since version 4.14.1 the filesystem size is not minimized. Please see option *--shrink* if you need that functionality.

--shrink

Shrink the filesystem to its minimal size, only works with *--rootdir* option.

If the destination block device is a regular file, this option will also truncate the file to the minimal size. Otherwise it will reduce the filesystem available space. Extra space will not be usable unless the filesystem is mounted and resized using *btrfs filesystem resize*.

Note

prior to version 4.14.1, the shrinking was done automatically.

-O|—features <feature1>[,<feature2>...]

A list of filesystem features turned on at mkfs time. Not all features are supported by old kernels. To disable a feature, prefix it with ^.

See section **FILESYSTEM FEATURES** for more details. To see all available features that mkfs.btrfs supports run:

mkfs.btrfs -O list-all

-R|—runtime-features <feature1>[,<feature2>...]

A list of features that can be enabled at mkfs time, otherwise would have to be turned on a mounted filesystem. Although no runtime feature is enabled by default, to disable a feature, prefix it with ^.

See section **RUNTIME FEATURES** for more details. To see all available runtime features that mkfs.btrfs supports run:

mkfs.btrfs -R list-all

-f|—force

Forcibly overwrite the block devices when an existing filesystem is detected. By default, mkfs.btrfs will utilize *libblkid* to check for any known filesystem on the devices. Alternatively you can use the **wipefs** utility to clear the devices.

-q|—quiet

Print only error or warning messages. Options --features or --help are unaffected. Resets any previous effects of --verbose.

-U|—uuid <UUID>

Create the filesystem with the given *UUID*. The UUID must not exist on any filesystem currently present.

-v|—verbose

Increase verbosity level, default is 1.

-V|—version

Print the **mkfs.btrfs** version and exit.

--help

Print help.

SIZE UNITS

The default unit is *byte*. All size parameters accept suffixes in the 1024 base. The recognized suffixes are: *k*, *m*, *g*, *t*, *p*, *e*, both uppercase and lowercase.

MULTIPLE DEVICES

Before mounting a multiple device filesystem, the kernel module must know the association of the block devices that are attached to the filesystem **UUID**.

There is typically no action needed from the user. On a system that utilizes a udev-like daemon, any new block device is automatically registered. The rules call **btrfs device scan**.

The same command can be used to trigger the device scanning if the btrfs kernel module is reloaded (naturally all previous information about the device registration is lost).

Another possibility is to use the mount options **device** to specify the list of devices to scan at the time of mount.

```
# mount -o device=/dev/sdb,device=/dev/sdc /dev/sda /mnt
```

Note

that this means only scanning, if the devices do not exist in the system, mount will fail anyway. This can happen on systems without initramfs/initrd and root partition created with RAID1/10/5/6 profiles. The mount action can happen before all block devices are discovered. The waiting is usually done on the initramfs/initrd systems.

RAID5/6 has known problems and should not be used in production.

FILESYSTEM FEATURES

Features that can be enabled during creation time. See also **btrfs(5)** section *FILESYSTEM FEATURES*.

mixed-bg

(kernel support since 2.6.37)

mixed data and metadata block groups, also set by option *--mixed*

extref

(default since btrfs-progs 3.12, kernel support since 3.7)

increased hardlink limit per file in a directory to 65536, older kernels supported a varying number of hardlinks depending on the sum of all file name sizes that can be stored into one metadata block

raid56

(kernel support since 3.9)

extended format for RAID5/6, also enabled if raid5 or raid6 block groups are selected

skinny-metadata

(default since btrfs-progs 3.18, kernel support since 3.10)

reduced-size metadata for extent references, saves a few percent of metadata

no-holes

(default since btrfs-progs 5.15, kernel support since 3.14)

improved representation of file extents where holes are not explicitly stored as an extent, saves a few percent of metadata if sparse files are used

zoned

(kernel support since 5.12)

zoned mode, data allocation and write friendly to zoned/SMR/ZBC/ZNS devices, see *ZONED MODE* in **btrfs(5)**, the mode is automatically selected when a zoned device is detected

RUNTIME FEATURES

Features that are typically enabled on a mounted filesystem, eg. by a mount option or by an ioctl. Some of them can be enabled early, at mkfs time. This applies to features that need to be enabled once and then the status is permanent, this does not replace mount options.

quota

(kernel support since 3.4)

Enable quota support (qgroups). The qgroup accounting will be consistent, can be used together with *--rootdir*. See also **btrfs-quota(8)**.

free-space-tree

(default since btrfs-progs 5.15, kernel support since 4.5)

Enable the free space tree (mount option space_cache=v2) for persisting the free space cache.

BLOCK GROUPS, CHUNKS, RAID

The highlevel organizational units of a filesystem are block groups of three types: data, metadata and system.

DATA

store data blocks and nothing else

METADATA

store internal metadata in b-trees, can store file data if they fit into the inline limit

SYSTEM

store structures that describe the mapping between the physical devices and the linear logical space representing the filesystem

Other terms commonly used:

block group, chunk

a logical range of space of a given profile, stores data, metadata or both; sometimes the terms are used interchangeably

A typical size of metadata block group is 256MiB (filesystem smaller than 50GiB) and 1GiB (larger than 50GiB), for data it's 1GiB. The system block group size is a few megabytes.

RAID

a block group profile type that utilizes RAID-like features on multiple devices: striping, mirroring, parity

profile

when used in connection with block groups refers to the allocation strategy and constraints, see the section *PROFILES* for more details

PROFILES

There are the following block group types available:

Profile	Redundancy			Space utilization	Min/max devices
	Copies	Parity	Striping		
single	1			100%	1/any
DUP	2 / 1 device			50%	1/any ^(see note 1)
RAID0			1 to N	100%	1/any ^(see note 5)
RAID1	2			50%	2/any
RAID1C3	3			33%	3/any
RAID1C4	4			25%	4/any
RAID10	2		1 to N	50%	2/any ^(see note 5)
RAID5	1	1	2 to N-1	(N-1)/N	2/any ^(see note 2)
RAID6	1	2	3 to N-2	(N-2)/N	3/any ^(see note 3)

Warning

It's not recommended to create filesystems with RAID0/1/10/5/6 profiles on partitions from the same device. Neither redundancy nor performance will be improved.

Note 1: DUP may exist on more than 1 device if it starts on a single device and another one is added. Since version 4.5.1, **mkfs.btrfs** will let you create DUP on multiple devices without restrictions.

Note 2: It's not recommended to use 2 devices with RAID5. In that case, parity stripe will contain the same data as the data stripe, making RAID5 degraded to RAID1 with more overhead.

Note 3: It's also not recommended to use 3 devices with RAID6, unless you want to get effectively 3 copies in a RAID1-like manner (but not exactly that).

Note 4: Since kernel 5.5 it's possible to use RAID1C3 as replacement for RAID6, higher space cost but reliable.

Note 5: Since kernel 5.15 it's possible to use (mount, convert profiles) RAID0 on one device and RAID10 on two devices.

PROFILE LAYOUT

For the following examples, assume devices numbered by 1, 2, 3 and 4, data or metadata blocks A, B, C, D, with possible stripes eg. A1, A2 that would be logically A, etc. For parity profiles PA and QA are parity and syndrom, associated with the given stripe. The simple layouts single or DUP are left out. Actual physical block placement on devices depends on current state of the free/allocated space and may appear random. All devices are assumed to be present at the time of the blocks would have been written.

RAID1

device 1	device 2	device 3	device 4
A	D		
B			C
C			
D	A	B	

RAID1C3

device 1	device 2	device 3	device 4
A	A	D	
B		B	
C		A	C
D	D	C	B

RAID0

device 1	device 2	device 3	device 4
A2	C3	A3	C2
B1	A1	D2	B3
C1	D3	B4	D1
D4	B2	C4	A4

RAID5

device 1	device 2	device 3	device 4
A2	C3	A3	C2
B1	A1	D2	B3
C1	D3	PB	D1
PD	B2	PC	PA

RAID6

device 1	device 2	device 3	device 4
A2	QC	QA	C2
B1	A1	D2	QB
C1	QD	PB	D1
PD	B2	PC	PA

DUP PROFILES ON A SINGLE DEVICE

The mkfs utility will let the user create a filesystem with profiles that write the logical blocks to 2 physical locations. Whether there are really 2 physical copies highly depends on the underlying device type.

For example, a SSD drive can remap the blocks internally to a single copy—thus deduplicating them. This negates the purpose of increased redundancy and just wastes filesystem space without providing the expected level of redundancy.

The duplicated data/metadata may still be useful to statistically improve the chances on a device that might perform some internal optimizations. The actual details are not usually disclosed by vendors. For example we could expect that not all blocks get deduplicated. This will provide a non-zero probability of recovery compared to a zero chance if the single profile is used. The user should make the tradeoff decision. The deduplication in SSDs is thought to be widely available so the reason behind the mkfs default is to not give a false sense of redundancy.

As another example, the widely used USB flash or SD cards use a translation layer between the logical and physical view of the device. The data lifetime may be affected by frequent plugging. The memory cells could get damaged, hopefully not destroying both copies of particular data in case of DUP.

The wear levelling techniques can also lead to reduced redundancy, even if the device does not do any deduplication. The controllers may put data written in a short timespan into the same physical storage unit (cell, block etc). In case this unit dies, both copies are lost. BTRFS does not add any artificial delay between metadata writes.

The traditional rotational hard drives usually fail at the sector level.

In any case, a device that starts to misbehave and repairs from the DUP copy should be replaced! **DUP is not backup.**

KNOWN ISSUES

SMALL FILESYSTEMS AND LARGE NODESIZE

The combination of small filesystem size and large nodesize is not recommended in general and can lead to various ENOSPC-related issues during mount time or runtime.

Since mixed block group creation is optional, we allow small filesystem instances with differing values for *sectorsize* and *nodesize* to be created and could end up in the following situation:

```
# mkfs.btrfs -f -n 65536 /dev/loop0
btrfs-progs v3.19-rc2-405-g976307c
See http://btrfs.wiki.kernel.org for more information.
```

mount: mount /dev/loop0 on /mnt failed: No space left on device
```

The ENOSPC occurs during the creation of the UUID tree. This is caused by large metadata blocks and space reservation strategy that allocates more than can fit into the filesystem.

AVAILABILITY

mkfs.btrfs is part of btrfs-progs. Please refer to the btrfs wiki <http://btrfs.wiki.kernel.org> for further details.

NAME

mkfs.exfat – create an exFAT filesystem

SYNOPSIS

```
mkfs.exfat [ -b boundary_alignment ] [ -c cluster_size ] [ -f ] [ -h ] [ -L volume_label ] [ --pack-bitmap ] [ -v ] device
mkfs.exfat -V
```

DESCRIPTION

mkfs.exfat creates an exFAT filesystem by writing on a special file using the values found in the arguments of the command line. It is invoked automatically by **mkfs(8)** when it is given the **-t exfat** option.

As an example, to make a filesystem on the first partition on the first SCSI disk, use:

```
mkfs.exfat /dev/sda1
```

OPTIONS

-b, --boundary-align=alignment

Specifies the alignment for the FAT and the start of the cluster heap. The *alignment* argument is specified in bytes or may be specified with **m/M** suffix for mebibytes or **k/K** suffix for kibibytes and should be a power of two. Some media like SD cards need this for optimal performance and endurance, in which case *alignment* should be set to half of the card's native boundary unit size. If the card's native boundary unit size is not known, refer to the following table of boundary unit sizes recommended by the SD Card Association.

Card Capacity Range	Cluster Size	Boundary Unit
$\leq 8 \text{ MiB}$	8 KiB	8 KiB
$>8 \text{ MiB} \leq 64 \text{ MiB}$	16 KiB	16 KiB
$>64 \text{ MiB} \leq 256 \text{ MiB}$	16 KiB	32 KiB
$>256 \text{ MiB} \leq 1 \text{ GiB}$	16 KiB	64 KiB
$>1 \text{ GiB} \leq 2 \text{ GiB}$	32 KiB	64 KiB
$>2 \text{ GiB} \leq 32 \text{ GiB}$	32 KiB	4 MiB
$>32 \text{ GiB} \leq 128 \text{ GiB}$	128 KiB	16 MiB
$>128 \text{ GiB} \leq 512 \text{ GiB}$	256 KiB	32 MiB
$>512 \text{ GiB} \leq 2 \text{ TiB}$	512 KiB	64 MiB

-c, --cluster-size=size

Specifies the cluster size of the exFAT file system. The *size* argument is specified in bytes or may be specified with **m/M** suffix for mebibytes or **k/K** suffix for kibibytes and must be a power of two.

-f, --full-format

Performs a full format. This zeros the entire disk device while creating the exFAT filesystem.

-h, --help

Prints the help and exit.

-L, --volume-label=label

Specifies the volume label to be associated with the exFAT filesystem.

--pack-bitmap

Attempts to relocate the exFAT allocation bitmap so that it ends at the alignment boundary immediately following the FAT rather than beginning at that boundary. This strictly violates the SD card specification but may improve performance and endurance on SD cards and other flash media not designed for use with exFAT by allowing file-system metadata updates to touch fewer flash allocation units. Furthermore, many SD cards and other flash devices specially optimize the allocation unit where the FAT resides so as to support tiny writes with reduced write amplification but expect only larger writes in subsequent allocation units — where the exFAT bitmap would be placed by default. Specifying **--pack-bitmap** attempts to avoid the potential problems associated with issuing many small writes to the bitmap by making it share an allocation unit with the FAT. If there is insufficient space for the bitmap there, then this option will have no effect, and the

bitmap will be aligned at the boundary as by default.

-v, --verbose

Prints verbose debugging information while creating the exFAT filesystem.

-V, --version

Prints the version number and exits.

NAME

mke2fs – create an ext2/ext3/ext4 file system

SYNOPSIS

```
mke2fs [ -c | -I filename ] [ -b block-size ] [ -C cluster-size ] [ -d root-directory ] [ -D ] [ -g blocks-per-group ] [ -G number-of-groups ] [ -i bytes-per-inode ] [ -I inode-size ] [ -j ] [ -J journal-options ] [ -N number-of-inodes ] [ -n ] [ -m reserved-blocks-percentage ] [ -o creator-os ] [ -O [^]feature[,...] ] [ -q ] [ -r fs-revision-level ] [ -E extended-options ] [ -v ] [ -F ] [ -L volume-label ] [ -M last-mounted-directory ] [ -S ] [ -t fs-type ] [ -T usage-type ] [ -U UUID ] [ -V ] [ -e errors-behavior ] [ -z undo_file ] device [ fs-size ]
```

```
mke2fs -O journal_dev [ -b block-size ] [ -L volume-label ] [ -n ] [ -q ] [ -v ] external-journal [ fs-size ]
```

DESCRIPTION

mke2fs is used to create an ext2, ext3, or ext4 file system, usually in a disk partition (or file) named by *device*.

The file system size is specified by *fs-size*. If *fs-size* does not have a suffix, it is interpreted as power-of-two kilobytes, unless the **-b** *blocksize* option is specified, in which case *fs-size* is interpreted as the number of *blocksize* blocks. If the *fs-size* is suffixed by 'k', 'm', 'g', 't' (either upper-case or lower-case), then it is interpreted in power-of-two kilobytes, megabytes, gigabytes, terabytes, etc. If *fs-size* is omitted, **mke2fs** will create the file system based on the device size.

If **mke2fs** is run as **mkfs.XXX** (i.e., **mkfs.ext2**, **mkfs.ext3**, or **mkfs.ext4**) the option **-t XXX** is implied; so **mkfs.ext3** will create a file system for use with ext3, **mkfs.ext4** will create a file system for use with ext4, and so on.

The defaults of the parameters for the newly created file system, if not overridden by the options listed below, are controlled by the */etc/mke2fs.conf* configuration file. See the **mke2fs.conf(5)** manual page for more details.

OPTIONS**-b** *block-size*

Specify the size of blocks in bytes. Valid block-size values are powers of two from 1024 up to 65536 (however note that the kernel is able to mount only file systems with block-size smaller or equal to the system page size - 4k on x86 systems, up to 64k on ppc64 or aarch64 depending on kernel configuration). If omitted, block-size is heuristically determined by the file system size and the expected usage of the file system (see the **-T** option). In most common cases, the default block size is 4k. If *block-size* is preceded by a negative sign ('-'), then **mke2fs** will use heuristics to determine the appropriate block size, with the constraint that the block size will be at least *block-size* bytes. This is useful for certain hardware devices which require that the *blocksize* be a multiple of 2k.

-c Check the device for bad blocks before creating the file system. If this option is specified twice, then a slower read-write test is used instead of a fast read-only test.

-C *cluster-size*

Specify the size of cluster in bytes for file systems using the bigalloc feature. Valid cluster-size values are from 2048 to 256M bytes per cluster. This can only be specified if the bigalloc feature is enabled. (See the **ext4 (5)** man page for more details about bigalloc.) The default cluster size if bigalloc is enabled is 16 times the block size.

-d *root-directory*

Copy the contents of the given directory into the root directory of the file system.

-D Use direct I/O when writing to the disk. This avoids mke2fs dirtying a lot of buffer cache memory, which may impact other applications running on a busy server. This option will cause mke2fs to run much more slowly, however, so there is a tradeoff to using direct I/O.

-e error-behavior

Change the behavior of the kernel code when errors are detected. In all cases, a file system error will cause **e2fsck(8)** to check the file system on the next boot. *error-behavior* can be one of the following:

continue	Continue normal execution.
remount-ro	Remount file system read-only.
panic	Cause a kernel panic.

-E extended-options

Set extended options for the file system. Extended options are comma separated, and may take an argument using the equals ('=') sign. The **-E** option used to be **-R** in earlier versions of **mke2fs**. The **-R** option is still accepted for backwards compatibility, but is deprecated. The following extended options are supported:

encoding=encoding-name

Enable the *casemap* feature in the super block and set *encoding-name* as the encoding to be used. If *encoding-name* is not specified, the encoding defined in **mke2fs.conf(5)** is used.

encoding_flags=encoding-flags

Define parameters for file name character encoding operations. If a flag is not changed using this parameter, its default value is used. *encoding-flags* should be a comma-separated lists of flags to be enabled. To disable a flag, add it to the list with the prefix "no".

The only flag that can be set right now is *strict* which means that invalid strings should be rejected by the file system. In the default configuration, the *strict* flag is disabled.

mmp_update_interval=interval

Adjust the initial MMP update interval to *interval* seconds. Specifying an *interval* of 0 means to use the default interval. The specified interval must be less than 300 seconds. Requires that the **mmp** feature be enabled.

stride=stride-size

Configure the file system for a RAID array with *stride-size* file system blocks. This is the number of blocks read or written to disk before moving to the next disk, which is sometimes referred to as the *chunk size*. This mostly affects placement of file system metadata like bitmaps at **mke2fs** time to avoid placing them on a single disk, which can hurt performance. It may also be used by the block allocator.

stripe_width=stripe-width

Configure the file system for a RAID array with *stripe-width* file system blocks per stripe. This is typically *stride-size* * N, where N is the number of data-bearing disks in the RAID (e.g. for RAID 5 there is one parity disk, so N will be the number of disks in the array minus 1). This allows the block allocator to prevent read-modify-write of the parity in a RAID stripe if possible when the data is written.

offset=offset

Create the file system at an offset from the beginning of the device or file. This can be useful when creating disk images for virtual machines.

resize=max-online-resize

Reserve enough space so that the block group descriptor table can grow to support a file system that has *max-online-resize* blocks.

lazy_itable_init[= <0 to disable, 1 to enable>]

If enabled and the uninit_bg feature is enabled, the inode table will not be fully initialized by **mke2fs**. This speeds up file system initialization noticeably, but it requires the kernel to finish initializing the file system in the background when the file system is first mounted. If the option value is omitted, it defaults to 1 to enable lazy inode table zeroing.

lazy_journal_init[= <0 to disable, 1 to enable>]

If enabled, the journal inode will not be fully zeroed out by **mke2fs**. This speeds up file system initialization noticeably, but carries some small risk if the system crashes before the journal has been overwritten entirely one time. If the option value is omitted, it defaults to 1 to enable lazy journal inode zeroing.

no_copy_xattrs

Normally **mke2fs** will copy the extended attributes of the files in the directory hierarchy specified via the (optional) **-d** option. This will disable the copy and leaves the files in the newly created file system without any extended attributes.

num_backup_sb=<0/1/2>

If the **sparse_super2** file system feature is enabled this option controls whether there will be 0, 1, or 2 backup superblocks created in the file system.

packed_meta_blocks[= <0 to disable, 1 to enable>]

Place the allocation bitmaps and the inode table at the beginning of the disk. This option requires that the flex_bg file system feature to be enabled in order for it to have effect, and will also create the journal at the beginning of the file system. This option is useful for flash devices that use SLC flash at the beginning of the disk. It also maximizes the range of contiguous data blocks, which can be useful for certain specialized use cases, such as supported Shingled Drives.

root_owner[=uid:gid]

Specify the numeric user and group ID of the root directory. If no UID:GID is specified, use the user and group ID of the user running **mke2fs**. In **mke2fs** 1.42 and earlier the UID and GID of the root directory were set by default to the UID and GID of the user running the mke2fs command. The **root_owner=** option allows explicitly specifying these values, and avoid side-effects for users that do not expect the contents of the file system to change based on the user running **mke2fs**.

test_fs Set a flag in the file system superblock indicating that it may be mounted using experimental kernel code, such as the ext4dev file system.

discard

Attempt to discard blocks at mkfs time (discarding blocks initially is useful on solid state devices and sparse / thin-provisioned storage). When the device advertises that discard also zeroes data (any subsequent read after the discard and before write returns zero), then mark all not-yet-zeroed inode tables as zeroed. This significantly speeds up file system initialization. This is set as default.

nodiscard

Do not attempt to discard blocks at mkfs time.

quotatype

Specify the which quota types (usrquota, grpquota, prjquota) which should be enabled in the created file system. The argument of this extended option should be a colon separated list. This option has effect only if the **quota**

feature is set. The default quota types to be initialized if this option is not specified is both user and group quotas. If the project feature is enabled that project quotas will be initialized as well.

- F** Force **mke2fs** to create a file system, even if the specified device is not a partition on a block special device, or if other parameters do not make sense. In order to force **mke2fs** to create a file system even if the file system appears to be in use or is mounted (a truly dangerous thing to do), this option must be specified twice.

-g *blocks-per-group*

Specify the number of blocks in a block group. There is generally no reason for the user to ever set this parameter, as the default is optimal for the file system. (For administrators who are creating file systems on RAID arrays, it is preferable to use the *stride* RAID parameter as part of the **-E** option rather than manipulating the number of blocks per group.) This option is generally used by developers who are developing test cases.

If the bigalloc feature is enabled, the **-g** option will specify the number of clusters in a block group.

-G *number-of-groups*

Specify the number of block groups that will be packed together to create a larger virtual block group (or "flex_bg group") in an ext4 file system. This improves meta-data locality and performance on meta-data heavy workloads. The number of groups must be a power of 2 and may only be specified if the **flex_bg** file system feature is enabled.

-i *bytes-per-inode*

Specify the bytes/inode ratio. **mk e2fs** creates an inode for every *bytes-per-inode* bytes of space on the disk. The larger the *bytes-per-inode* ratio, the fewer inodes will be created. This value generally shouldn't be smaller than the blocksize of the file system, since in that case more inodes would be made than can ever be used. Be warned that it is not possible to change this ratio on a file system after it is created, so be careful deciding the correct value for this parameter. Note that resizing a file system changes the number of inodes to maintain this ratio.

-I *inode-size*

Specify the size of each inode in bytes. The *inode-size* value must be a power of 2 larger or equal to 128. The larger the *inode-size* the more space the inode table will consume, and this reduces the usable space in the file system and can also negatively impact performance. It is not possible to change this value after the file system is created.

File systems with an inode size of 128 bytes do not support timestamps beyond January 19, 2038. Inodes which are 256 bytes or larger will support extended timestamps, project id's, and the ability to store some extended attributes in the inode table for improved performance.

The default inode size is controlled by the **mke2fs.conf(5)** file. In the **mke2fs.conf** file shipped with e2fsprogs, the default inode size is 256 bytes for most file systems, except for small file systems where the inode size will be 128 bytes.

- j** Create the file system with an ext3 journal. If the **-J** option is not specified, the default journal parameters will be used to create an appropriately sized journal (given the size of the file system) stored within the file system. Note that you must be using a kernel which has ext3 support in order to actually make use of the journal.

-J *journal-options*

Create the ext3 journal using options specified on the command-line. Journal options are comma separated, and may take an argument using the equals ('=') sign. The following journal options are supported:

size=*journal-size*

Create an internal journal (i.e., stored inside the file system) of size *journal-size* megabytes. The size of the journal must be at least 1024 file system blocks (i.e., 1MB if using 1k blocks, 4MB if using 4k blocks, etc.) and may

be no more than 10,240,000 file system blocks or half the total file system size (whichever is smaller)

fast_commit_size=*fast-commit-size*

Create an additional fast commit journal area of size *fast-commit-size* kilobytes. This option is only valid if **fast_commit** feature is enabled on the file system. If this option is not specified and if **fast_commit** feature is turned on, fast commit area size defaults to *journal-size* / 64 me gabytes. The total size of the journal with **fast_commit** feature set is *journal-size* + (*fast-commit-size* * 1024) megabytes. The total journal size may be no more than 10,240,000 file system blocks or half the total file system size (whichever is smaller).

location=*journal-location*

Specify the location of the journal. The argument *journal-location* can either be specified as a block number, or if the number has a units suffix (e.g., 'M', 'G', etc.) interpret it as the offset from the beginning of the file system.

device=*external-journal*

Attach the file system to the journal block device located on *external-journal*. The external journal must already have been created using the command

mke2fs -O journal_dev *external-journal*

Note that *external-journal* must have been created with the same block size as the new file system. In addition, while there is support for attaching multiple file systems to a single external journal, the Linux kernel and **e2fsck(8)** do not currently support shared external journals yet.

Instead of specifying a device name directly, *external-journal* can also be specified by either **LABEL=***label* or **UUID=***UUID* to locate the external journal by either the volume label or UUID stored in the ext2 superblock at the start of the journal. Use **dumpe2fs(8)** to display a journal device's volume label and UUID. See also the **-L** option of **tune2fs(8)**.

Only one of the **size** or **device** options can be given for a file system.

-l *filename*

Read the bad blocks list from *filename*. Note that the block numbers in the bad block list must be generated using the same block size as used by **mke2fs**. As a result, the **-c** option to **mk e2fs** is a much simpler and less error-prone method of checking a disk for bad blocks before formatting it, as **mke2fs** will automatically pass the correct parameters to the **badblocks** program.

-L *new-volume-label*

Set the volume label for the file system to *new-volume-label*. The maximum length of the volume label is 16 bytes.

-m *reserved-blocks-percentage*

Specify the percentage of the file system blocks reserved for the super-user. This avoids fragmentation, and allows root-owned daemons, such as **syslogd(8)**, to continue to function correctly after non-privileged processes are prevented from writing to the file system. The default percentage is 5%.

-M *last-mounted-directory*

Set the last mounted directory for the file system. This might be useful for the sake of utilities that key off of the last mounted directory to determine where the file system should be mounted.

- n** Causes **mke2fs** to not actually create a file system, but display what it would do if it were to create a file system. This can be used to determine the location of the backup superblocks for a particular file system, so long as the **mke2fs** parameters that were passed when the file system was originally created are used again. (With the **-n** option added, of course!)

-N number-of-inodes

Overrides the default calculation of the number of inodes that should be reserved for the file system (which is based on the number of blocks and the *bytes-per-inode* ratio). This allows the user to specify the number of desired inodes directly.

-o creator-os

Overrides the default value of the "creator operating system" field of the file system. The creator field is set by default to the name of the OS the **mke2fs** executable was compiled for.

-O []feature[,...]

Create a file system with the given features (file system options), overriding the default file system options. The features that are enabled by default are specified by the *base_features* relation, either in the *[defaults]* section in the **/etc/mke2fs.conf** configuration file, or in the *[fs_types]* subsections for the usage types as specified by the **-T** option, further modified by the *features* relation found in the *[fs_types]* subsections for the file system and usage types. See the **mke2fs.conf(5)** manual page for more details. The file system type-specific configuration setting found in the *[fs_types]* section will override the global default found in *[defaults]*.

The file system feature set will be further edited using either the feature set specified by this option, or if this option is not given, by the *default_features* relation for the file system type being created, or in the *[defaults]* section of the configuration file.

The file system feature set is comprised of a list of features, separated by commas, that are to be enabled. To disable a feature, simply prefix the feature name with a caret (^) character. Features with dependencies will not be removed successfully. The pseudo-file system feature "none" will clear all file system features.

For more information about the features which can be set, please see the manual page **ext4(5)**.

-q Quiet execution. Useful if **mk e2fs** is run in a script.**-r revision**

Set the file system revision for the new file system. Note that 1.2 kernels only support revision 0 file systems. The default is to create revision 1 file systems.

-S

Write superblock and group descriptors only. This is an extreme measure to be taken only in the very unlikely case that all of the superblock and backup superblocks are corrupted, and a last-ditch recovery method is desired by experienced users. It causes **mke2fs** to reinitialize the superblock and group descriptors, while not touching the inode table and the block and inode bitmaps. The **e2fsck** program should be run immediately after this option is used, and there is no guarantee that any data will be salvageable. Due to the wide variety of possible options to **mke2fs** that affect the on-disk layout, it is critical to specify exactly the same format options, such as blocksize, fs-type, feature flags, and other tunables when using this option, or the file system will be further corrupted. In some cases, such as file systems that have been resized, or have had features enabled after format time, it is impossible to overwrite all of the superblocks correctly, and at least some file system corruption will occur. It is best to run this on a full copy of the file system so other options can be tried if this doesn't work.

-t fs-type

Specify the file system type (i.e., ext2, ext3, ext4, etc.) that is to be created. If this option is not specified, **mke2fs** will pick a default either via how the command was run (for example, using a name of the form **mkfs.ext2**, **mkfs.ext3**, etc.) or via a default as defined by the **/etc/mke2fs.conf** file. This option controls which file system options are used by default, based on the **fstypes** configuration stanza in **/etc/mke2fs.conf**.

If the **-O** option is used to explicitly add or remove file system options that should be set in the newly created file system, the resulting file system may not be supported by the requested *fs-type*. (e.g., "**mke2fs -t ext3 -O extent /dev/sdXX**" will create a file system that is not supported by the

ext3 implementation as found in the Linux kernel; and "**mke2fs -t ext3 -O ^has_journal /dev/hdXX**" will create a file system that does not have a journal and hence will not be supported by the ext3 file system code in the Linux kernel.)

-T usage-type[,...]

Specify how the file system is going to be used, so that **mke2fs** can choose optimal file system parameters for that use. The usage types that are supported are defined in the configuration file **/etc/mke2fs.conf**. The user may specify one or more usage types using a comma separated list.

If this option is not specified, **mke2fs** will pick a single default usage type based on the size of the file system to be created. If the file system size is less than 3 megabytes, **mke2fs** will use the file system type *floppy*. If the file system size is greater than or equal to 3 but less than 512 megabytes, **mke2fs(8)** will use the file system type *small*. If the file system size is greater than or equal to 4 terabytes but less than 16 terabytes, **mke2fs(8)** will use the file system type *big*. If the file system size is greater than or equal to 16 terabytes, **mke2fs(8)** will use the file system type *huge*. Otherwise, **mke2fs(8)** will use the default file system type *default*.

-U UUID

Set the universally unique identifier (UUID) of the file system to *UUID*. The format of the UUID is a series of hex digits separated by hyphens, like this: "c1b9d5a2-f162-11cf-9ece-0020afc76f16". The *UUID* parameter may also be one of the following:

<i>clear</i>	clear the file system UUID
<i>random</i>	generate a new randomly-generated UUID
<i>time</i>	generate a new time-based UUID

-v Verbose execution.

-V Print the version number of **mke2fs** and exit.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the *undo_file* argument, the undo file will be written to a file named **mke2fs-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable or the *undo_dir* directive in the configuration file.

WARNING: The undo file cannot be used to recover from a power or system crash.

ENVIRONMENT

MKE2FS_SYNC

If set to non-zero integer value, its value is used to determine how often **sync(2)** is called during inode table initialization.

MKE2FS_CONFIG

Determines the location of the configuration file (see **mke2fs.conf(5)**).

MKE2FS_FIRST_META_BG

If set to non-zero integer value, its value is used to determine first meta block group. This is mostly for debugging purposes.

MKE2FS_DEVICE_SECTSIZE

If set to non-zero integer value, its value is used to determine logical sector size of the *device*.

MKE2FS_DEVICE_PHYS_SECTSIZE

If set to non-zero integer value, its value is used to determine physical sector size of the *device*.

MKE2FS_SKIP_CHECK_MSG

If set, do not show the message of file system automatic check caused by mount count or check interval.

AUTHOR

This version of **mke2fs** has been written by Theodore Ts'o <tytso@mit.edu>.

AVAILABILITY

mke2fs is part of the e2fsprogs package and is available from <http://e2fsprogs.sourceforge.net>.

NAME

mke2fs – create an ext2/ext3/ext4 file system

SYNOPSIS

```
mke2fs [ -c | -I filename ] [ -b block-size ] [ -C cluster-size ] [ -d root-directory ] [ -D ] [ -g blocks-per-group ] [ -G number-of-groups ] [ -i bytes-per-inode ] [ -I inode-size ] [ -j ] [ -J journal-options ] [ -N number-of-inodes ] [ -n ] [ -m reserved-blocks-percentage ] [ -o creator-os ] [ -O [^]feature[,...] ] [ -q ] [ -r fs-revision-level ] [ -E extended-options ] [ -v ] [ -F ] [ -L volume-label ] [ -M last-mounted-directory ] [ -S ] [ -t fs-type ] [ -T usage-type ] [ -U UUID ] [ -V ] [ -e errors-behavior ] [ -z undo_file ] device [ fs-size ]
```

```
mke2fs -O journal_dev [ -b block-size ] [ -L volume-label ] [ -n ] [ -q ] [ -v ] external-journal [ fs-size ]
```

DESCRIPTION

mke2fs is used to create an ext2, ext3, or ext4 file system, usually in a disk partition (or file) named by *device*.

The file system size is specified by *fs-size*. If *fs-size* does not have a suffix, it is interpreted as power-of-two kilobytes, unless the **-b** *blocksize* option is specified, in which case *fs-size* is interpreted as the number of *blocksize* blocks. If the *fs-size* is suffixed by 'k', 'm', 'g', 't' (either upper-case or lower-case), then it is interpreted in power-of-two kilobytes, megabytes, gigabytes, terabytes, etc. If *fs-size* is omitted, **mke2fs** will create the file system based on the device size.

If **mke2fs** is run as **mkfs.XXX** (i.e., **mkfs.ext2**, **mkfs.ext3**, or **mkfs.ext4**) the option **-t XXX** is implied; so **mkfs.ext3** will create a file system for use with ext3, **mkfs.ext4** will create a file system for use with ext4, and so on.

The defaults of the parameters for the newly created file system, if not overridden by the options listed below, are controlled by the */etc/mke2fs.conf* configuration file. See the **mke2fs.conf(5)** manual page for more details.

OPTIONS**-b** *block-size*

Specify the size of blocks in bytes. Valid block-size values are powers of two from 1024 up to 65536 (however note that the kernel is able to mount only file systems with block-size smaller or equal to the system page size - 4k on x86 systems, up to 64k on ppc64 or aarch64 depending on kernel configuration). If omitted, block-size is heuristically determined by the file system size and the expected usage of the file system (see the **-T** option). In most common cases, the default block size is 4k. If *block-size* is preceded by a negative sign ('-'), then **mke2fs** will use heuristics to determine the appropriate block size, with the constraint that the block size will be at least *block-size* bytes. This is useful for certain hardware devices which require that the *blocksize* be a multiple of 2k.

-c Check the device for bad blocks before creating the file system. If this option is specified twice, then a slower read-write test is used instead of a fast read-only test.

-C *cluster-size*

Specify the size of cluster in bytes for file systems using the bigalloc feature. Valid cluster-size values are from 2048 to 256M bytes per cluster. This can only be specified if the bigalloc feature is enabled. (See the **ext4 (5)** man page for more details about bigalloc.) The default cluster size if bigalloc is enabled is 16 times the block size.

-d *root-directory*

Copy the contents of the given directory into the root directory of the file system.

-D Use direct I/O when writing to the disk. This avoids mke2fs dirtying a lot of buffer cache memory, which may impact other applications running on a busy server. This option will cause mke2fs to run much more slowly, however, so there is a tradeoff to using direct I/O.

-e error-behavior

Change the behavior of the kernel code when errors are detected. In all cases, a file system error will cause **e2fsck(8)** to check the file system on the next boot. *error-behavior* can be one of the following:

continue	Continue normal execution.
remount-ro	Remount file system read-only.
panic	Cause a kernel panic.

-E extended-options

Set extended options for the file system. Extended options are comma separated, and may take an argument using the equals ('=') sign. The **-E** option used to be **-R** in earlier versions of **mke2fs**. The **-R** option is still accepted for backwards compatibility, but is deprecated. The following extended options are supported:

encoding=encoding-name

Enable the *casemap* feature in the super block and set *encoding-name* as the encoding to be used. If *encoding-name* is not specified, the encoding defined in **mke2fs.conf(5)** is used.

encoding_flags=encoding-flags

Define parameters for file name character encoding operations. If a flag is not changed using this parameter, its default value is used. *encoding-flags* should be a comma-separated lists of flags to be enabled. To disable a flag, add it to the list with the prefix "no".

The only flag that can be set right now is *strict* which means that invalid strings should be rejected by the file system. In the default configuration, the *strict* flag is disabled.

mmp_update_interval=interval

Adjust the initial MMP update interval to *interval* seconds. Specifying an *interval* of 0 means to use the default interval. The specified interval must be less than 300 seconds. Requires that the **mmp** feature be enabled.

stride=stride-size

Configure the file system for a RAID array with *stride-size* file system blocks. This is the number of blocks read or written to disk before moving to the next disk, which is sometimes referred to as the *chunk size*. This mostly affects placement of file system metadata like bitmaps at **mke2fs** time to avoid placing them on a single disk, which can hurt performance. It may also be used by the block allocator.

stripe_width=stripe-width

Configure the file system for a RAID array with *stripe-width* file system blocks per stripe. This is typically *stride-size* * N, where N is the number of data-bearing disks in the RAID (e.g. for RAID 5 there is one parity disk, so N will be the number of disks in the array minus 1). This allows the block allocator to prevent read-modify-write of the parity in a RAID stripe if possible when the data is written.

offset=offset

Create the file system at an offset from the beginning of the device or file. This can be useful when creating disk images for virtual machines.

resize=max-online-resize

Reserve enough space so that the block group descriptor table can grow to support a file system that has *max-online-resize* blocks.

lazy_itable_init[= <0 to disable, 1 to enable>]

If enabled and the uninit_bg feature is enabled, the inode table will not be fully initialized by **mke2fs**. This speeds up file system initialization noticeably, but it requires the kernel to finish initializing the file system in the background when the file system is first mounted. If the option value is omitted, it defaults to 1 to enable lazy inode table zeroing.

lazy_journal_init[= <0 to disable, 1 to enable>]

If enabled, the journal inode will not be fully zeroed out by **mke2fs**. This speeds up file system initialization noticeably, but carries some small risk if the system crashes before the journal has been overwritten entirely one time. If the option value is omitted, it defaults to 1 to enable lazy journal inode zeroing.

no_copy_xattrs

Normally **mke2fs** will copy the extended attributes of the files in the directory hierarchy specified via the (optional) **-d** option. This will disable the copy and leaves the files in the newly created file system without any extended attributes.

num_backup_sb=<0/1/2>

If the **sparse_super2** file system feature is enabled this option controls whether there will be 0, 1, or 2 backup superblocks created in the file system.

packed_meta_blocks[= <0 to disable, 1 to enable>]

Place the allocation bitmaps and the inode table at the beginning of the disk. This option requires that the flex_bg file system feature to be enabled in order for it to have effect, and will also create the journal at the beginning of the file system. This option is useful for flash devices that use SLC flash at the beginning of the disk. It also maximizes the range of contiguous data blocks, which can be useful for certain specialized use cases, such as supported Shingled Drives.

root_owner[=uid:gid]

Specify the numeric user and group ID of the root directory. If no UID:GID is specified, use the user and group ID of the user running **mke2fs**. In **mke2fs** 1.42 and earlier the UID and GID of the root directory were set by default to the UID and GID of the user running the mke2fs command. The **root_owner=** option allows explicitly specifying these values, and avoid side-effects for users that do not expect the contents of the file system to change based on the user running **mke2fs**.

test_fs Set a flag in the file system superblock indicating that it may be mounted using experimental kernel code, such as the ext4dev file system.

discard

Attempt to discard blocks at mkfs time (discarding blocks initially is useful on solid state devices and sparse / thin-provisioned storage). When the device advertises that discard also zeroes data (any subsequent read after the discard and before write returns zero), then mark all not-yet-zeroed inode tables as zeroed. This significantly speeds up file system initialization. This is set as default.

nodiscard

Do not attempt to discard blocks at mkfs time.

quotatype

Specify the which quota types (usrquota, grpquota, prjquota) which should be enabled in the created file system. The argument of this extended option should be a colon separated list. This option has effect only if the **quota**

feature is set. The default quota types to be initialized if this option is not specified is both user and group quotas. If the project feature is enabled that project quotas will be initialized as well.

- F** Force **mke2fs** to create a file system, even if the specified device is not a partition on a block special device, or if other parameters do not make sense. In order to force **mke2fs** to create a file system even if the file system appears to be in use or is mounted (a truly dangerous thing to do), this option must be specified twice.

-g *blocks-per-group*

Specify the number of blocks in a block group. There is generally no reason for the user to ever set this parameter, as the default is optimal for the file system. (For administrators who are creating file systems on RAID arrays, it is preferable to use the *stride* RAID parameter as part of the **-E** option rather than manipulating the number of blocks per group.) This option is generally used by developers who are developing test cases.

If the bigalloc feature is enabled, the **-g** option will specify the number of clusters in a block group.

-G *number-of-groups*

Specify the number of block groups that will be packed together to create a larger virtual block group (or "flex_bg group") in an ext4 file system. This improves meta-data locality and performance on meta-data heavy workloads. The number of groups must be a power of 2 and may only be specified if the **flex_bg** file system feature is enabled.

-i *bytes-per-inode*

Specify the bytes/inode ratio. **mk e2fs** creates an inode for every *bytes-per-inode* bytes of space on the disk. The larger the *bytes-per-inode* ratio, the fewer inodes will be created. This value generally shouldn't be smaller than the blocksize of the file system, since in that case more inodes would be made than can ever be used. Be warned that it is not possible to change this ratio on a file system after it is created, so be careful deciding the correct value for this parameter. Note that resizing a file system changes the number of inodes to maintain this ratio.

-I *inode-size*

Specify the size of each inode in bytes. The *inode-size* value must be a power of 2 larger or equal to 128. The larger the *inode-size* the more space the inode table will consume, and this reduces the usable space in the file system and can also negatively impact performance. It is not possible to change this value after the file system is created.

File systems with an inode size of 128 bytes do not support timestamps beyond January 19, 2038. Inodes which are 256 bytes or larger will support extended timestamps, project id's, and the ability to store some extended attributes in the inode table for improved performance.

The default inode size is controlled by the **mke2fs.conf(5)** file. In the **mke2fs.conf** file shipped with e2fsprogs, the default inode size is 256 bytes for most file systems, except for small file systems where the inode size will be 128 bytes.

- j** Create the file system with an ext3 journal. If the **-J** option is not specified, the default journal parameters will be used to create an appropriately sized journal (given the size of the file system) stored within the file system. Note that you must be using a kernel which has ext3 support in order to actually make use of the journal.

-J *journal-options*

Create the ext3 journal using options specified on the command-line. Journal options are comma separated, and may take an argument using the equals ('=') sign. The following journal options are supported:

size=*journal-size*

Create an internal journal (i.e., stored inside the file system) of size *journal-size* megabytes. The size of the journal must be at least 1024 file system blocks (i.e., 1MB if using 1k blocks, 4MB if using 4k blocks, etc.) and may

be no more than 10,240,000 file system blocks or half the total file system size (whichever is smaller)

fast_commit_size=*fast-commit-size*

Create an additional fast commit journal area of size *fast-commit-size* kilobytes. This option is only valid if **fast_commit** feature is enabled on the file system. If this option is not specified and if **fast_commit** feature is turned on, fast commit area size defaults to *journal-size* / 64 me gabytes. The total size of the journal with **fast_commit** feature set is *journal-size* + (*fast-commit-size* * 1024) megabytes. The total journal size may be no more than 10,240,000 file system blocks or half the total file system size (whichever is smaller).

location=*journal-location*

Specify the location of the journal. The argument *journal-location* can either be specified as a block number, or if the number has a units suffix (e.g., 'M', 'G', etc.) interpret it as the offset from the beginning of the file system.

device=*external-journal*

Attach the file system to the journal block device located on *external-journal*. The external journal must already have been created using the command

mke2fs -O journal_dev *external-journal*

Note that *external-journal* must have been created with the same block size as the new file system. In addition, while there is support for attaching multiple file systems to a single external journal, the Linux kernel and **e2fsck(8)** do not currently support shared external journals yet.

Instead of specifying a device name directly, *external-journal* can also be specified by either **LABEL=***label* or **UUID=***UUID* to locate the external journal by either the volume label or UUID stored in the ext2 superblock at the start of the journal. Use **dumpe2fs(8)** to display a journal device's volume label and UUID. See also the **-L** option of **tune2fs(8)**.

Only one of the **size** or **device** options can be given for a file system.

-l *filename*

Read the bad blocks list from *filename*. Note that the block numbers in the bad block list must be generated using the same block size as used by **mke2fs**. As a result, the **-c** option to **mk e2fs** is a much simpler and less error-prone method of checking a disk for bad blocks before formatting it, as **mke2fs** will automatically pass the correct parameters to the **badblocks** program.

-L *new-volume-label*

Set the volume label for the file system to *new-volume-label*. The maximum length of the volume label is 16 bytes.

-m *reserved-blocks-percentage*

Specify the percentage of the file system blocks reserved for the super-user. This avoids fragmentation, and allows root-owned daemons, such as **syslogd(8)**, to continue to function correctly after non-privileged processes are prevented from writing to the file system. The default percentage is 5%.

-M *last-mounted-directory*

Set the last mounted directory for the file system. This might be useful for the sake of utilities that key off of the last mounted directory to determine where the file system should be mounted.

- n** Causes **mke2fs** to not actually create a file system, but display what it would do if it were to create a file system. This can be used to determine the location of the backup superblocks for a particular file system, so long as the **mke2fs** parameters that were passed when the file system was originally created are used again. (With the **-n** option added, of course!)

-N number-of-inodes

Overrides the default calculation of the number of inodes that should be reserved for the file system (which is based on the number of blocks and the *bytes-per-inode* ratio). This allows the user to specify the number of desired inodes directly.

-o creator-os

Overrides the default value of the "creator operating system" field of the file system. The creator field is set by default to the name of the OS the **mke2fs** executable was compiled for.

-O []feature[,...]

Create a file system with the given features (file system options), overriding the default file system options. The features that are enabled by default are specified by the *base_features* relation, either in the *[defaults]* section in the **/etc/mke2fs.conf** configuration file, or in the *[fs_types]* subsections for the usage types as specified by the **-T** option, further modified by the *features* relation found in the *[fs_types]* subsections for the file system and usage types. See the **mke2fs.conf(5)** manual page for more details. The file system type-specific configuration setting found in the *[fs_types]* section will override the global default found in *[defaults]*.

The file system feature set will be further edited using either the feature set specified by this option, or if this option is not given, by the *default_features* relation for the file system type being created, or in the *[defaults]* section of the configuration file.

The file system feature set is comprised of a list of features, separated by commas, that are to be enabled. To disable a feature, simply prefix the feature name with a caret (^) character. Features with dependencies will not be removed successfully. The pseudo-file system feature "none" will clear all file system features.

For more information about the features which can be set, please see the manual page **ext4(5)**.

-q Quiet execution. Useful if **mke2fs** is run in a script.**-r revision**

Set the file system revision for the new file system. Note that 1.2 kernels only support revision 0 file systems. The default is to create revision 1 file systems.

-S

Write superblock and group descriptors only. This is an extreme measure to be taken only in the very unlikely case that all of the superblock and backup superblocks are corrupted, and a last-ditch recovery method is desired by experienced users. It causes **mke2fs** to reinitialize the superblock and group descriptors, while not touching the inode table and the block and inode bitmaps. The **e2fsck** program should be run immediately after this option is used, and there is no guarantee that any data will be salvageable. Due to the wide variety of possible options to **mke2fs** that affect the on-disk layout, it is critical to specify exactly the same format options, such as blocksize, fs-type, feature flags, and other tunables when using this option, or the file system will be further corrupted. In some cases, such as file systems that have been resized, or have had features enabled after format time, it is impossible to overwrite all of the superblocks correctly, and at least some file system corruption will occur. It is best to run this on a full copy of the file system so other options can be tried if this doesn't work.

-t fs-type

Specify the file system type (i.e., ext2, ext3, ext4, etc.) that is to be created. If this option is not specified, **mke2fs** will pick a default either via how the command was run (for example, using a name of the form **mkfs.ext2**, **mkfs.ext3**, etc.) or via a default as defined by the **/etc/mke2fs.conf** file. This option controls which file system options are used by default, based on the **fstypes** configuration stanza in **/etc/mke2fs.conf**.

If the **-O** option is used to explicitly add or remove file system options that should be set in the newly created file system, the resulting file system may not be supported by the requested *fs-type*. (e.g., "**mke2fs -t ext3 -O extent /dev/sdXX**" will create a file system that is not supported by the

ext3 implementation as found in the Linux kernel; and "**mke2fs -t ext3 -O ^has_journal /dev/hdXX**" will create a file system that does not have a journal and hence will not be supported by the ext3 file system code in the Linux kernel.)

-T usage-type[,...]

Specify how the file system is going to be used, so that **mke2fs** can choose optimal file system parameters for that use. The usage types that are supported are defined in the configuration file **/etc/mke2fs.conf**. The user may specify one or more usage types using a comma separated list.

If this option is not specified, **mke2fs** will pick a single default usage type based on the size of the file system to be created. If the file system size is less than 3 megabytes, **mke2fs** will use the file system type *floppy*. If the file system size is greater than or equal to 3 but less than 512 megabytes, **mke2fs(8)** will use the file system type *small*. If the file system size is greater than or equal to 4 terabytes but less than 16 terabytes, **mke2fs(8)** will use the file system type *big*. If the file system size is greater than or equal to 16 terabytes, **mke2fs(8)** will use the file system type *huge*. Otherwise, **mke2fs(8)** will use the default file system type *default*.

-U UUID

Set the universally unique identifier (UUID) of the file system to *UUID*. The format of the UUID is a series of hex digits separated by hyphens, like this: "c1b9d5a2-f162-11cf-9ece-0020afc76f16". The *UUID* parameter may also be one of the following:

<i>clear</i>	clear the file system UUID
<i>random</i>	generate a new randomly-generated UUID
<i>time</i>	generate a new time-based UUID

-v Verbose execution.

-V Print the version number of **mke2fs** and exit.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the *undo_file* argument, the undo file will be written to a file named **mke2fs-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable or the *undo_dir* directive in the configuration file.

WARNING: The undo file cannot be used to recover from a power or system crash.

ENVIRONMENT

MKE2FS_SYNC

If set to non-zero integer value, its value is used to determine how often **sync(2)** is called during inode table initialization.

MKE2FS_CONFIG

Determines the location of the configuration file (see **mke2fs.conf(5)**).

MKE2FS_FIRST_META_BG

If set to non-zero integer value, its value is used to determine first meta block group. This is mostly for debugging purposes.

MKE2FS_DEVICE_SECTSIZE

If set to non-zero integer value, its value is used to determine logical sector size of the *device*.

MKE2FS_DEVICE_PHYS_SECTSIZE

If set to non-zero integer value, its value is used to determine physical sector size of the *device*.

MKE2FS_SKIP_CHECK_MSG

If set, do not show the message of file system automatic check caused by mount count or check interval.

AUTHOR

This version of **mke2fs** has been written by Theodore Ts'o <tytso@mit.edu>.

AVAILABILITY

mke2fs is part of the e2fsprogs package and is available from <http://e2fsprogs.sourceforge.net>.

NAME

mke2fs – create an ext2/ext3/ext4 file system

SYNOPSIS

```
mke2fs [ -c | -I filename ] [ -b block-size ] [ -C cluster-size ] [ -d root-directory ] [ -D ] [ -g blocks-per-group ] [ -G number-of-groups ] [ -i bytes-per-inode ] [ -I inode-size ] [ -j ] [ -J journal-options ] [ -N number-of-inodes ] [ -n ] [ -m reserved-blocks-percentage ] [ -o creator-os ] [ -O [^]feature[,...] ] [ -q ] [ -r fs-revision-level ] [ -E extended-options ] [ -v ] [ -F ] [ -L volume-label ] [ -M last-mounted-directory ] [ -S ] [ -t fs-type ] [ -T usage-type ] [ -U UUID ] [ -V ] [ -e errors-behavior ] [ -z undo_file ] device [ fs-size ]
```

```
mke2fs -O journal_dev [ -b block-size ] [ -L volume-label ] [ -n ] [ -q ] [ -v ] external-journal [ fs-size ]
```

DESCRIPTION

mke2fs is used to create an ext2, ext3, or ext4 file system, usually in a disk partition (or file) named by *device*.

The file system size is specified by *fs-size*. If *fs-size* does not have a suffix, it is interpreted as power-of-two kilobytes, unless the **-b** *blocksize* option is specified, in which case *fs-size* is interpreted as the number of *blocksize* blocks. If the *fs-size* is suffixed by 'k', 'm', 'g', 't' (either upper-case or lower-case), then it is interpreted in power-of-two kilobytes, megabytes, gigabytes, terabytes, etc. If *fs-size* is omitted, **mke2fs** will create the file system based on the device size.

If **mke2fs** is run as **mkfs.XXX** (i.e., **mkfs.ext2**, **mkfs.ext3**, or **mkfs.ext4**) the option **-t XXX** is implied; so **mkfs.ext3** will create a file system for use with ext3, **mkfs.ext4** will create a file system for use with ext4, and so on.

The defaults of the parameters for the newly created file system, if not overridden by the options listed below, are controlled by the */etc/mke2fs.conf* configuration file. See the **mke2fs.conf(5)** manual page for more details.

OPTIONS**-b** *block-size*

Specify the size of blocks in bytes. Valid block-size values are powers of two from 1024 up to 65536 (however note that the kernel is able to mount only file systems with block-size smaller or equal to the system page size - 4k on x86 systems, up to 64k on ppc64 or aarch64 depending on kernel configuration). If omitted, block-size is heuristically determined by the file system size and the expected usage of the file system (see the **-T** option). In most common cases, the default block size is 4k. If *block-size* is preceded by a negative sign ('-'), then **mke2fs** will use heuristics to determine the appropriate block size, with the constraint that the block size will be at least *block-size* bytes. This is useful for certain hardware devices which require that the *blocksize* be a multiple of 2k.

-c Check the device for bad blocks before creating the file system. If this option is specified twice, then a slower read-write test is used instead of a fast read-only test.

-C *cluster-size*

Specify the size of cluster in bytes for file systems using the bigalloc feature. Valid cluster-size values are from 2048 to 256M bytes per cluster. This can only be specified if the bigalloc feature is enabled. (See the **ext4 (5)** man page for more details about bigalloc.) The default cluster size if bigalloc is enabled is 16 times the block size.

-d *root-directory*

Copy the contents of the given directory into the root directory of the file system.

-D Use direct I/O when writing to the disk. This avoids mke2fs dirtying a lot of buffer cache memory, which may impact other applications running on a busy server. This option will cause mke2fs to run much more slowly, however, so there is a tradeoff to using direct I/O.

-e error-behavior

Change the behavior of the kernel code when errors are detected. In all cases, a file system error will cause **e2fsck(8)** to check the file system on the next boot. *error-behavior* can be one of the following:

continue	Continue normal execution.
remount-ro	Remount file system read-only.
panic	Cause a kernel panic.

-E extended-options

Set extended options for the file system. Extended options are comma separated, and may take an argument using the equals ('=') sign. The **-E** option used to be **-R** in earlier versions of **mke2fs**. The **-R** option is still accepted for backwards compatibility, but is deprecated. The following extended options are supported:

encoding=encoding-name

Enable the *casemap* feature in the super block and set *encoding-name* as the encoding to be used. If *encoding-name* is not specified, the encoding defined in **mke2fs.conf(5)** is used.

encoding_flags=encoding-flags

Define parameters for file name character encoding operations. If a flag is not changed using this parameter, its default value is used. *encoding-flags* should be a comma-separated lists of flags to be enabled. To disable a flag, add it to the list with the prefix "no".

The only flag that can be set right now is *strict* which means that invalid strings should be rejected by the file system. In the default configuration, the *strict* flag is disabled.

mmp_update_interval=interval

Adjust the initial MMP update interval to *interval* seconds. Specifying an *interval* of 0 means to use the default interval. The specified interval must be less than 300 seconds. Requires that the **mmp** feature be enabled.

stride=stride-size

Configure the file system for a RAID array with *stride-size* file system blocks. This is the number of blocks read or written to disk before moving to the next disk, which is sometimes referred to as the *chunk size*. This mostly affects placement of file system metadata like bitmaps at **mke2fs** time to avoid placing them on a single disk, which can hurt performance. It may also be used by the block allocator.

stripe_width=stripe-width

Configure the file system for a RAID array with *stripe-width* file system blocks per stripe. This is typically *stride-size* * N, where N is the number of data-bearing disks in the RAID (e.g. for RAID 5 there is one parity disk, so N will be the number of disks in the array minus 1). This allows the block allocator to prevent read-modify-write of the parity in a RAID stripe if possible when the data is written.

offset=offset

Create the file system at an offset from the beginning of the device or file. This can be useful when creating disk images for virtual machines.

resize=max-online-resize

Reserve enough space so that the block group descriptor table can grow to support a file system that has *max-online-resize* blocks.

lazy_itable_init[= <0 to disable, 1 to enable>]

If enabled and the uninit_bg feature is enabled, the inode table will not be fully initialized by **mke2fs**. This speeds up file system initialization noticeably, but it requires the kernel to finish initializing the file system in the background when the file system is first mounted. If the option value is omitted, it defaults to 1 to enable lazy inode table zeroing.

lazy_journal_init[= <0 to disable, 1 to enable>]

If enabled, the journal inode will not be fully zeroed out by **mke2fs**. This speeds up file system initialization noticeably, but carries some small risk if the system crashes before the journal has been overwritten entirely one time. If the option value is omitted, it defaults to 1 to enable lazy journal inode zeroing.

no_copy_xattrs

Normally **mke2fs** will copy the extended attributes of the files in the directory hierarchy specified via the (optional) **-d** option. This will disable the copy and leaves the files in the newly created file system without any extended attributes.

num_backup_sb=<0/1/2>

If the **sparse_super2** file system feature is enabled this option controls whether there will be 0, 1, or 2 backup superblocks created in the file system.

packed_meta_blocks[= <0 to disable, 1 to enable>]

Place the allocation bitmaps and the inode table at the beginning of the disk. This option requires that the flex_bg file system feature to be enabled in order for it to have effect, and will also create the journal at the beginning of the file system. This option is useful for flash devices that use SLC flash at the beginning of the disk. It also maximizes the range of contiguous data blocks, which can be useful for certain specialized use cases, such as supported Shingled Drives.

root_owner[=uid:gid]

Specify the numeric user and group ID of the root directory. If no UID:GID is specified, use the user and group ID of the user running **mke2fs**. In **mke2fs** 1.42 and earlier the UID and GID of the root directory were set by default to the UID and GID of the user running the mke2fs command. The **root_owner=** option allows explicitly specifying these values, and avoid side-effects for users that do not expect the contents of the file system to change based on the user running **mke2fs**.

test_fs Set a flag in the file system superblock indicating that it may be mounted using experimental kernel code, such as the ext4dev file system.

discard

Attempt to discard blocks at mkfs time (discarding blocks initially is useful on solid state devices and sparse / thin-provisioned storage). When the device advertises that discard also zeroes data (any subsequent read after the discard and before write returns zero), then mark all not-yet-zeroed inode tables as zeroed. This significantly speeds up file system initialization. This is set as default.

nodiscard

Do not attempt to discard blocks at mkfs time.

quotatype

Specify the which quota types (usrquota, grpquota, prjquota) which should be enabled in the created file system. The argument of this extended option should be a colon separated list. This option has effect only if the **quota**

feature is set. The default quota types to be initialized if this option is not specified is both user and group quotas. If the project feature is enabled that project quotas will be initialized as well.

- F** Force **mke2fs** to create a file system, even if the specified device is not a partition on a block special device, or if other parameters do not make sense. In order to force **mke2fs** to create a file system even if the file system appears to be in use or is mounted (a truly dangerous thing to do), this option must be specified twice.

-g *blocks-per-group*

Specify the number of blocks in a block group. There is generally no reason for the user to ever set this parameter, as the default is optimal for the file system. (For administrators who are creating file systems on RAID arrays, it is preferable to use the *stride* RAID parameter as part of the **-E** option rather than manipulating the number of blocks per group.) This option is generally used by developers who are developing test cases.

If the bigalloc feature is enabled, the **-g** option will specify the number of clusters in a block group.

-G *number-of-groups*

Specify the number of block groups that will be packed together to create a larger virtual block group (or "flex_bg group") in an ext4 file system. This improves meta-data locality and performance on meta-data heavy workloads. The number of groups must be a power of 2 and may only be specified if the **flex_bg** file system feature is enabled.

-i *bytes-per-inode*

Specify the bytes/inode ratio. **mk e2fs** creates an inode for every *bytes-per-inode* bytes of space on the disk. The larger the *bytes-per-inode* ratio, the fewer inodes will be created. This value generally shouldn't be smaller than the blocksize of the file system, since in that case more inodes would be made than can ever be used. Be warned that it is not possible to change this ratio on a file system after it is created, so be careful deciding the correct value for this parameter. Note that resizing a file system changes the number of inodes to maintain this ratio.

-I *inode-size*

Specify the size of each inode in bytes. The *inode-size* value must be a power of 2 larger or equal to 128. The larger the *inode-size* the more space the inode table will consume, and this reduces the usable space in the file system and can also negatively impact performance. It is not possible to change this value after the file system is created.

File systems with an inode size of 128 bytes do not support timestamps beyond January 19, 2038. Inodes which are 256 bytes or larger will support extended timestamps, project id's, and the ability to store some extended attributes in the inode table for improved performance.

The default inode size is controlled by the **mke2fs.conf(5)** file. In the **mke2fs.conf** file shipped with e2fsprogs, the default inode size is 256 bytes for most file systems, except for small file systems where the inode size will be 128 bytes.

- j** Create the file system with an ext3 journal. If the **-J** option is not specified, the default journal parameters will be used to create an appropriately sized journal (given the size of the file system) stored within the file system. Note that you must be using a kernel which has ext3 support in order to actually make use of the journal.

-J *journal-options*

Create the ext3 journal using options specified on the command-line. Journal options are comma separated, and may take an argument using the equals ('=') sign. The following journal options are supported:

size=*journal-size*

Create an internal journal (i.e., stored inside the file system) of size *journal-size* megabytes. The size of the journal must be at least 1024 file system blocks (i.e., 1MB if using 1k blocks, 4MB if using 4k blocks, etc.) and may

be no more than 10,240,000 file system blocks or half the total file system size (whichever is smaller)

fast_commit_size=*fast-commit-size*

Create an additional fast commit journal area of size *fast-commit-size* kilobytes. This option is only valid if **fast_commit** feature is enabled on the file system. If this option is not specified and if **fast_commit** feature is turned on, fast commit area size defaults to *journal-size* / 64 me gabytes. The total size of the journal with **fast_commit** feature set is *journal-size* + (*fast-commit-size* * 1024) megabytes. The total journal size may be no more than 10,240,000 file system blocks or half the total file system size (whichever is smaller).

location=*journal-location*

Specify the location of the journal. The argument *journal-location* can either be specified as a block number, or if the number has a units suffix (e.g., 'M', 'G', etc.) interpret it as the offset from the beginning of the file system.

device=*external-journal*

Attach the file system to the journal block device located on *external-journal*. The external journal must already have been created using the command

mke2fs -O journal_dev *external-journal*

Note that *external-journal* must have been created with the same block size as the new file system. In addition, while there is support for attaching multiple file systems to a single external journal, the Linux kernel and **e2fsck(8)** do not currently support shared external journals yet.

Instead of specifying a device name directly, *external-journal* can also be specified by either **LABEL=***label* or **UUID=***UUID* to locate the external journal by either the volume label or UUID stored in the ext2 superblock at the start of the journal. Use **dumpe2fs(8)** to display a journal device's volume label and UUID. See also the **-L** option of **tune2fs(8)**.

Only one of the **size** or **device** options can be given for a file system.

-l *filename*

Read the bad blocks list from *filename*. Note that the block numbers in the bad block list must be generated using the same block size as used by **mke2fs**. As a result, the **-c** option to **mk e2fs** is a much simpler and less error-prone method of checking a disk for bad blocks before formatting it, as **mke2fs** will automatically pass the correct parameters to the **badblocks** program.

-L *new-volume-label*

Set the volume label for the file system to *new-volume-label*. The maximum length of the volume label is 16 bytes.

-m *reserved-blocks-percentage*

Specify the percentage of the file system blocks reserved for the super-user. This avoids fragmentation, and allows root-owned daemons, such as **syslogd(8)**, to continue to function correctly after non-privileged processes are prevented from writing to the file system. The default percentage is 5%.

-M *last-mounted-directory*

Set the last mounted directory for the file system. This might be useful for the sake of utilities that key off of the last mounted directory to determine where the file system should be mounted.

- n** Causes **mke2fs** to not actually create a file system, but display what it would do if it were to create a file system. This can be used to determine the location of the backup superblocks for a particular file system, so long as the **mke2fs** parameters that were passed when the file system was originally created are used again. (With the **-n** option added, of course!)

-N number-of-inodes

Overrides the default calculation of the number of inodes that should be reserved for the file system (which is based on the number of blocks and the *bytes-per-inode* ratio). This allows the user to specify the number of desired inodes directly.

-o creator-os

Overrides the default value of the "creator operating system" field of the file system. The creator field is set by default to the name of the OS the **mke2fs** executable was compiled for.

-O []feature[,...]

Create a file system with the given features (file system options), overriding the default file system options. The features that are enabled by default are specified by the *base_features* relation, either in the *[defaults]* section in the **/etc/mke2fs.conf** configuration file, or in the *[fs_types]* subsections for the usage types as specified by the **-T** option, further modified by the *features* relation found in the *[fs_types]* subsections for the file system and usage types. See the **mke2fs.conf(5)** manual page for more details. The file system type-specific configuration setting found in the *[fs_types]* section will override the global default found in *[defaults]*.

The file system feature set will be further edited using either the feature set specified by this option, or if this option is not given, by the *default_features* relation for the file system type being created, or in the *[defaults]* section of the configuration file.

The file system feature set is comprised of a list of features, separated by commas, that are to be enabled. To disable a feature, simply prefix the feature name with a caret (^) character. Features with dependencies will not be removed successfully. The pseudo-file system feature "none" will clear all file system features.

For more information about the features which can be set, please see the manual page **ext4(5)**.

-q Quiet execution. Useful if **mke2fs** is run in a script.**-r revision**

Set the file system revision for the new file system. Note that 1.2 kernels only support revision 0 file systems. The default is to create revision 1 file systems.

-S

Write superblock and group descriptors only. This is an extreme measure to be taken only in the very unlikely case that all of the superblock and backup superblocks are corrupted, and a last-ditch recovery method is desired by experienced users. It causes **mke2fs** to reinitialize the superblock and group descriptors, while not touching the inode table and the block and inode bitmaps. The **e2fsck** program should be run immediately after this option is used, and there is no guarantee that any data will be salvageable. Due to the wide variety of possible options to **mke2fs** that affect the on-disk layout, it is critical to specify exactly the same format options, such as blocksize, fs-type, feature flags, and other tunables when using this option, or the file system will be further corrupted. In some cases, such as file systems that have been resized, or have had features enabled after format time, it is impossible to overwrite all of the superblocks correctly, and at least some file system corruption will occur. It is best to run this on a full copy of the file system so other options can be tried if this doesn't work.

-t fs-type

Specify the file system type (i.e., ext2, ext3, ext4, etc.) that is to be created. If this option is not specified, **mke2fs** will pick a default either via how the command was run (for example, using a name of the form **mkfs.ext2**, **mkfs.ext3**, etc.) or via a default as defined by the **/etc/mke2fs.conf** file. This option controls which file system options are used by default, based on the **fstypes** configuration stanza in **/etc/mke2fs.conf**.

If the **-O** option is used to explicitly add or remove file system options that should be set in the newly created file system, the resulting file system may not be supported by the requested *fs-type*. (e.g., "**mke2fs -t ext3 -O extent /dev/sdXX**" will create a file system that is not supported by the

ext3 implementation as found in the Linux kernel; and "**mke2fs -t ext3 -O ^has_journal /dev/hdXX**" will create a file system that does not have a journal and hence will not be supported by the ext3 file system code in the Linux kernel.)

-T usage-type[,...]

Specify how the file system is going to be used, so that **mke2fs** can choose optimal file system parameters for that use. The usage types that are supported are defined in the configuration file **/etc/mke2fs.conf**. The user may specify one or more usage types using a comma separated list.

If this option is not specified, **mke2fs** will pick a single default usage type based on the size of the file system to be created. If the file system size is less than 3 megabytes, **mke2fs** will use the file system type *floppy*. If the file system size is greater than or equal to 3 but less than 512 megabytes, **mke2fs(8)** will use the file system type *small*. If the file system size is greater than or equal to 4 terabytes but less than 16 terabytes, **mke2fs(8)** will use the file system type *big*. If the file system size is greater than or equal to 16 terabytes, **mke2fs(8)** will use the file system type *huge*. Otherwise, **mke2fs(8)** will use the default file system type *default*.

-U UUID

Set the universally unique identifier (UUID) of the file system to *UUID*. The format of the UUID is a series of hex digits separated by hyphens, like this: "c1b9d5a2-f162-11cf-9ece-0020afc76f16". The *UUID* parameter may also be one of the following:

<i>clear</i>	clear the file system UUID
<i>random</i>	generate a new randomly-generated UUID
<i>time</i>	generate a new time-based UUID

-v Verbose execution.

-V Print the version number of **mke2fs** and exit.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the *undo_file* argument, the undo file will be written to a file named **mke2fs-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable or the *undo_dir* directive in the configuration file.

WARNING: The undo file cannot be used to recover from a power or system crash.

ENVIRONMENT

MKE2FS_SYNC

If set to non-zero integer value, its value is used to determine how often **sync(2)** is called during inode table initialization.

MKE2FS_CONFIG

Determines the location of the configuration file (see **mke2fs.conf(5)**).

MKE2FS_FIRST_META_BG

If set to non-zero integer value, its value is used to determine first meta block group. This is mostly for debugging purposes.

MKE2FS_DEVICE_SECTSIZE

If set to non-zero integer value, its value is used to determine logical sector size of the *device*.

MKE2FS_DEVICE_PHYS_SECTSIZE

If set to non-zero integer value, its value is used to determine physical sector size of the *device*.

MKE2FS_SKIP_CHECK_MSG

If set, do not show the message of file system automatic check caused by mount count or check interval.

NAME

mkfs.f2fs – create an F2FS file system

SYNOPSIS

```
mkfs.f2fs [ -a heap-based-allocation ] [ -c device-list ] [ -d debug-level ] [ -e extension-list ] [ -E extension-list ] [ -f ] [ -g ] [ -i ] [ -l volume-label ] [ -m ] [ -o overprovision-ratio-percentage ] [ -O feature-list ] [ -C encoding:flags ] [ -q ] [ -r ] [ -R root_owner ] [ -s #-of-segments-per-section ] [ -S ] [ -t nodiscard/discard ] [ -T timestamp ] [ -w wanted-sector-size ] [ -z #-of-sections-per-zone ] [ -V ] device [ sectors ]
```

DESCRIPTION

mkfs.f2fs is used to create a f2fs file system (usually in a disk partition). *device* is the special file corresponding to the device (e.g. */dev/sdXX*). *sectors* is optionally given for specifying the filesystem size.

The exit code returned by **mkfs.f2fs** is 0 on success and 1 on failure.

OPTIONS**-a heap-based-allocation**

Specify 1 or 0 to enable/disable heap based block allocation policy. If the value is equal to 1, each of active log areas are initially assigned separately according to the whole volume size. The default value is 1.

-c device-list

Build f2fs with these additional comma separated devices, so that the user can see all the devices as one big volume. Supports up to 7 devices except meta device.

-d debug-level

Specify the level of debugging options. The default number is 0, which shows basic debugging messages.

-e extension-list

Specify a list of file extensions that f2fs will treat as cold files. The data of files with those extensions will be stored in the cold log. The default list includes most of the multimedia file extensions such as jpg, gif, mpeg, mkv, and so on.

-E extension-list

Specify a list of file extensions that f2fs will treat as hot files. The data of files with those extensions will be stored in the hot log. The default list includes database file extensions, such as db.

-f Force overwrite when an existing filesystem is detected on the device. By default, **mkfs.f2fs** will not write to the device if it suspects that there is a filesystem or partition table on the device already.

-g Add default Android options.

-i Enable extended node bitmap. **-l volume-label** Specify the volume label to the partition mounted as F2FS.

-m Specify f2fs filesystem to supports the block zoned feature. Without it, the filesystem doesn't support the feature.

-o overprovision-ratio-percentage

Specify the percentage of the volume that will be used as overprovision area. This area is hidden to users, and utilized by F2FS cleaner. If not specified, the best number will be assigned automatically according to the partition size.

-O feature-list

Set additional features for the filesystem. Features are comma separated, and the flag can be repeated. The following features are supported:

encrypt	Enable support for filesystem level encryption.
----------------	---

extra_attr	Enable extra attr feature, required for some of the other features.
-------------------	---

project_quota	Enable project ID tracking. This is used for project quota accounting. Requires extra attr.
inode_checksum	Enable inode checksum. Requires extra attr.
flexible_inline_xattr	Enable flexible inline xattr. Requires extra attr.
quota	Enable quotas.
inode_crttime	Enable inode creation time feature. Requires extra attr.
lost_found	Enable lost+found feature.
verity	Reserved feature.
sb_checksum	Enable superblock checksum.
casemap	Enable casemap support in the filesystem. Optional flags can be passed with -C
compression	Enable support for filesystem level compression. Requires extra attr.

-C *encoding:flags*

Support casemapping with a specific encoding, with optional comma separated flags.

encoding:

utf8 Use UTF-8 for casemapping.

flags:

strict This flag specifies that invalid strings should be rejected by the filesystem. Default is disabled.

-q Quiet mode. With it, mkfs.f2fs does not show any messages, including the basic messages.

-r Sets the checkpointing strand seed to 0.

-R Give root_owner option for initial uid/gid assignment. Default is set by getuid()/getgid(), and assigned by "-R \$uid:\$gid".

-s #*of-segments-per-section*

Specify the number of segments per section. A section consists of multiple consecutive segments, and is the unit of garbage collection. The default number is 1, which means one segment is assigned to a section.

-S Enable sparse mode.

-t 1/0 Specify 1 or 0 to enable or disable discard policy, respectively. The default value is 1.

-T *timestamp*

Set inodes times to a given timestamp. By default, the current time will be used. This behaviour corresponds to the value -1.

-w *wanted-sector-size*

Specify the sector size in bytes. Without it, the sectors will be calculated by device sector size.

-z #*of-sections-per-zone*

Specify the number of sections per zone. A zone consists of multiple sections. F2FS allocates segments for active logs with separated zones as much as possible. The default number is 1, which means a zone consists of one section.

sectors Number of sectors. Default is determined by device size.

-V Print the version number and exit.

NAME

mkfs.fat – create an MS-DOS FAT filesystem

SYNOPSIS

mkfs.fat [*OPTIONS*] *DEVICE* [*BLOCK-COUNT*]

DESCRIPTION

mkfs.fat is used to create a FAT filesystem on a device or in an image file. *DEVICE* is the special file corresponding to the device (e.g. `/dev/sdXX`) or the image file (which does not need to exist when the option **-C** is given). *BLOCK-COUNT* is the number of blocks on the device and size of one block is always 1024 bytes, independently of the sector size or the cluster size. Therefore *BLOCK-COUNT* specifies size of filesystem in KiB unit and not in the number of sectors (like for all other **mkfs.fat** options). If omitted, **mkfs.fat** automatically chooses a filesystem size to fill the available space.

Two different variants of the FAT filesystem are supported. Standard is the FAT12, FAT16 and FAT32 filesystems as defined by Microsoft and widely used on hard disks and removable media like USB sticks and SD cards. The other is the legacy Atari variant used on Atari ST.

In Atari mode, if not directed otherwise by the user, **mkfs.fat** will always use 2 sectors per cluster, since GEMDOS doesn't like other values very much. It will also obey the maximum number of sectors GEMDOS can handle. Larger filesystems are managed by raising the logical sector size. An Atari-compatible serial number for the filesystem is generated, and a 12 bit FAT is used only for filesystems that have one of the usual floppy sizes (720k, 1.2M, 1.44M, 2.88M), a 16 bit FAT otherwise. This can be overridden with the **-F** option. Some PC-specific boot sector fields aren't written, and a boot message (option **-m**) is ignored.

OPTIONS

- a** Normally, for any filesystem except very small ones, **mkfs.fat** will align all the data structures to cluster size, to make sure that as long as the partition is properly aligned, so will all the data structures in the filesystem. This option disables alignment; this may provide a handful of additional clusters of storage at the expense of a significant performance degradation on RAIDs, flash media or large-sector hard disks.
- A** Select using the Atari variation of the FAT filesystem if that isn't active already, otherwise select standard FAT filesystem. This is selected by default if **mkfs.fat** is run on 68k Atari Linux.
- b SECTOR-OF-BACKUP**
Selects the location of the backup boot sector for FAT32. Default depends on number of reserved sectors, but usually is sector 6. If there is a free space available after the backup boot sector then backup of the FAT32 info sector is put after the backup boot sector, usually at sector 7. The backup must be within the range of reserved sectors. Value 0 completely disables creating of backup boot and info FAT32 sectors.
- c** Check the device for bad blocks before creating the filesystem.
- C** Create the file given as *DEVICE* on the command line, and write the to-be-created filesystem to it. This can be used to create the new filesystem in a file instead of on a real device, and to avoid using **dd** in advance to create a file of appropriate size. With this option, the *BLOCK-COUNT* must be given, because otherwise the intended size of the filesystem wouldn't be known. The file created is a sparse file, which actually only contains the meta-data areas (boot sector, FATs, and root directory). The data portions won't be stored on the disk, but the file nevertheless will have the correct size. The resulting file can be copied later to a floppy disk or other device, or mounted through a loop device.

-D DRIVE-NUMBER

Specify the BIOS drive number to be stored in the FAT boot sector. For hard disks and removable media it is usually 0x80–0xFF (0x80 is first hard disk C:, 0x81 is second hard disk D:, ...), for floppy devices or partitions to be used for floppy emulation it is 0x00–0x7F (0x00 is first floppy A:, 0x01 is second floppy B:).

-f NUMBER-OF-FATS

Specify the number of file allocation tables in the filesystem. The default is 2.

-F FAT-SIZE

Specifies the type of file allocation tables used (12, 16 or 32 bit). If nothing is specified, **mkfs.fat** will automatically select between 12, 16 and 32 bit, whatever fits better for the filesystem size.

-g HEADS/SECTORS-PER-TRACK

Specify *HEADS* and *SECTORS-PER-TRACK* numbers which represents disk geometry of *DEVICE*. Both numbers are stored into the FAT boot sector. Number *SECTORS-PER-TRACK* is used also for aligning the total count of FAT sectors. By default disk geometry is read from *DEVICE* itself. If it is not available then *LBA-Assist Translation* and translation table from the *SD Card Part 2 File System Specification* based on total number of disk sectors is used.

-h NUMBER-OF-HIDDEN-SECTORS

Specify the number of so-called *hidden sectors*, as stored in the FAT boot sector: this number represents the beginning sector of the partition containing the file system. Normally this is an offset (in sectors) relative to the start of the disk, although for MBR logical volumes contained in an extended partition of type 0x05 (a non-LBA extended partition), a quirk in the MS-DOS implementation of FAT requires it to be relative to the partition's immediate containing Extended Boot Record. Boot code and other software handling FAT volumes may also rely on this field being set up correctly; most modern FAT implementations will ignore it. By default, if the *DEVICE* is a partition block device, **mkfs.fat** uses the partition offset relative to disk start. Otherwise, **mkfs.fat** assumes zero. Use this option to override this behaviour.

-i VOLUME-ID

Sets the volume ID of the newly created filesystem; *VOLUME-ID* is a 32-bit hexadecimal number (for example, 2e24ec82). The default is a number which depends on the filesystem creation time.

-I

Ignore and disable safety checks. By default **mkfs.fat** refuses to create a filesystem on a device with partitions or virtual mapping. **mkfs.fat** will complain and tell you that it refuses to work. This is different when using MO disks. One doesn't always need partitions on MO disks. The filesystem can go directly to the whole disk. Under other OSes this is known as the *superfloppy* format. This switch will force **mkfs.fat** to work properly.

-l FILENAME

Read the bad blocks list from *FILENAME*.

-m MESSAGE-FILE

Sets the message the user receives on attempts to boot this filesystem without having properly installed an operating system. The message file must not exceed 418 bytes once line feeds have been converted to carriage return-line feed combinations, and tabs have been expanded. If the filename is a hyphen (-), the text is taken from standard input.

-M FAT-MEDIA-TYPE

Specify the media type to be stored in the FAT boot sector. This value is usually 0xF8 for hard disks and is 0xF0 or a value from 0xF9 to 0xFF for floppies or partitions to be used for floppy emulation.

--mbr[=y|yes|n|no|a|auto]

Fill (fake) MBR table with disk signature one partition which starts at sector 0 (includes MBR itself) and spans whole disk device. It is needed only for non-removable disks used on Microsoft Windows systems and only when formatting whole unpartitioned disk. Location of the disk signature and partition table overlaps with the end of the first FAT sector (boot code location), therefore there is no additional space usage. Default is *auto* mode in which **mkfs.fat** put MBR table only for non-removable disks when formatting whole unpartitioned disk.

-n VOLUME-NAME

Sets the volume name (label) of the filesystem. The volume name can be up to 11 characters long. Supplying an empty string, a string consisting only of white space or the string "NO NAME" as *VOLUME-NAME* has the same effect as not giving the **-n** option. The default is no label.

--codepage=PAGE

Use DOS codepage *PAGE* to encode label. By default codepage 850 is used.

-r ROOT-DIR-ENTRIES

Select the minimal number of entries available in the root directory. The default is 112 or 224 for floppies and 512 for hard disks. Note that this is minimal number and it may be increased by **mkfs.fat** due to alignment of structures. See also **mkfs.fat** option **-a**.

-R NUMBER-OF-RESERVED-SECTORS

Select the minimal number of reserved sectors. With FAT32 format at least 2 reserved sectors are needed, the default is 32. Otherwise the default is 1 (only the boot sector). Note that this is minimal number and it may be increased by **mkfs.fat** due to alignment of structures. See also **mkfs.fat** option **-a**.

-s SECTORS-PER-CLUSTER

Specify the number of disk sectors per cluster. Must be a power of 2, i.e. 1, 2, 4, 8, ... 128.

-S LOGICAL-SECTOR-SIZE

Specify the number of bytes per logical sector. Must be a power of 2 and greater than or equal to 512, i.e. 512, 1024, 2048, 4096, 8192, 16384, or 32768. Values larger than 4096 are not conforming to the FAT file system specification and may not work everywhere.

-v Verbose execution.**--offset SECTOR**

Write the filesystem at a specific sector into the device file. This is useful for creating a filesystem in a partitioned disk image without having to set up a loop device.

--variant TYPE

Create a filesystem of variant *TYPE*. Acceptable values are *standard* and *atari* (in any combination of upper/lower case). See above under DESCRIPTION for the differences.

--help

Display option summary and exit.

--invariant

Use constants for normally randomly generated or time based data such as volume ID and creation time. Multiple runs of **mkfs.fat** on the same device create identical results with this option. Its main purpose is testing **mkfs.fat**.

BUGS

mkfs.fat can not create boot-able filesystems. This isn't as easy as you might think at first glance for various reasons and has been discussed a lot already. **mkfs.fat** simply will not support it ;)

NAME

mkfs.fat – create an MS-DOS FAT filesystem

SYNOPSIS

mkfs.fat [OPTIONS] DEVICE [BLOCK-COUNT]

DESCRIPTION

mkfs.fat is used to create a FAT filesystem on a device or in an image file. *DEVICE* is the special file corresponding to the device (e.g. `/dev/sdXX`) or the image file (which does not need to exist when the option **-C** is given). *BLOCK-COUNT* is the number of blocks on the device and size of one block is always 1024 bytes, independently of the sector size or the cluster size. Therefore *BLOCK-COUNT* specifies size of filesystem in KiB unit and not in the number of sectors (like for all other **mkfs.fat** options). If omitted, **mkfs.fat** automatically chooses a filesystem size to fill the available space.

Two different variants of the FAT filesystem are supported. Standard is the FAT12, FAT16 and FAT32 filesystems as defined by Microsoft and widely used on hard disks and removable media like USB sticks and SD cards. The other is the legacy Atari variant used on Atari ST.

In Atari mode, if not directed otherwise by the user, **mkfs.fat** will always use 2 sectors per cluster, since GEMDOS doesn't like other values very much. It will also obey the maximum number of sectors GEMDOS can handle. Larger filesystems are managed by raising the logical sector size. An Atari-compatible serial number for the filesystem is generated, and a 12 bit FAT is used only for filesystems that have one of the usual floppy sizes (720k, 1.2M, 1.44M, 2.88M), a 16 bit FAT otherwise. This can be overridden with the **-F** option. Some PC-specific boot sector fields aren't written, and a boot message (option **-m**) is ignored.

OPTIONS

- a** Normally, for any filesystem except very small ones, **mkfs.fat** will align all the data structures to cluster size, to make sure that as long as the partition is properly aligned, so will all the data structures in the filesystem. This option disables alignment; this may provide a handful of additional clusters of storage at the expense of a significant performance degradation on RAIDs, flash media or large-sector hard disks.
- A** Select using the Atari variation of the FAT filesystem if that isn't active already, otherwise select standard FAT filesystem. This is selected by default if **mkfs.fat** is run on 68k Atari Linux.
- b SECTOR-OF-BACKUP**
Selects the location of the backup boot sector for FAT32. Default depends on number of reserved sectors, but usually is sector 6. If there is a free space available after the backup boot sector then backup of the FAT32 info sector is put after the backup boot sector, usually at sector 7. The backup must be within the range of reserved sectors. Value 0 completely disables creating of backup boot and info FAT32 sectors.
- c** Check the device for bad blocks before creating the filesystem.
- C** Create the file given as *DEVICE* on the command line, and write the to-be-created filesystem to it. This can be used to create the new filesystem in a file instead of on a real device, and to avoid using **dd** in advance to create a file of appropriate size. With this option, the *BLOCK-COUNT* must be given, because otherwise the intended size of the filesystem wouldn't be known. The file created is a sparse file, which actually only contains the meta-data areas (boot sector, FATs, and root directory). The data portions won't be stored on the disk, but the file nevertheless will have the correct size. The resulting file can be copied later to a floppy disk or other device, or mounted through a loop device.
- D DRIVE-NUMBER**
Specify the BIOS drive number to be stored in the FAT boot sector. For hard disks and removable media it is usually 0x80–0xFF (0x80 is first hard disk C:, 0x81 is second hard disk D:, ...), for floppy devices or partitions to be used for floppy emulation it is 0x00–0x7F (0x00 is first floppy A:, 0x01 is second floppy B:).

-f NUMBER-OF-FATS

Specify the number of file allocation tables in the filesystem. The default is 2.

-F FAT-SIZE

Specifies the type of file allocation tables used (12, 16 or 32 bit). If nothing is specified, **mkfs.fat** will automatically select between 12, 16 and 32 bit, whatever fits better for the filesystem size.

-g HEADS/SECTORS-PER-TRACK

Specify *HEADS* and *SECTORS-PER-TRACK* numbers which represents disk geometry of *DEVICE*. Both numbers are stored into the FAT boot sector. Number *SECTORS-PER-TRACK* is used also for aligning the total count of FAT sectors. By default disk geometry is read from *DEVICE* itself. If it is not available then *LBA-Assist Translation* and translation table from the *SD Card Part 2 File System Specification* based on total number of disk sectors is used.

-h NUMBER-OF-HIDDEN-SECTORS

Specify the number of so-called *hidden sectors*, as stored in the FAT boot sector: this number represents the beginning sector of the partition containing the file system. Normally this is an offset (in sectors) relative to the start of the disk, although for MBR logical volumes contained in an extended partition of type 0x05 (a non-LBA extended partition), a quirk in the MS-DOS implementation of FAT requires it to be relative to the partition's immediate containing Extended Boot Record. Boot code and other software handling FAT volumes may also rely on this field being set up correctly; most modern FAT implementations will ignore it. By default, if the *DEVICE* is a partition block device, **mkfs.fat** uses the partition offset relative to disk start. Otherwise, **mkfs.fat** assumes zero. Use this option to override this behaviour.

-i VOLUME-ID

Sets the volume ID of the newly created filesystem; *VOLUME-ID* is a 32-bit hexadecimal number (for example, 2e24ec82). The default is a number which depends on the filesystem creation time.

-I

Ignore and disable safety checks. By default **mkfs.fat** refuses to create a filesystem on a device with partitions or virtual mapping. **mkfs.fat** will complain and tell you that it refuses to work. This is different when using MO disks. One doesn't always need partitions on MO disks. The filesystem can go directly to the whole disk. Under other OSes this is known as the *superfloppy* format. This switch will force **mkfs.fat** to work properly.

-l FILENAME

Read the bad blocks list from *FILENAME*.

-m MESSAGE-FILE

Sets the message the user receives on attempts to boot this filesystem without having properly installed an operating system. The message file must not exceed 418 bytes once line feeds have been converted to carriage return-line feed combinations, and tabs have been expanded. If the filename is a hyphen (-), the text is taken from standard input.

-M FAT-MEDIA-TYPE

Specify the media type to be stored in the FAT boot sector. This value is usually 0xF8 for hard disks and is 0xF0 or a value from 0xF9 to 0xFF for floppies or partitions to be used for floppy emulation.

--mbr[=y|yes|n|no|a|auto]

Fill (fake) MBR table with disk signature one partition which starts at sector 0 (includes MBR itself) and spans whole disk device. It is needed only for non-removable disks used on Microsoft Windows systems and only when formatting whole unpartitioned disk. Location of the disk signature and partition table overlaps with the end of the first FAT sector (boot code location), therefore there is no additional space usage. Default is *auto* mode in which **mkfs.fat** put MBR table only for non-removable disks when formatting whole unpartitioned disk.

-n VOLUME-NAME

Sets the volume name (label) of the filesystem. The volume name can be up to 11 characters long. Supplying an empty string, a string consisting only of white space or the string "NO NAME" as *VOLUME-NAME* has the same effect as not giving the **-n** option. The default is no label.

--codepage=PAGE

Use DOS codepage *PAGE* to encode label. By default codepage 850 is used.

-r ROOT-DIR-ENTRIES

Select the minimal number of entries available in the root directory. The default is 112 or 224 for floppies and 512 for hard disks. Note that this is minimal number and it may be increased by **mkfs.fat** due to alignment of structures. See also **mkfs.fat** option **-a**.

-R NUMBER-OF-RESERVED-SECTORS

Select the minimal number of reserved sectors. With FAT32 format at least 2 reserved sectors are needed, the default is 32. Otherwise the default is 1 (only the boot sector). Note that this is minimal number and it may be increased by **mkfs.fat** due to alignment of structures. See also **mkfs.fat** option **-a**.

-s SECTORS-PER-CLUSTER

Specify the number of disk sectors per cluster. Must be a power of 2, i.e. 1, 2, 4, 8, ... 128.

-S LOGICAL-SECTOR-SIZE

Specify the number of bytes per logical sector. Must be a power of 2 and greater than or equal to 512, i.e. 512, 1024, 2048, 4096, 8192, 16384, or 32768. Values larger than 4096 are not conforming to the FAT file system specification and may not work everywhere.

-v Verbose execution.**--offset SECTOR**

Write the filesystem at a specific sector into the device file. This is useful for creating a filesystem in a partitioned disk image without having to set up a loop device.

--variant TYPE

Create a filesystem of variant *TYPE*. Acceptable values are *standard* and *atari* (in any combination of upper/lower case). See above under DESCRIPTION for the differences.

--help

Display option summary and exit.

--invariant

Use constants for normally randomly generated or time based data such as volume ID and creation time. Multiple runs of **mkfs.fat** on the same device create identical results with this option. Its main purpose is testing **mkfs.fat**.

BUGS

mkfs.fat can not create boot-able filesystems. This isn't as easy as you might think at first glance for various reasons and has been discussed a lot already. **mkfs.fat** simply will not support it ;)

NAME

mkntfs – create an NTFS file system

SYNOPSIS

```
mkntfs [options] device [number-of-sectors]  

mkntfs [ -C ] [ -c cluster-size ] [ -F ] [ -f ] [ -H heads ] [ -h ] [ -I ] [ -L volume-label ] [ -l ] [ -n ] [  

-p part-start-sect ] [ -Q ] [ -q ] [ -S sectors-per-track ] [ -s sector-size ] [ -T ] [ -U ] [ -V ] [ -v ] [  

-z mft-zone-multiplier ] [ --debug ] device [number-of-sectors]
```

DESCRIPTION

mkntfs is used to create an NTFS file system on a device (usually a disk partition) or file. *device* is the special file corresponding to the device (e.g. */dev/hdXX*). *number-of-sectors* is the number of sectors on the device. If omitted, **mkntfs** automagically figures the file system size.

OPTIONS

Below is a summary of all the options that **mkntfs** accepts. Nearly all options have two equivalent names. The short name is preceded by **-** and the long name is preceded by **--**. Any single letter options, that don't take an argument, can be combined into a single command, e.g. **-fv** is equivalent to **-f -v**. Long named options can be abbreviated to any unique prefix of their name.

Basic options

-f, --fast, -Q, --quick

Perform quick (fast) format. This will skip both zeroing of the volume and bad sector checking.

-L, --label STRING

Set the volume label for the filesystem.

-C, --enable-compression

Enable compression on the volume.

-n, --no-action

Causes **mkntfs** to not actually create a filesystem, but display what it would do if it were to create a filesystem. All steps of the format are carried out except the actual writing to the device.

Advanced options

-c, --cluster-size BYTES

Specify the size of clusters in bytes. Valid cluster size values are powers of two, with at least 256, and at most 2097152 bytes (2MB) per cluster. If omitted, **mkntfs** uses 4096 bytes as the default cluster size.

Note that the default cluster size is set to be at least equal to the sector size as a cluster cannot be smaller than a sector. Also, note that values greater than 4096 have the side effect that compression is disabled on the volume (due to limitations in the NTFS compression algorithm currently in use by Windows).

-s, --sector-size BYTES

Specify the size of sectors in bytes. Valid sector size values are 256, 512, 1024, 2048 and 4096 bytes per sector. If omitted, **mkntfs** attempts to determine the *sector-size* automatically and if that fails a default of 512 bytes per sector is used.

-p, --partition-start SECTOR

Specify the partition start sector. The maximum is 4294967295 ($2^{32}-1$). If omitted, **mkntfs** attempts to determine *part-start-sect* automatically and if that fails or the value is oversized, a default of 0 is used. The partition is usable despite a wrong value, however note that a correct *part-start-sect* is required for Windows to be able to boot from the created volume.

-H, --heads NUM

Specify the number of heads. The maximum is 65535 (0xffff). If omitted, **mkntfs** attempts to determine the number of *heads* automatically and if that fails a default of 0 is used. Note that *heads* is required for Windows to be able to boot from the created volume.

-S, --sectors-per-track NUM

Specify the number of sectors per track. The maximum is 65535 (0xffff). If omitted, **mkntfs** attempts to determine the number of *sectors-per-track* automatically and if that fails a default of 0 is used. Note that *sectors-per-track* is required for Windows to be able to boot from the created volume.

-z, --mft-zone-multiplier NUM

Set the MFT zone multiplier, which determines the size of the MFT zone to use on the volume. The MFT zone is the area at the beginning of the volume reserved for the master file table (MFT), which stores the on disk inodes (MFT records). It is noteworthy that small files are stored entirely within the inode; thus, if you expect to use the volume for storing large numbers of very small files, it is useful to set the zone multiplier to a higher value. Note, that the MFT zone is resized on the fly as required during operation of the NTFS driver but choosing a good value will reduce fragmentation. Valid values are 1, 2, 3 and 4. The values have the following meaning:

MFT zone multiplier	MFT zone size (% of volume size)
1	12.5% (default)
2	25.0%
3	37.5%
4	50.0%

-T, --zero-time

Fake the time to be 00:00:00 UTC, Jan 1, 1970 instead of the current system time. This is only really useful for debugging purposes.

-U, --with-uuid

Generate a random volume UUID.

-I, --no-indexing

Disable content indexing on the volume. (This is only meaningful on Windows 2000 and later. Windows NT 4.0 and earlier ignore this as they do not implement content indexing at all.)

-F, --force

Force **mkntfs** to run, even if the specified *device* is not a block special device, or appears to be mounted.

Output options**-q, --quiet**

Quiet execution; only errors are written to stderr, no output to stdout occurs at all. Useful if **mkntfs** is run in a script.

-v, --verbose

Verbose execution.

--debug

Really verbose execution; includes the verbose output from the **-v** option as well as additional output useful for debugging **mkntfs**.

Help options**-V, --version**

Print the version number of **mkntfs** and exit.

-l, --license

Print the licensing information of **mkntfs** and exit.

-h, --help

Show a list of options with a brief description of each one.

KNOWN ISSUES

When applying chkdsk to a file system, it sometimes throws a warning "Correcting errors in the uppercase file." The uppercase file is created while formatting and it defines the mapping of lower case characters to upper case ones, as needed to sort file names in directories. The warning means that the uppercase file defined on the file system is not the same as the one used by the Windows OS on which chkdsk is running, and this may happen because newer versions of Windows take into account new characters defined by the Unicode consortium.

Currently, mkntfs creates the uppercase table so that no warning is thrown by Windows Vista, Windows 7 or Windows 8. A warning may be thrown by other Windows versions, or if chkdsk is applied in succession on different Windows versions.

BUGS

If you find a bug please send an email describing the problem to the development team:
ntfs-3g-devel@lists.sf.net

AUTHORS

mkntfs was written by Anton Altaparmakov, Richard Russon, Erik Sornes and Szabolcs Szakacsits. It was ported to ntfs-3g by Erik Larsson and Jean-Pierre Andre.

AVAILABILITY

mkntfs is part of the **ntfs-3g** package and is available from:

NAME

mkfs.fat – create an MS-DOS FAT filesystem

SYNOPSIS

mkfs.fat [OPTIONS] DEVICE [BLOCK-COUNT]

DESCRIPTION

mkfs.fat is used to create a FAT filesystem on a device or in an image file. *DEVICE* is the special file corresponding to the device (e.g. `/dev/sdXX`) or the image file (which does not need to exist when the option **-C** is given). *BLOCK-COUNT* is the number of blocks on the device and size of one block is always 1024 bytes, independently of the sector size or the cluster size. Therefore *BLOCK-COUNT* specifies size of filesystem in KiB unit and not in the number of sectors (like for all other **mkfs.fat** options). If omitted, **mkfs.fat** automatically chooses a filesystem size to fill the available space.

Two different variants of the FAT filesystem are supported. Standard is the FAT12, FAT16 and FAT32 filesystems as defined by Microsoft and widely used on hard disks and removable media like USB sticks and SD cards. The other is the legacy Atari variant used on Atari ST.

In Atari mode, if not directed otherwise by the user, **mkfs.fat** will always use 2 sectors per cluster, since GEMDOS doesn't like other values very much. It will also obey the maximum number of sectors GEMDOS can handle. Larger filesystems are managed by raising the logical sector size. An Atari-compatible serial number for the filesystem is generated, and a 12 bit FAT is used only for filesystems that have one of the usual floppy sizes (720k, 1.2M, 1.44M, 2.88M), a 16 bit FAT otherwise. This can be overridden with the **-F** option. Some PC-specific boot sector fields aren't written, and a boot message (option **-m**) is ignored.

OPTIONS

- a** Normally, for any filesystem except very small ones, **mkfs.fat** will align all the data structures to cluster size, to make sure that as long as the partition is properly aligned, so will all the data structures in the filesystem. This option disables alignment; this may provide a handful of additional clusters of storage at the expense of a significant performance degradation on RAIDs, flash media or large-sector hard disks.
- A** Select using the Atari variation of the FAT filesystem if that isn't active already, otherwise select standard FAT filesystem. This is selected by default if **mkfs.fat** is run on 68k Atari Linux.
- b SECTOR-OF-BACKUP**
Selects the location of the backup boot sector for FAT32. Default depends on number of reserved sectors, but usually is sector 6. If there is a free space available after the backup boot sector then backup of the FAT32 info sector is put after the backup boot sector, usually at sector 7. The backup must be within the range of reserved sectors. Value 0 completely disables creating of backup boot and info FAT32 sectors.
- c** Check the device for bad blocks before creating the filesystem.
- C** Create the file given as *DEVICE* on the command line, and write the to-be-created filesystem to it. This can be used to create the new filesystem in a file instead of on a real device, and to avoid using **dd** in advance to create a file of appropriate size. With this option, the *BLOCK-COUNT* must be given, because otherwise the intended size of the filesystem wouldn't be known. The file created is a sparse file, which actually only contains the meta-data areas (boot sector, FATs, and root directory). The data portions won't be stored on the disk, but the file nevertheless will have the correct size. The resulting file can be copied later to a floppy disk or other device, or mounted through a loop device.
- D DRIVE-NUMBER**
Specify the BIOS drive number to be stored in the FAT boot sector. For hard disks and removable media it is usually 0x80–0xFF (0x80 is first hard disk C:, 0x81 is second hard disk D:, ...), for floppy devices or partitions to be used for floppy emulation it is 0x00–0x7F (0x00 is first floppy A:, 0x01 is second floppy B:).

-f NUMBER-OF-FATS

Specify the number of file allocation tables in the filesystem. The default is 2.

-F FAT-SIZE

Specifies the type of file allocation tables used (12, 16 or 32 bit). If nothing is specified, **mkfs.fat** will automatically select between 12, 16 and 32 bit, whatever fits better for the filesystem size.

-g HEADS/SECTORS-PER-TRACK

Specify *HEADS* and *SECTORS-PER-TRACK* numbers which represents disk geometry of *DEVICE*. Both numbers are stored into the FAT boot sector. Number *SECTORS-PER-TRACK* is used also for aligning the total count of FAT sectors. By default disk geometry is read from *DEVICE* itself. If it is not available then *LBA-Assist Translation* and translation table from the *SD Card Part 2 File System Specification* based on total number of disk sectors is used.

-h NUMBER-OF-HIDDEN-SECTORS

Specify the number of so-called *hidden sectors*, as stored in the FAT boot sector: this number represents the beginning sector of the partition containing the file system. Normally this is an offset (in sectors) relative to the start of the disk, although for MBR logical volumes contained in an extended partition of type 0x05 (a non-LBA extended partition), a quirk in the MS-DOS implementation of FAT requires it to be relative to the partition's immediate containing Extended Boot Record. Boot code and other software handling FAT volumes may also rely on this field being set up correctly; most modern FAT implementations will ignore it. By default, if the *DEVICE* is a partition block device, **mkfs.fat** uses the partition offset relative to disk start. Otherwise, **mkfs.fat** assumes zero. Use this option to override this behaviour.

-i VOLUME-ID

Sets the volume ID of the newly created filesystem; *VOLUME-ID* is a 32-bit hexadecimal number (for example, 2e24ec82). The default is a number which depends on the filesystem creation time.

-I

Ignore and disable safety checks. By default **mkfs.fat** refuses to create a filesystem on a device with partitions or virtual mapping. **mkfs.fat** will complain and tell you that it refuses to work. This is different when using MO disks. One doesn't always need partitions on MO disks. The filesystem can go directly to the whole disk. Under other OSes this is known as the *superfloppy* format. This switch will force **mkfs.fat** to work properly.

-l FILENAME

Read the bad blocks list from *FILENAME*.

-m MESSAGE-FILE

Sets the message the user receives on attempts to boot this filesystem without having properly installed an operating system. The message file must not exceed 418 bytes once line feeds have been converted to carriage return-line feed combinations, and tabs have been expanded. If the filename is a hyphen (-), the text is taken from standard input.

-M FAT-MEDIA-TYPE

Specify the media type to be stored in the FAT boot sector. This value is usually 0xF8 for hard disks and is 0xF0 or a value from 0xF9 to 0xFF for floppies or partitions to be used for floppy emulation.

--mbr[=y|yes|n|no|a|auto]

Fill (fake) MBR table with disk signature one partition which starts at sector 0 (includes MBR itself) and spans whole disk device. It is needed only for non-removable disks used on Microsoft Windows systems and only when formatting whole unpartitioned disk. Location of the disk signature and partition table overlaps with the end of the first FAT sector (boot code location), therefore there is no additional space usage. Default is *auto* mode in which **mkfs.fat** put MBR table only for non-removable disks when formatting whole unpartitioned disk.

-n VOLUME-NAME

Sets the volume name (label) of the filesystem. The volume name can be up to 11 characters long. Supplying an empty string, a string consisting only of white space or the string "NO NAME" as *VOLUME-NAME* has the same effect as not giving the **-n** option. The default is no label.

--codepage=PAGE

Use DOS codepage *PAGE* to encode label. By default codepage 850 is used.

-r ROOT-DIR-ENTRIES

Select the minimal number of entries available in the root directory. The default is 112 or 224 for floppies and 512 for hard disks. Note that this is minimal number and it may be increased by **mkfs.fat** due to alignment of structures. See also **mkfs.fat** option **-a**.

-R NUMBER-OF-RESERVED-SECTORS

Select the minimal number of reserved sectors. With FAT32 format at least 2 reserved sectors are needed, the default is 32. Otherwise the default is 1 (only the boot sector). Note that this is minimal number and it may be increased by **mkfs.fat** due to alignment of structures. See also **mkfs.fat** option **-a**.

-s SECTORS-PER-CLUSTER

Specify the number of disk sectors per cluster. Must be a power of 2, i.e. 1, 2, 4, 8, ... 128.

-S LOGICAL-SECTOR-SIZE

Specify the number of bytes per logical sector. Must be a power of 2 and greater than or equal to 512, i.e. 512, 1024, 2048, 4096, 8192, 16384, or 32768. Values larger than 4096 are not conforming to the FAT file system specification and may not work everywhere.

-v Verbose execution.**--offset SECTOR**

Write the filesystem at a specific sector into the device file. This is useful for creating a filesystem in a partitioned disk image without having to set up a loop device.

--variant TYPE

Create a filesystem of variant *TYPE*. Acceptable values are *standard* and *atari* (in any combination of upper/lower case). See above under DESCRIPTION for the differences.

--help

Display option summary and exit.

--invariant

Use constants for normally randomly generated or time based data such as volume ID and creation time. Multiple runs of **mkfs.fat** on the same device create identical results with this option. Its main purpose is testing **mkfs.fat**.

BUGS

mkfs.fat can not create boot-able filesystems. This isn't as easy as you might think at first glance for various reasons and has been discussed a lot already. **mkfs.fat** simply will not support it ;)

dosfstools were written by Werner Almesberger <werner.almesberger@lrc.di.epfl.ch>, Roman Hodek <Roman.Hodek@informatik.uni-erlangen.de>, and others. Current maintainers are Andreas Bombe <aeb@debian.org> and Pali Rohár <pali.rohar@gmail.com>.

NAME

mkfs.xfs – construct an XFS filesystem

SYNOPSIS

```
mkfs.xfs [ -b block_size_options ] [ -m global_metadata_options ] [ -d data_section_options ] [ -f ] [ -i inode_options ] [ -l log_section_options ] [ -n naming_options ] [ -p protofile ] [ -q ] [ -r realtime_section_options ] [ -s sector_size_options ] [ -L label ] [ -N ] [ -K ] device
```

```
mkfs.xfs -V
```

DESCRIPTION

mkfs.xfs constructs an XFS filesystem by writing on a special file using the values found in the arguments of the command line. It is invoked automatically by **mkfs(8)** when it is given the **-t xfs** option.

In its simplest (and most commonly used form), the size of the filesystem is determined from the disk driver. As an example, to make a filesystem with an internal log on the first partition on the first SCSI disk, use:

```
mkfs.xfs /dev/sda1
```

The metadata log can be placed on another device to reduce the number of disk seeks. To create a filesystem on the first partition on the first SCSI disk with a 10MiB log located on the first partition on the second SCSI disk, use:

```
mkfs.xfs -l logdev=/dev/sdb1,size=10m /dev/sda1
```

Each of the *option* elements in the argument list above can be given as multiple comma-separated suboptions if multiple suboptions apply to the same option. Equivalently, each main option can be given multiple times with different suboptions. For example, **-l internal,size=10m** and **-l internal -l size=10m** are equivalent.

In the descriptions below, sizes are given in sectors, bytes, blocks, kilobytes, megabytes, gigabytes, etc. Sizes are treated as hexadecimal if prefixed by 0x or 0X, octal if prefixed by 0, or decimal otherwise. The following lists possible multiplication suffixes:

- s** – multiply by sector size (default = 512, see **-s** option below).
- b** – multiply by filesystem block size (default = 4K, see **-b** option below).
- k** – multiply by one kilobyte (1,024 bytes).
- m** – multiply by one megabyte (1,048,576 bytes).
- g** – multiply by one gigabyte (1,073,741,824 bytes).
- t** – multiply by one terabyte (1,099,511,627,776 bytes).
- p** – multiply by one petabyte (1,024 terabytes).
- e** – multiply by one exabyte (1,048,576 terabytes).

When specifying parameters in units of sectors or filesystem blocks, the **-s** option or the **-b** option may be used to specify the size of the sector or block. If the size of the block or sector is not specified, the default sizes (block: 4KiB, sector: 512B) will be used.

Many feature options allow an optional argument of 0 or 1, to explicitly disable or enable the functionality.

OPTIONS

Options may be specified either on the command line or in a configuration file. Not all command line options can be specified in configuration files; only the command line options followed by a **[section]** label can be used in a configuration file.

Options that can be used in configuration files are grouped into related sections containing multiple options. The command line options and configuration files use the same option sections and grouping. Configuration file section names are listed in the command line option sections below. Option names and values are the same for both command line and configuration file specification.

Options specified are the combined set of command line parameters and configuration file parameters. Duplicated options will result in a respecification error, regardless of the location they were specified at.

-c configuration_file_option

This option specifies the files that mkfs configuration will be obtained from. The valid *configuration_file_option* is:

options=name

The configuration options will be sourced from the file specified by the *name* option string. This option can be used either an absolute or relative path to the configuration file to be read.

-b block_size_options**Section Name: [block]**

This option specifies the fundamental block size of the filesystem. The valid *block_size_option* is:

size=value

The filesystem block size is specified with a *value* in bytes. The default value is 4096 bytes (4 KiB), the minimum is 512, and the maximum is 65536 (64 KiB).

Although **mkfs.xfs** will accept any of these values and create a valid filesystem, XFS on Linux can only mount filesystems with pagesize or smaller blocks.

-m global_metadata_options**Section Name: [metadata]**

These options specify metadata format options that either apply to the entire filesystem or aren't easily characterised by a specific functionality group. The valid *global_metadata_options* are:

bigtime=value

This option enables filesystems that can handle inode timestamps from December 1901 to July 2486, and quota timer expirations from January 1970 to July 2486. The value is either 0 to disable the feature, or 1 to enable large timestamps.

If this feature is not enabled, the filesystem can only handle timestamps from December 1901 to January 2038, and quota timers from January 1970 to February 2106.

By default, **mkfs.xfs** will not enable this feature. If the option **-m crc=0** is used, the large timestamp feature is not supported and is disabled.

crc=value

This is used to create a filesystem which maintains and checks CRC information in all metadata objects on disk. The value is either 0 to disable the feature, or 1 to enable the use of CRCs.

CRCs enable enhanced error detection due to hardware issues, whilst the format changes also improves crash recovery algorithms and the ability of various tools to validate and repair metadata corruptions when they are found. The CRC algorithm used is CRC32c, so the overhead is dependent on CPU architecture as some CPUs have hardware acceleration of this algorithm. Typically the overhead of calculating and checking the CRCs is not noticeable in normal operation.

By default, **mkfs.xfs** will enable metadata CRCs.

Formatting a filesystem without CRCs selects the V4 format, which is deprecated and will be removed from upstream in September 2030. Distributors may choose to withdraw support for the V4 format earlier than this date. Several other options, noted below, are only tunable on V4 formats, and will be removed along with the V4 format itself.

finobt=value

This option enables the use of a separate free inode btree index in each allocation group. The value is either 0 to disable the feature, or 1 to create a free inode btree in each allocation group.

The free inode btree mirrors the existing allocated inode btree index which indexes both used and free inodes. The free inode btree does not index used inodes, allowing faster, more consistent inode allocation performance as filesystems age.

By default, **mkfs.xfs** will create free inode btrees for filesystems created with the (default) **-m crc=1** option set. When the option **-m crc=0** is used, the free inode btree feature is not supported and is disabled.

inobtcount=value

This option causes the filesystem to record the number of blocks used by the inode btree and the free inode btree. This can be used to reduce mount times when the free inode btree is enabled.

By default, **mkfs.xfs** will not enable this option. This feature is only available for filesystems created with the (default) **-m finobt=1** option set. When the option **-m finobt=0** is used, the inode btree counter feature is not supported and is disabled.

uuid=value

Use the given value as the filesystem UUID for the newly created filesystem. The default is to generate a random UUID.

rmapbt=value

This option enables the creation of a reverse-mapping btree index in each allocation group. The value is either 0 to disable the feature, or 1 to create the btree.

The reverse mapping btree maps filesystem blocks to the owner of the filesystem block. Most of the mappings will be to an inode number and an offset, though there will also be mappings to filesystem metadata. This secondary metadata can be used to validate the primary metadata or to pinpoint exactly which data has been lost when a disk error occurs.

By default, **mkfs.xfs** will not create reverse mapping btrees. This feature is only available for filesystems created with the (default) **-m crc=1** option set. When the option **-m crc=0** is used, the reverse mapping btree feature is not supported and is disabled.

reflink=value

This option enables the use of a separate reference count btree index in each allocation group. The value is either 0 to disable the feature, or 1 to create a reference count btree in each allocation group.

The reference count btree enables the sharing of physical extents between the data forks of different files, which is commonly known as "reflink". Unlike traditional Unix filesystems which assume that every inode and logical block pair map to a unique physical block, a reflink-capable XFS filesystem removes the uniqueness requirement, allowing up to four billion arbitrary inode/logical block pairs to map to a physical block. If a program tries to write to a multiply-referenced block in a file, the write will be redirected to a new block, and that file's logical-to-physical mapping will be changed to the new block ("copy on write"). This feature enables the creation of per-file snapshots and deduplication. It is only available for the data forks of regular files.

By default, **mkfs.xfs** will create reference count btrees and therefore will enable the reflink feature. This feature is only available for filesystems created with the (default) **-m crc=1** option set. When the option **-m crc=0** is used, the reference count btree feature is not supported and reflink is disabled.

Note: the filesystem DAX mount option (**-o dax**) is incompatible with reflink-enabled XFS filesystems. To use filesystem DAX with XFS, specify the **-m reflink=0** option to **mkfs.xfs** to disable the reflink feature.

-d *data_section_options*

Section Name: *[data]*

These options specify the location, size, and other parameters of the data section of the filesystem. The valid *data_section_options* are:

agcount=value

This is used to specify the number of allocation groups. The data section of the filesystem is divided into allocation groups to improve the performance of XFS. More allocation groups imply that more parallelism can be achieved when allocating blocks and inodes. The minimum allocation group size is 16 MiB; the maximum size is just under 1 TiB. The data section of the filesystem is divided into *value* allocation groups (default value is scaled automatically based on the underlying device size).

agsize=value

This is an alternative to using the **agcount** suboption. The *value* is the desired size of the allocation group expressed in bytes (usually using the **m** or **g** suffixes). This value must be a multiple of the filesystem block size, and must be at least 16MiB, and no more than 1TiB, and may be automatically adjusted to properly align with the stripe geometry. The **agcount** and **agsize** suboptions are mutually exclusive.

cowextsize=value

Set the copy-on-write extent size hint on all inodes created by **mkfs.xfs**. The value must be provided in units of filesystem blocks. If the value is zero, the default value (currently 32 blocks) will be used. Directories will pass on this hint to newly created regular files and directories.

name=value

This can be used to specify the name of the special file containing the filesystem. In this case, the log section must be specified as **internal** (with a size, see the **-l** option below) and there can be no real-time section.

file[=value]

This is used to specify that the file given by the **name** suboption is a regular file. The *value* is either 0 or 1, with 1 signifying that the file is regular. This suboption is used only to make a filesystem image. If the *value* is omitted then 1 is assumed.

size=value

This is used to specify the size of the data section. This suboption is required if **-d file[=1]** is given. Otherwise, it is only needed if the filesystem should occupy less space than the size of the special file.

sunit=value

This is used to specify the stripe unit for a RAID device or a logical volume. The *value* has to be specified in 512-byte block units. Use the **su** suboption to specify the stripe unit size in bytes. This suboption ensures that data allocations will be stripe unit aligned when the current end of file is being extended and the file size is larger than 512KiB. Also inode allocations and the internal log will be stripe unit aligned.

su=value

This is an alternative to using **sunit**. The **su** suboption is used to specify the stripe unit for a RAID device or a striped logical volume. The *value* has to be specified in bytes, (usually using the **m** or **g** suffixes). This *value* must be a multiple of the filesystem block size.

swidth=value

This is used to specify the stripe width for a RAID device or a striped logical volume. The *value* has to be specified in 512-byte block units. Use the **sw** suboption to specify the stripe width size in bytes. This suboption is required if **-d sunit** has been specified and it has to be a multiple of the **-d sunit** suboption.

sw=value

suboption is an alternative to using **swidth**. The **sw** suboption is used to specify the stripe width for a RAID device or striped logical volume. The *value* is expressed as a multiplier of the stripe unit, usually the same as the number of stripe members in the logical volume configuration, or data disks in a RAID device.

When a filesystem is created on a logical volume device, **mkfs.xfs** will automatically query the logical volume for appropriate **sunit** and **swidth** values.

noalign

This option disables automatic geometry detection and creates the filesystem without stripe geometry alignment even if the underlying storage device provides this information.

rtinherit=value

If *value* is set to 1, all inodes created by **mkfs.xfs** will be created with the realtime flag set. The default is 0. Directories will pass on this flag to newly created regular files and directories.

projinherit=value

All inodes created by **mkfs.xfs** will be assigned the project quota id provided in *value*. Directories will pass on the project id to newly created regular files and directories.

extszinherit=value

All inodes created by **mkfs.xfs** will have this *value* extent size hint applied. The value must be provided in units of filesystem blocks. Directories will pass on this hint to newly created regular files and directories.

daxinherit=value

If *value* is set to 1, all inodes created by **mkfs.xfs** will be created with the DAX flag set. The default is 0. Directories will pass on this flag to newly created regular files and directories. By default, **mkfs.xfs** will not enable DAX mode.

- f** Force overwrite when an existing filesystem is detected on the device. By default, **mkfs.xfs** will not write to the device if it suspects that there is a filesystem or partition table on the device already.

-i inode_options**Section Name: [inode]**

This option specifies the inode size of the filesystem, and other inode allocation parameters. The XFS inode contains a fixed-size part and a variable-size part. The variable-size part, whose size is affected by this option, can contain: directory data, for small directories; attribute data, for small attribute sets; symbolic link data, for small symbolic links; the extent list for the file, for files with a small number of extents; and the root of a tree describing the location of extents for the file, for

files with a large number of extents.

The valid *inode_options* are:

size=value | perblock=value

The inode size is specified either as a *value* in bytes with **size=** or as the number fitting in a filesystem block with **perblock=**. The minimum (and default) *value* is 256 bytes without crc, 512 bytes with crc enabled. The maximum *value* is 2048 (2 KiB) subject to the restriction that the inode size cannot exceed one half of the filesystem block size.

XFS uses 64-bit inode numbers internally; however, the number of significant bits in an inode number is affected by filesystem geometry. In practice, filesystem size and inode size are the predominant factors. The Linux kernel (on 32 bit hardware platforms) and most applications cannot currently handle inode numbers greater than 32 significant bits, so if no inode size is given on the command line, **mkfs.xfs** will attempt to choose a size such that inode numbers will be < 32 bits. If an inode size is specified, or if a filesystem is sufficiently large, **mkfs.xfs** will warn if this will create inode numbers > 32 significant bits.

maxpct=value

This specifies the maximum percentage of space in the filesystem that can be allocated to inodes. The default *value* is 25% for filesystems under 1TB, 5% for filesystems under 50TB and 1% for filesystems over 50TB.

In the default inode allocation mode, inode blocks are chosen such that inode numbers will not exceed 32 bits, which restricts the inode blocks to the lower portion of the filesystem. The data block allocator will avoid these low blocks to accommodate the specified maxpct, so a high value may result in a filesystem with nothing but inodes in a significant portion of the lower blocks of the filesystem. (This restriction is not present when the filesystem is mounted with the *inode64* option on 64-bit platforms).

Setting the value to 0 means that essentially all of the filesystem can become inode blocks, subject to inode32 restrictions.

This value can be modified with *xfs_growfs(8)*.

align[=value]

This is used to specify that inode allocation is or is not aligned. The *value* is either 0 or 1, with 1 signifying that inodes are allocated aligned. If the *value* is omitted, 1 is assumed. The default is that inodes are aligned. Aligned inode access is normally more efficient than unaligned access; alignment must be established at the time the filesystem is created, since inodes are allocated at that time. This option can be used to turn off inode alignment when the filesystem needs to be mountable by a version of IRIX that does not have the inode alignment feature (any release of IRIX before 6.2, and IRIX 6.2 without XFS patches).

This option is only tunable on the deprecated V4 format.

attr=value

This is used to specify the version of extended attribute inline allocation policy to be used. By default, this is 2, which uses an efficient algorithm for managing the available inline inode space between attribute and extent data.

The previous version 1, which has fixed regions for attribute and extent data, is kept for backwards compatibility with kernels older than version 2.6.16.

This option is only tunable on the deprecated V4 format.

projid32bit[=value]

This is used to enable 32bit quota project identifiers. The *value* is either 0 or 1, with 1 signifying that 32bit projid are to be enabled. If the value is omitted, 1 is assumed. (This default changed in release version 3.2.0.)

This option is only tunable on the deprecated V4 format.

sparse[=value]

Enable sparse inode chunk allocation. The *value* is either 0 or 1, with 1 signifying that sparse allocation is enabled. If the value is omitted, 1 is assumed. Sparse inode allocation is disabled by default. This feature is only available for filesystems formatted with **-m crc=1**.

When enabled, sparse inode allocation allows the filesystem to allocate smaller than the standard 64-inode chunk when free space is severely limited. This feature is useful for filesystems that might fragment free space over time such that no free extents are large enough to accommodate a chunk of 64 inodes. Without this feature enabled, inode allocations can fail with out of space errors under severe fragmented free space conditions.

-l log_section_options

Section Name: [log]

These options specify the location, size, and other parameters of the log section of the filesystem. The valid *log_section_options* are:

agnum=value

If the log is internal, allocate it in this AG.

internal[=value]

This is used to specify that the log section is a piece of the data section instead of being another device or logical volume. The *value* is either 0 or 1, with 1 signifying that the log is internal. If the *value* is omitted, 1 is assumed.

logdev=device

This is used to specify that the log section should reside on the *device* separate from the data section. The **internal=1** and **logdev** options are mutually exclusive.

size=value

This is used to specify the size of the log section.

If the log is contained within the data section and **size** isn't specified, **mkfs.xfs** will try to select a suitable log size depending on the size of the filesystem. The actual logsize depends on the filesystem block size and the directory block size.

Otherwise, the **size** suboption is only needed if the log section of the filesystem should occupy less space than the size of the special file. The *value* is specified in bytes or blocks, with a **b** suffix meaning multiplication by the filesystem block size, as described above. The overriding minimum value for size is 512 blocks. With some combinations of filesystem block size, inode size, and directory block size, the minimum log size is larger than 512 blocks.

version=value

This specifies the version of the log. The current default is 2, which allows for larger log buffer sizes, as well as supporting stripe-aligned log writes (see the **sunit** and **su** options, below).

The previous version 1, which is limited to 32k log buffers and does not support stripe-aligned writes, is kept for backwards compatibility with very old

2.4 kernels.

This option is only tunable on the deprecated V4 format.

sunit=*value*

This specifies the alignment to be used for log writes. The *value* has to be specified in 512-byte block units. Use the **su** suboption to specify the log stripe unit size in bytes. Log writes will be aligned on this boundary, and rounded up to this boundary. This gives major improvements in performance on some configurations such as software RAID5 when the **sunit** is specified as the filesystem block size. The equivalent byte value must be a multiple of the filesystem block size. Version 2 logs are automatically selected if the log **sunit** suboption is specified.

The **su** suboption is an alternative to using **sunit**.

su=*value*

This is used to specify the log stripe. The *value* has to be specified in bytes, (usually using the **s** or **b** suffixes). This value must be a multiple of the filesystem block size. Version 2 logs are automatically selected if the log **su** suboption is specified.

lazy-count=*value*

This changes the method of logging various persistent counters in the superblock. Under metadata intensive workloads, these counters are updated and logged frequently enough that the superblock updates become a serialization point in the filesystem. The *value* can be either 0 or 1.

With **lazy-count=1**, the superblock is not modified or logged on every change of the persistent counters. Instead, enough information is kept in other parts of the filesystem to be able to maintain the persistent counter values without needed to keep them in the superblock. This gives significant improvements in performance on some configurations. The default *value* is 1 (on) so you must specify **lazy-count=0** if you want to disable this feature for older kernels which don't support it.

This option is only tunable on the deprecated V4 format.

-n *naming_options*

Section Name: *[naming]*

These options specify the version and size parameters for the naming (directory) area of the filesystem. The valid *naming_options* are:

size=*value*

The directory block size is specified with a *value* in bytes. The block size must be a power of 2 and cannot be less than the filesystem block size. The default size *value* for version 2 directories is 4096 bytes (4 KiB), unless the filesystem block size is larger than 4096, in which case the default *value* is the filesystem block size. For version 1 directories the block size is the same as the filesystem block size.

version=*value*

The naming (directory) version *value* can be either 2 or 'ci', defaulting to 2 if unspecified. With version 2 directories, the directory block size can be any power of 2 size from the filesystem block size up to 65536.

The **version=ci** option enables ASCII only case-insensitive filename lookup and version 2 directories. Filenames are case-preserving, that is, the names are stored in directories using the case they were created with.

Note: Version 1 directories are not supported.

f*type*=*value*

This feature allows the inode type to be stored in the directory structure so that the **readdir**(3) and **getdents**(2) do not need to look up the inode to determine the inode type.

The *value* is either 0 or 1, with 1 signifying that filetype information will be stored in the directory structure. The default value is 1.

When CRCs are enabled (the default), the ftype functionality is always enabled, and cannot be turned off.

In other words, this option is only tunable on the deprecated V4 format.

-p *protofile*

If the optional **-p** *protofile* argument is given, **mkfs.xfs** uses *protofile* as a prototype file and takes its directions from that file. The blocks and inodes specifiers in the *protofile* are provided for backwards compatibility, but are otherwise unused. The syntax of the protofile is defined by a number of tokens separated by spaces or newlines. Note that the line numbers are not part of the syntax but are meant to help you in the following discussion of the file contents.

```

1      /stand/diskboot
2      4872 110
3      d--777 3 1
4      usr      d--777 3 1
5      sh       ---755 3 1 /bin/sh
6      ken      d--755 6 1
7      $
8      b0      b--644 3 1 0 0
9      c0      c--644 3 1 0 0
10     fifo     p--644 3 1
11     slink    l--644 3 1 /a/symbolic/link
12     : This is a comment line
13     $
14     $
```

Line 1 is a dummy string. (It was formerly the bootfilename.) It is present for backward compatibility; boot blocks are not used on SGI systems.

Note that some string of characters must be present as the first line of the proto file to cause it to be parsed correctly; the value of this string is immaterial since it is ignored.

Line 2 contains two numeric values (formerly the numbers of blocks and inodes). These are also merely for backward compatibility: two numeric values must appear at this point for the proto file to be correctly parsed, but their values are immaterial since they are ignored.

The lines 3 through 11 specify the files and directories you want to include in this filesystem. Line 3 defines the root directory. Other directories and files that you want in the filesystem are indicated by lines 4 through 6 and lines 8 through 10. Line 11 contains symbolic link syntax.

Notice the dollar sign (\$) syntax on line 7. This syntax directs the **mkfs.xfs** command to terminate the branch of the filesystem it is currently on and then continue from the directory specified by the next line, in this case line 8. It must be the last character on a line. The colon on line 12 introduces a comment; all characters up until the following newline are ignored. Note that this means you cannot have a file in a prototype file whose name contains a colon. The \$ on lines 13 and 14 end the process, since no additional specifications follow.

File specifications provide the following:

- * file mode
- * user ID

* group ID
 * the file's beginning contents

A 6-character string defines the mode for a file. The first character of this string defines the file type. The character range for this first character is **-bcdpl**. A file may be a regular file, a block special file, a character special file, directory files, named pipes (first-in, first out files), and symbolic links. The second character of the mode string is used to specify setuserID mode, in which case it is **u**. If setuserID mode is not specified, the second character is **-**. The third character of the mode string is used to specify the setgroupID mode, in which case it is **g**. If setgroupID mode is not specified, the third character is **-**. The remaining characters of the mode string are a three digit octal number. This octal number defines the owner, group, and other read, write, and execute permissions for the file, respectively. For more information on file permissions, see the **chmod(1)** command.

Following the mode character string are two decimal number tokens that specify the user and group IDs of the file's owner.

In a regular file, the next token specifies the pathname from which the contents and size of the file are copied. In a block or character special file, the next token are two decimal numbers that specify the major and minor device numbers. When a file is a symbolic link, the next token specifies the contents of the link.

When the file is a directory, the **mkfs.xfs** command creates the entries **dot** (.) and **dot-dot** (..) and then reads the list of names and file specifications in a recursive manner for all of the entries in the directory. A scan of the protofile is always terminated with the dollar (\$) token.

-q Quiet option. Normally **mkfs.xfs** prints the parameters of the filesystem to be constructed; the **-q** flag suppresses this.

-r realtime_section_options

Section Name: *[realtime]*

These options specify the location, size, and other parameters of the real-time section of the filesystem. The valid *realtime_section_options* are:

rtdev=device

This is used to specify the *device* which should contain the real-time section of the filesystem. The suboption value is the name of a block device.

extsize=value

This is used to specify the size of the blocks in the real-time section of the filesystem. This *value* must be a multiple of the filesystem block size. The minimum allowed size is the filesystem block size or 4 KiB (whichever is larger); the default size is the stripe width for striped volumes or 64 KiB for non-striped volumes; the maximum allowed size is 1 GiB. The real-time extent size should be carefully chosen to match the parameters of the physical media used.

size=value

This is used to specify the size of the real-time section. This suboption is only needed if the real-time section of the filesystem should occupy less space than the size of the partition or logical volume containing the section.

noalign

This option disables stripe size detection, enforcing a realtime device with no stripe geometry.

-s sector_size_options

Section Name: *[sector]*

This option specifies the fundamental sector size of the filesystem. The valid *sector_size_option* is:

size=value

The sector size is specified with a *value* in bytes. The default *sector_size* is 512 bytes. The minimum value for sector size is 512; the maximum is 32768 (32 KiB). The *sector_size* must be a power of 2 size and cannot be made larger than the filesystem block size.

-L label

Set the filesystem *label*. XFS filesystem labels can be at most 12 characters long; if *label* is longer than 12 characters, **mkfs.xfs** will not proceed with creating the filesystem. Refer to the **mount(8)** and **xfs_admin(8)** manual entries for additional information.

- N** Causes the file system parameters to be printed out without really creating the file system.
- K** Do not attempt to discard blocks at mkfs time.
- V** Prints the version number and exits.

Configuration File Format

The configuration file uses a basic INI format to specify sections and options within a section. Section and option names are case sensitive. Section names must not contain whitespace. Options are name-value pairs, ended by the first whitespace in the line. Option names cannot contain whitespace. Full line comments can be added by starting a line with a # symbol. If values contain whitespace, then it must be quoted.

The following example configuration file sets the block size to 4096 bytes, turns on reverse mapping btrees and sets the inode size to 2048 bytes.

```
# Example mkfs.xfs configuration file
```

```
[block]
size=4k
```

```
[metadata]
rmapbt=1
```

```
[inode]
size=2048
```

BUGS

With a prototype file, it is not possible to specify hard links.

NAME

modinfo – Show information about a Linux Kernel module

SYNOPSIS

modinfo [**-0**] [**-F field**] [**-k kernel**] [modulename|filename...]

modinfo -V

modinfo -h

DESCRIPTION

modinfo extracts information from the Linux Kernel modules given on the command line. If the module name is not a filename, then the `/lib/modules/version` directory is searched, as is also done by **modprobe(8)** when loading kernel modules.

modinfo by default lists each attribute of the module in form *fieldname* : *value*, for easy reading. The filename is listed the same way (although it's not really an attribute).

This version of **modinfo** can understand modules of any Linux Kernel architecture.

OPTIONS

-V, --version

Print the modinfo version.

-F, --field

Only print this field value, one per line. This is most useful for scripts. Field names are case-insensitive. Common fields (which may not be in every module) include author, description, license, parm, depends, and alias. There are often multiple parm, alias and depends fields. The special field filename lists the filename of the module.

-b basedir, --basedir basedir

Root directory for modules, / by default.

-k kernel

Provide information about a kernel other than the running one. This is particularly useful for distributions needing to extract information from a newly installed (but not yet running) set of kernel modules. For example, you wish to find which firmware files are needed by various modules in a new kernel for which you must make an initrd/initramfs image prior to booting.

-0, --null

Use the ASCII zero character to separate field values, instead of a new line. This is useful for scripts, since a new line can theoretically appear inside a field.

-a --author, -d --description, -l --license, -p --parameters, -n --filename

These are shortcuts for the **--field** flag's author, description, license, parm and filename arguments, to ease the transition from the old modutils **modinfo**.

NAME

modprobe – Add and remove modules from the Linux Kernel

SYNOPSIS

```
modprobe [-v] [-V] [-C config-file] [-n] [-i] [-q] [-b] [modulename] [module parameters...]
modprobe [-r] [-v] [-n] [-i] [modulename...]
modprobe [-c]
modprobe [--dump-modversions] [filename]
```

DESCRIPTION

modprobe intelligently adds or removes a module from the Linux kernel: note that for convenience, there is no difference between _ and – in module names (automatic underscore conversion is performed). **modprobe** looks in the module directory /lib/modules/`uname -r` for all the modules and other files, except for the optional configuration files in the /etc/modprobe.d directory (see **modprobe.d(5)**). **modprobe** will also use module options specified on the kernel command line in the form of <module>,<option> and blacklists in the form of modprobe.blacklist=<module>.

Note that unlike in 2.4 series Linux kernels (which are not supported by this tool) this version of **modprobe** does not do anything to the module itself: the work of resolving symbols and understanding parameters is done inside the kernel. So module failure is sometimes accompanied by a kernel message: see **dmesg(8)**.

modprobe expects an up-to-date modules.dep.bin file as generated by the corresponding **depmod** utility shipped along with **modprobe** (see **depmod(8)**). This file lists what other modules each module needs (if any), and **modprobe** uses this to add or remove these dependencies automatically.

If any arguments are given after the *modulename*, they are passed to the kernel (in addition to any options listed in the configuration file).

OPTIONS**-a, --all**

Insert all module names on the command line.

-b, --use-blacklist

This option causes **modprobe** to apply the **blacklist** commands in the configuration files (if any) to module names as well. It is usually used by **udev(7)**.

-C, --config

This option overrides the default configuration directory (/etc/modprobe.d).

This option is passed through **install** or **remove** commands to other **modprobe** commands in the MODPROBE_OPTIONS environment variable.

-c, --showconfig

Dump out the effective configuration from the config directory and exit.

--dump-modversions

Print out a list of module versioning information required by a module. This option is commonly used by distributions in order to package up a Linux kernel module using module versioning deps.

-d, --dirname

Root directory for modules, / by default.

--first-time

Normally, **modprobe** will succeed (and do nothing) if told to insert a module which is already present or to remove a module which isn't present. This is ideal for simple scripts; however, more complicated scripts often want to know whether **modprobe** really did something: this option makes modprobe fail in the case that it actually didn't do anything.

--force-vermagic

Every module contains a small string containing important information, such as the kernel and compiler versions. If a module fails to load and the kernel complains that the "version magic" doesn't

match, you can use this option to remove it. Naturally, this check is there for your protection, so using this option is dangerous unless you know what you're doing.

This applies to any modules inserted: both the module (or alias) on the command line and any modules on which it depends.

--force-modversion

When modules are compiled with CONFIG_MODVERSIONS set, a section detailing the versions of every interface used by (or supplied by) the module is created. If a module fails to load and the kernel complains that the module disagrees about a version of some interface, you can use "--force-modversion" to remove the version information altogether. Naturally, this check is there for your protection, so using this option is dangerous unless you know what you're doing.

This applies any modules inserted: both the module (or alias) on the command line and any modules on which it depends.

-f, --force

Try to strip any versioning information from the module which might otherwise stop it from loading: this is the same as using both **--force-vermagic** and **--force-modversion**. Naturally, these checks are there for your protection, so using this option is dangerous unless you know what you are doing.

This applies to any modules inserted: both the module (or alias) on the command line and any modules it on which it depends.

-i, --ignore-install, --ignore-remove

This option causes **modprobe** to ignore **install** and **remove** commands in the configuration file (if any) for the module specified on the command line (any dependent modules are still subject to commands set for them in the configuration file). Both **install** and **remove** commands will currently be ignored when this option is used regardless of whether the request was more specifically made with only one or other (and not both) of **--ignore-install** or **--ignore-remove**. See **modprobe.d(5)**.

-n, --dry-run, --show

This option does everything but actually insert or delete the modules (or run the install or remove commands). Combined with **-v**, it is useful for debugging problems. For historical reasons both **--dry-run** and **--show** actually mean the same thing and are interchangeable.

-q, --quiet

With this flag, **modprobe** won't print an error message if you try to remove or insert a module it can't find (and isn't an alias or **install/remove** command). However, it will still return with a non-zero exit status. The kernel uses this to opportunistically probe for modules which might exist using **request_module**.

-R, --resolve-alias

Print all module names matching an alias. This can be useful for debugging module alias problems.

-r, --remove

This option causes **modprobe** to remove rather than insert a module. If the modules it depends on are also unused, **modprobe** will try to remove them too. Unlike insertion, more than one module can be specified on the command line (it does not make sense to specify module parameters when removing modules).

There is usually no reason to remove modules, but some buggy modules require it. Your distribution kernel may not have been built to support removal of modules at all.

-S, --set-version

Set the kernel version, rather than using **uname(2)** to decide on the kernel version (which dictates where to find the modules).

--show-dependents

List the dependencies of a module (or alias), including the module itself. This produces a (possibly

empty) set of module filenames, one per line, each starting with "insmod" and is typically used by distributions to determine which modules to include when generating initrd/initramfs images. **Install** commands which apply are shown prefixed by "install". It does not run any of the install commands. Note that **modinfo(8)** can be used to extract dependencies of a module from the module itself, but knows nothing of aliases or install commands.

-s, --syslog

This option causes any error messages to go through the syslog mechanism (as LOG_DAEMON with level LOG_NOTICE) rather than to standard error. This is also automatically enabled when stderr is unavailable.

This option is passed through **install** or **remove** commands to other **modprobe** commands in the MODPROBE_OPTIONS environment variable.

-V, --version

Show version of program and exit.

-v, --verbose

Print messages about what the program is doing. Usually **modprobe** only prints messages if something goes wrong.

This option is passed through **install** or **remove** commands to other **modprobe** commands in the MODPROBE_OPTIONS environment variable.

ENVIRONMENT

The MODPROBE_OPTIONS environment variable can also be used to pass arguments to **modprobe**.

NAME

modprobe.d – Configuration directory for modprobe

SYNOPSIS

```
/lib/modprobe.d/*.conf
/usr/local/lib/modprobe.d/*.conf
/run/modprobe.d/*.conf
/etc/modprobe.d/*.conf
```

DESCRIPTION

Because the **modprobe** command can add or remove more than one module, due to modules having dependencies, we need a method of specifying what options are to be used with those modules. All files underneath the /etc/modprobe.d directory which end with the .conf extension specify those options as required. They can also be used to create convenient aliases: alternate names for a module, or they can override the normal **modprobe** behavior altogether for those with special requirements (such as inserting more than one module).

Note that module and alias names (like other module names) can have – or _ in them: both are interchangeable throughout all the module commands as underscore conversion happens automatically.

The format of files under modprobe.d is simple: one command per line, with blank lines and lines starting with #' ignored (useful for adding comments). A \' at the end of a line causes it to continue on the next line, which makes the file a bit neater.

COMMANDS*alias wildcard modulename*

This allows you to give alternate names for a module. For example: "alias my-mod really_long_modulename" means you can use "modprobe my-mod" instead of "modprobe really_long_modulename". You can also use shell-style wildcards, so "alias my-mod* really_long_modulename" means that "modprobe my-mod–something" has the same effect. You can't have aliases to other aliases (that way lies madness), but aliases can have options, which will be added to any other options.

Note that modules can also contain their own aliases, which you can see using **modinfo**. These aliases are used as a last resort (ie. if there is no real module, **install**, **remove**, or **alias** command in the configuration).

blacklist modulename

Modules can contain their own aliases: usually these are aliases describing the devices they support, such as "pci:123...". These "internal" aliases can be overridden by normal "alias" keywords, but there are cases where two or more modules both support the same devices, or a module invalidly claims to support a device that it does not: the **blacklist** keyword indicates that all of that particular module's internal aliases are to be ignored.

install modulename command...

This command instructs **modprobe** to run your command instead of inserting the module in the kernel as normal. The command can be any shell command: this allows you to do any kind of complex processing you might wish. For example, if the module "fred" works better with the module "barney" already installed (but it doesn't depend on it, so **modprobe** won't automatically load it), you could say "install fred /sbin/modprobe barney; /sbin/modprobe --ignore-install fred", which would do what you wanted. Note the **--ignore-install**, which stops the second **modprobe** from running the same **install** command again. See also **remove** below.

The long term future of this command as a solution to the problem of providing additional module dependencies is not assured and it is intended to replace this command with a warning about its eventual removal or deprecation at some point in a future release. Its use complicates the automated determination of module dependencies by distribution utilities, such as mkinitrd (because these now

need to somehow interpret what the **install** commands might be doing. In a perfect world, modules would provide all dependency information without the use of this command and work is underway to implement soft dependency support within the Linux kernel.

If you use the string "\$CMDLINE_OPTS" in the command, it will be replaced by any options specified on the modprobe command line. This can be useful because users expect "modprobe fred opt=1" to pass the "opt=1" arg to the module, even if there's an install command in the configuration file. So our above example becomes "install fred /sbin/modprobe barney; /sbin/modprobe ---ignore--install fred \$CMDLINE_OPTS"

options modulename option...

This command allows you to add options to the module *modulename* (which might be an alias) every time it is inserted into the kernel: whether directly (using **modprobe modulename**) or because the module being inserted depends on this module.

All options are added together: they can come from an **option** for the module itself, for an alias, and on the command line.

remove modulename command...

This is similar to the **install** command above, except it is invoked when "modprobe -r" is run.

softdep modulename pre: modules... post: modules...

The **softdep** command allows you to specify soft, or optional, module dependencies. *modulename* can be used without these optional modules installed, but usually with some features missing. For example, a driver for a storage HBA might require another module be loaded in order to use management features.

pre-deps and post-deps modules are lists of names and/or aliases of other modules that modprobe will attempt to install (or remove) in order before and after the main module given in the *modulename* argument.

Example: Assume "softdep c pre: a b post: d e" is provided in the configuration. Running "modprobe c" is now equivalent to "modprobe a b c d e" without the softdep. Flags such as --use-blacklist are applied to all the specified modules, while module parameters only apply to module c.

Note: if there are **install** or **remove** commands with the same *modulename* argument, **softdep** takes precedence.

COMPATIBILITY

A future version of kmod will come with a strong warning to avoid use of the **install** as explained above. This will happen once support for soft dependencies in the kernel is complete. That support will complement the existing softdep support within this utility by providing such dependencies directly within the modules.

MODPROBE.D(5)

modprobe.d

MODPROBE.D(5)

NAME

/etc/modules - kernel modules to load at boot time

DESCRIPTION

The **/etc/modules** file contains the names of kernel modules that are to be loaded at boot time, one per line. Options can only be specified using **modprobe.d** configuration files. Lines beginning with a '#' are ignored.

EXAMPLE

```
# /etc/modules: kernel modules to load at boot time.  
#  
# This file contains the names of kernel modules that  
# should be loaded at boot time, one per line. Lines  
# beginning with "#" are ignored.

NAME

more – file perusal filter for crt viewing

SYNOPSIS

more [options] *file* ...

DESCRIPTION

more is a filter for paging through text one screenful at a time. This version is especially primitive. Users should realize that **less(1)** provides **more(1)** emulation plus extensive enhancements.

OPTIONS

Options are also taken from the environment variable **MORE** (make sure to precede them with a dash (-)) but command-line options will override those.

-d, --silent

Prompt with "[Press space to continue, 'q' to quit.]", and display "[Press 'h' for instructions.]" instead of ringing the bell when an illegal key is pressed.

-l, --logical

Do not pause after any line containing a ^L (form feed).

-e, --exit-on-eof

Exit on End-Of-File, enabled by default if not executed on terminal.

-f, --no-pause

Count logical lines, rather than screen lines (i.e., long lines are not folded).

-p, --print-over

Do not scroll. Instead, clear the whole screen and then display the text. Notice that this option is switched on automatically if the executable is named **page**.

-c, --clean-print

Do not scroll. Instead, paint each screen from the top, clearing the remainder of each line as it is displayed.

-s, --squeeze

Squeeze multiple blank lines into one.

-u, --plain

Suppress underlining. This option is silently ignored as backwards compatibility.

-n, --lines *number*

Specify the *number* of lines per screenful. The *number* argument is a positive decimal integer. The **--lines** option shall override any values obtained from any other source, such as number of lines reported by terminal.

number

A numeric option means the same as **--lines** option argument.

+*number*

Start displaying each file at line *number*.

+/*string*

The *string* to be searched in each file before starting to display it.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

COMMANDS

Interactive commands for **more** are based on **vi(1)**. Some commands may be preceded by a decimal number, called k in the descriptions below. In the following descriptions, **^X** means **control-X**.

h or ?

Help; display a summary of these commands. If you forget all other commands, remember this one.

SPACE

Display next k lines of text. Defaults to current screen size.

z

Display next k lines of text. Defaults to current screen size. Argument becomes new default.

RETURN

Display next k lines of text. Defaults to 1. Argument becomes new default.

d or ^D

Scroll k lines. Default is current scroll size, initially 11. Argument becomes new default.

q or Q or INTERRUPT

Exit.

s

Skip forward k lines of text. Defaults to 1.

f

Skip forward k screenfuls of text. Defaults to 1.

b or ^B

Skip backwards k screenfuls of text. Defaults to 1. Only works with files, not pipes.

,

Go to the place where the last search started.

=

Display current line number.

/pattern

Search for kth occurrence of regular expression. Defaults to 1.

n

Search for kth occurrence of last regular expression. Defaults to 1.

!command or :!command

Execute *command* in a subshell.

v

Start up an editor at current line. The editor is taken from the environment variable **VISUAL** if defined, or **EDITOR** if **VISUAL** is not defined, or defaults to **vi(1)** if neither **VISUAL** nor **EDITOR** is defined.

^L

Redraw screen.

:n

Go to kth next file. Defaults to 1.

:p

Go to kth previous file. Defaults to 1.

:f

Display current file name and line number.

.

Repeat previous command.

ENVIRONMENT

The **more** command respects the following environment variables, if they exist:

MORE

This variable may be set with favored options to **more**.

SHELL

Current shell in use (normally set by the shell at login time).

TERM

The terminal type used by **more** to get the terminal characteristics necessary to manipulate the screen.

VISUAL

The editor the user prefers. Invoked when command key *v* is pressed.

EDITOR

The editor of choice when **VISUAL** is not specified.

HISTORY

The **more** command appeared in 3.0BSD. This man page documents **more** version 5.19 (Berkeley 6/29/88), which is currently in use in the Linux community. Documentation was produced using several other versions of the man page, and extensive inspection of the source code.

AUTHORS

Eric Shienbrood, UC Berkeley.

Modified by Geoff Peck, UCB to add underlining, single spacing.

Modified by John Foderaro, UCB to add -c and MORE environment variable.

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **more** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

`mount` – mount filesystem

LIBRARY

Standard C library (`libc, -lc`)

SYNOPSIS

```
#include <sys/mount.h>
int mount(const char *source, const char *target,
          const char *filesystemtype, unsigned long mountflags,
          const void *_Nullable data);
```

DESCRIPTION

`mount()` attaches the filesystem specified by *source* (which is often a pathname referring to a device, but can also be the pathname of a directory or file, or a dummy string) to the location (a directory or file) specified by the pathname in *target*.

Appropriate privilege (Linux: the **CAP_SYS_ADMIN** capability) is required to mount filesystems.

Values for the *filesystemtype* argument supported by the kernel are listed in */proc/filesystems* (e.g., "btrfs", "ext4", "jfs", "xfs", "vfat", "fuse", "tmpfs", "cgroup", "proc", "mqueue", "nfs", "cifs", "iso9660"). Further types may become available when the appropriate modules are loaded.

The *data* argument is interpreted by the different filesystems. Typically it is a string of comma-separated options understood by this filesystem. See **mount(8)** for details of the options available for each filesystem type. This argument may be specified as NULL, if there are no options.

A call to `mount()` performs one of a number of general types of operation, depending on the bits specified in *mountflags*. The choice of which operation to perform is determined by testing the bits set in *mountflags*, with the tests being conducted in the order listed here:

- Remount an existing mount: *mountflags* includes **MS_REMOUNT**.
- Create a bind mount: *mountflags* includes **MS_BIND**.
- Change the propagation type of an existing mount: *mountflags* includes one of **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE**.
- Move an existing mount to a new location: *mountflags* includes **MS_MOVE**.
- Create a new mount: *mountflags* includes none of the above flags.

Each of these operations is detailed later in this page. Further flags may be specified in *mountflags* to modify the behavior of `mount()`, as described below.

Additional mount flags

The list below describes the additional flags that can be specified in *mountflags*. Note that some operation types ignore some or all of these flags, as described later in this page.

MS_DIRSYNC (since Linux 2.5.19)

Make directory changes on this filesystem synchronous. (This property can be obtained for individual directories or subtrees using **chattr(1)**.)

MS_LAZYTIME (since Linux 4.0)

Reduce on-disk updates of inode timestamps (atime, mtime, ctime) by maintaining these changes only in memory. The on-disk timestamps are updated only when:

- the inode needs to be updated for some change unrelated to file timestamps;
- the application employs **fsync(2)**, **syncfs(2)**, or **sync(2)**;
- an undeleted inode is evicted from memory; or
- more than 24 hours have passed since the inode was written to disk.

This mount option significantly reduces writes needed to update the inode's timestamps, especially mtime and atime. However, in the event of a system crash, the atime and mtime fields on disk

might be out of date by up to 24 hours.

Examples of workloads where this option could be of significant benefit include frequent random writes to preallocated files, as well as cases where the **MS_STRICTATIME** mount option is also enabled. (The advantage of combining **MS_STRICTATIME** and **MS_LAZYTIME** is that **stat(2)** will return the correctly updated atime, but the atime updates will be flushed to disk only in the cases listed above.)

MS_MANDLOCK

Permit mandatory locking on files in this filesystem. (Mandatory locking must still be enabled on a per-file basis, as described in **fctl(2)**.) Since Linux 4.5, this mount option requires the **CAP_SYS_ADMIN** capability and a kernel configured with the **CONFIG_MANDATORY_FILE_LOCKING** option. Mandatory locking has been fully deprecated in Linux 5.15, so this flag should be considered deprecated.

MS_NOATIME

Do not update access times for (all types of) files on this filesystem.

MS_NODEV

Do not allow access to devices (special files) on this filesystem.

MS_NODIRATIME

Do not update access times for directories on this filesystem. This flag provides a subset of the functionality provided by **MS_NOATIME**; that is, **MS_NOATIME** implies **MS_NODIRATIME**.

MS_NOEXEC

Do not allow programs to be executed from this filesystem.

MS_NOSUID

Do not honor set-user-ID and set-group-ID bits or file capabilities when executing programs from this filesystem. In addition, SELinux domain transitions require the permission *nosuid_transition*, which in turn needs also the policy capability *nnp_nosuid_transition*.

MS_RDONLY

Mount filesystem read-only.

MS_REC (since Linux 2.4.11)

Used in conjunction with **MS_BIND** to create a recursive bind mount, and in conjunction with the propagation type flags to recursively change the propagation type of all of the mounts in a subtree. See below for further details.

MS_RELATIME (since Linux 2.6.20)

When a file on this filesystem is accessed, update the file's last access time (atime) only if the current value of atime is less than or equal to the file's last modification time (mtime) or last status change time (ctime). This option is useful for programs, such as **mutt(1)**, that need to know when a file has been read since it was last modified. Since Linux 2.6.30, the kernel defaults to the behavior provided by this flag (unless **MS_NOATIME** was specified), and the **MS_STRICTATIME** flag is required to obtain traditional semantics. In addition, since Linux 2.6.30, the file's last access time is always updated if it is more than 1 day old.

MS_SILENT (since Linux 2.6.17)

Suppress the display of certain (*printk()*) warning messages in the kernel log. This flag supersedes the misnamed and obsolete **MS_VERBOSE** flag (available since Linux 2.4.12), which has the same meaning.

MS_STRICTATIME (since Linux 2.6.30)

Always update the last access time (atime) when files on this filesystem are accessed. (This was the default behavior before Linux 2.6.30.) Specifying this flag overrides the effect of setting the **MS_NOATIME** and **MS_RELATIME** flags.

MS_SYNCHRONOUS

Make writes on this filesystem synchronous (as though the **O_SYNC** flag to **open(2)** was specified for all file opens to this filesystem).

MS_NOSYMFOLLOW (since Linux 5.10)

Do not follow symbolic links when resolving paths. Symbolic links can still be created, and **readlink(1)**, **readlink(2)**, **realpath(1)**, and **realpath(3)** all still work properly.

From Linux 2.4 onward, some of the above flags are settable on a per-mount basis, while others apply to the superblock of the mounted filesystem, meaning that all mounts of the same filesystem share those flags. (Previously, all of the flags were per-superblock.)

The per-mount-point flags are as follows:

- Since Linux 2.4: **MS_NODEV**, **MS_NOEXEC**, and **MS_NOSUID** flags are settable on a per-mount-point basis.
- Additionally, since Linux 2.6.16: **MS_NOATIME** and **MS_NODIRATIME**.
- Additionally, since Linux 2.6.20: **MS_RELATIME**.

The following flags are per-superblock: **MS_DIRSYNC**, **MS_LAZYTIME**, **MS_MANDLOCK**, **MS_SILENT**, and **MS_SYNCHRONOUS**. The initial settings of these flags are determined on the first mount of the filesystem, and will be shared by all subsequent mounts of the same filesystem. Subsequently, the settings of the flags can be changed via a remount operation (see below). Such changes will be visible via all mounts associated with the filesystem.

Since Linux 2.6.16, **MS_RDONLY** can be set or cleared on a per-mount-point basis as well as on the underlying filesystem superblock. The mounted filesystem will be writable only if neither the filesystem nor the mountpoint are flagged as read-only.

Remounting an existing mount

An existing mount may be remounted by specifying **MS_REMOUNT** in *mountflags*. This allows you to change the *mountflags* and *data* of an existing mount without having to unmount and remount the filesystem. *target* should be the same value specified in the initial **mount()** call.

The *source* and *filesystemtype* arguments are ignored.

The *mountflags* and *data* arguments should match the values used in the original **mount()** call, except for those parameters that are being deliberately changed.

The following *mountflags* can be changed: **MS_LAZYTIME**, **MS_MANDLOCK**, **MS_NOATIME**, **MS_NODEV**, **MS_NODIRATIME**, **MS_NOEXEC**, **MS_NOSUID**, **MS_RELATIME**, **MS_RDONLY**, **MS_STRICTATIME** (whose effect is to clear the **MS_NOATIME** and **MS_RELATIME** flags), and **MS_SYNCHRONOUS**. Attempts to change the setting of the **MS_DIRSYNC** and **MS_SILENT** flags during a remount are silently ignored. Note that changes to per-superblock flags are visible via all mounts of the associated filesystem (because the per-superblock flags are shared by all mounts).

Since Linux 3.17, if none of **MS_NOATIME**, **MS_NODIRATIME**, **MS_RELATIME**, or **MS_STRICTATIME** is specified in *mountflags*, then the remount operation preserves the existing values of these flags (rather than defaulting to **MS_RELATIME**).

Since Linux 2.6.26, the **MS_REMOUNT** flag can be used with **MS_BIND** to modify only the per-mount-point flags. This is particularly useful for setting or clearing the "read-only" flag on a mount without changing the underlying filesystem. Specifying *mountflags* as:

```
MS_REMOUNT | MS_BIND | MS_RDONLY
```

will make access through this mountpoint read-only, without affecting other mounts.

Creating a bind mount

If *mountflags* includes **MS_BIND** (available since Linux 2.4), then perform a bind mount. A bind mount makes a file or a directory subtree visible at another point within the single directory hierarchy. Bind mounts may cross filesystem boundaries and span **chroot(2)** jails.

The *filesystemtype* and *data* arguments are ignored.

The remaining bits (other than **MS_REC**, described below) in the *mountflags* argument are also ignored. (The bind mount has the same mount options as the underlying mount.) However, see the discussion of re-mounting above, for a method of making an existing bind mount read-only.

By default, when a directory is bind mounted, only that directory is mounted; if there are any submounts under the directory tree, they are not bind mounted. If the **MS_REC** flag is also specified, then a recursive bind mount operation is performed: all submounts under the *source* subtree (other than unbindable mounts) are also bind mounted at the corresponding location in the *target* subtree.

Changing the propagation type of an existing mount

If *mountflags* includes one of **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE** (all available since Linux 2.6.15), then the propagation type of an existing mount is changed. If more than one of these flags is specified, an error results.

The only other flags that can be specified while changing the propagation type are **MS_REC** (described below) and **MS_SILENT** (which is ignored).

The *source*, *filesystemtype*, and *data* arguments are ignored.

The meanings of the propagation type flags are as follows:

MS_SHARED

Make this mount shared. Mount and unmount events immediately under this mount will propagate to the other mounts that are members of this mount's peer group. Propagation here means that the same mount or unmount will automatically occur under all of the other mounts in the peer group. Conversely, mount and unmount events that take place under peer mounts will propagate to this mount.

MS_PRIVATE

Make this mount private. Mount and unmount events do not propagate into or out of this mount.

MS_SLAVE

If this is a shared mount that is a member of a peer group that contains other members, convert it to a slave mount. If this is a shared mount that is a member of a peer group that contains no other members, convert it to a private mount. Otherwise, the propagation type of the mount is left unchanged.

When a mount is a slave, mount and unmount events propagate into this mount from the (master) shared peer group of which it was formerly a member. Mount and unmount events under this mount do not propagate to any peer.

A mount can be the slave of another peer group while at the same time sharing mount and unmount events with a peer group of which it is a member.

MS_UNBINDABLE

Make this mount unbindable. This is like a private mount, and in addition this mount can't be bind mounted. When a recursive bind mount (**mount()** with the **MS_BIND** and **MS_REC** flags) is performed on a directory subtree, any unbindable mounts within the subtree are automatically pruned (i.e., not replicated) when replicating that subtree to produce the target subtree.

By default, changing the propagation type affects only the *target* mount. If the **MS_REC** flag is also specified in *mountflags*, then the propagation type of all mounts under *target* is also changed.

For further details regarding mount propagation types (including the default propagation type assigned to new mounts), see **mount_namespaces(7)**.

Moving a mount

If *mountflags* contains the flag **MS_MOVE** (available since Linux 2.4.18), then move a subtree: *source* specifies an existing mount and *target* specifies the new location to which that mount is to be relocated. The move is atomic: at no point is the subtree unmounted.

The remaining bits in the *mountflags* argument are ignored, as are the *filesystemtype* and *data* arguments.

Creating a new mount

If none of **MS_REMOUNT**, **MS_BIND**, **MS_MOVE**, **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE** is specified in *mountflags*, then **mount()** performs its default action: creating a new mount. *source* specifies the source for the new mount, and *target* specifies the directory at which to create the mount point.

The *filesystemtype* and *data* arguments are employed, and further bits may be specified in *mountflags* to modify the behavior of the call.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

The error values given below result from filesystem type independent errors. Each filesystem type may have its own special errors and its own special behavior. See the Linux kernel source code for details.

EACCES

A component of a path was not searchable. (See also **path_resolution(7)**.)

EACCES

Mounting a read-only filesystem was attempted without giving the **MS_RDONLY** flag.

The filesystem may be read-only for various reasons, including: it resides on a read-only optical disk; it is resides on a device with a physical switch that has been set to mark the device read-only; the filesystem implementation was compiled with read-only support; or errors were detected when initially mounting the filesystem, so that it was marked read-only and can't be remounted as read-write (until the errors are fixed).

Some filesystems instead return the error **EROFS** on an attempt to mount a read-only filesystem.

EACCES

The block device *source* is located on a filesystem mounted with the **MS_NODEV** option.

EBUSY

An attempt was made to stack a new mount directly on top of an existing mount point that was created in this mount namespace with the same *source* and *target*.

EBUSY

source cannot be remounted read-only, because it still holds files open for writing.

EFAULT

One of the pointer arguments points outside the user address space.

EINVAL

source had an invalid superblock.

EINVAL

A remount operation (**MS_REMOUNT**) was attempted, but *source* was not already mounted on *target*.

EINVAL

A move operation (**MS_MOVE**) was attempted, but the mount tree under *source* includes unbindable mounts and *target* is a mount that has propagation type **MS_SHARED**.

EINVAL

A move operation (**MS_MOVE**) was attempted, but the parent mount of *source* mount has propagation type **MS_SHARED**.

EINVAL

A move operation (**MS_MOVE**) was attempted, but *source* was not a mount, or was '/'.

EINVAL

A bind operation (**MS_BIND**) was requested where *source* referred a mount namespace magic link (i.e., a */proc/[pid]/ns/mnt* magic link or a bind mount to such a link) and the propagation type of the parent mount of *target* was **MS_SHARED**, but propagation of the requested bind mount

could lead to a circular dependency that might prevent the mount namespace from ever being freed.

EINVAL

mountflags includes more than one of **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE**.

EINVAL

mountflags includes **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE** and also includes a flag other than **MS_REC** or **MS_SILENT**.

EINVAL

An attempt was made to bind mount an unbindable mount.

EINVAL

In an unprivileged mount namespace (i.e., a mount namespace owned by a user namespace that was created by an unprivileged user), a bind mount operation (**MS_BIND**) was attempted without specifying (**MS_REC**), which would have revealed the filesystem tree underneath one of the sub-mounts of the directory being bound.

ELOOP

Too many links encountered during pathname resolution.

ELOOP

A move operation was attempted, and *target* is a descendant of *source*.

EMFILE

(In case no block device is required:) Table of dummy devices is full.

ENAMETOOLONG

A pathname was longer than **MAXPATHLEN**.

ENODEV

filesystemtype not configured in the kernel.

ENOENT

A pathname was empty or had a nonexistent component.

ENOMEM

The kernel could not allocate a free page to copy filenames or data into.

ENOTBLK

source is not a block device (and a device was required).

ENOTDIR

target, or a prefix of *source*, is not a directory.

ENXIO

The major number of the block device *source* is out of range.

EPERM

The caller does not have the required privileges.

EPERM

An attempt was made to modify (**MS_REMOUNT**) the **MS_RDONLY**, **MS_NOSUID**, or **MS_NOEXEC** flag, or one of the "atime" flags (**MS_NOATIME**, **MS_NODIRATIME**, **MS_RELATIME**) of an existing mount, but the mount is locked; see **mount_namespaces(7)**.

EROFS

Mounting a read-only filesystem was attempted without giving the **MS_RDONLY** flag. See **EACCES**, above.

VERSIONS

The definitions of **MS_DIRSYNC**, **MS_MOVE**, **MS_PRIVATE**, **MS_REC**, **MS_RELATIME**, **MS_SHARED**, **MS_SLAVE**, **MS_STRICTATIME**, and **MS_UNBINDABLE** were added to glibc

headers in glibc 2.12.

STANDARDS

This function is Linux-specific and should not be used in programs intended to be portable.

NOTES

Since Linux 2.4 a single filesystem can be mounted at multiple mount points, and multiple mounts can be stacked on the same mount point.

The *mountflags* argument may have the magic number 0xC0ED (**MS_MGC_VAL**) in the top 16 bits. (All of the other flags discussed in DESCRIPTION occupy the low order 16 bits of *mountflags*.) Specifying **MS_MGC_VAL** was required before Linux 2.4, but since Linux 2.4 is no longer required and is ignored if specified.

The original **MS_SYNC** flag was renamed **MS_SYNCHRONOUS** in 1.1.69 when a different **MS_SYNC** was added to <*mman.h*>.

Before Linux 2.4 an attempt to execute a set-user-ID or set-group-ID program on a filesystem mounted with **MS_NOSUID** would fail with **EPERM**. Since Linux 2.4 the set-user-ID and set-group-ID bits are just silently ignored in this case.

Mount namespaces

Starting with Linux 2.4.19, Linux provides mount namespaces. A mount namespace is the set of filesystem mounts that are visible to a process. Mount namespaces can be (and usually are) shared between multiple processes, and changes to the namespace (i.e., mounts and unmounts) by one process are visible to all other processes sharing the same namespace. (The pre-2.4.19 Linux situation can be considered as one in which a single namespace was shared by every process on the system.)

A child process created by **fork(2)** shares its parent's mount namespace; the mount namespace is preserved across an **execve(2)**.

A process can obtain a private mount namespace if: it was created using the **clone(2)** **CLONE_NEWNS** flag, in which case its new namespace is initialized to be a *copy* of the namespace of the process that called **clone(2)**; or it calls **unshare(2)** with the **CLONE_NEWNS** flag, which causes the caller's mount namespace to obtain a private copy of the namespace that it was previously sharing with other processes, so that future mounts and unmounts by the caller are invisible to other processes (except child processes that the caller subsequently creates) and vice versa.

For further details on mount namespaces, see **mount_namespaces(7)**.

Parental relationship between mounts

Each mount has a parent mount. The overall parental relationship of all mounts defines the single directory hierarchy seen by the processes within a mount namespace.

The parent of a new mount is defined when the mount is created. In the usual case, the parent of a new mount is the mount of the filesystem containing the directory or file at which the new mount is attached. In the case where a new mount is stacked on top of an existing mount, the parent of the new mount is the previous mount that was stacked at that location.

The parental relationship between mounts can be discovered via the */proc/[pid]/mountinfo* file (see below).

/proc/[pid]/mounts and /proc/[pid]/mountinfo

The Linux-specific */proc/[pid]/mounts* file exposes the list of mounts in the mount namespace of the process with the specified ID. The */proc/[pid]/mountinfo* file exposes even more information about mounts, including the propagation type and mount ID information that makes it possible to discover the parental relationship between mounts. See **proc(5)** and **mount_namespaces(7)** for details of this file.

NAME

mount – mount a filesystem

SYNOPSIS

mount [**-h**|**-V**]

mount [**-l**] [**-t** *fstype*]

mount **-a** [**-fFnrvw**] [**-t** *fstype*] [**-O** *optlist*]

mount [**-fnrvw**] [**-o** *options*] *device|mountpoint*

mount [**-fnrvw**] [**-t** *fstype*] [**-o** *options*] *device mountpoint*

mount **--bind|--rbind|--move** *olddir newdir*

mount **--make-[shared|slave|private|unbindable|rshared|rslave|rprivate|runbindable]** *mountpoint*

DESCRIPTION

All files accessible in a Unix system are arranged in one big tree, the file hierarchy, rooted at /. These files can be spread out over several devices. The **mount** command serves to attach the filesystem found on some device to the big file tree. Conversely, the **umount(8)** command will detach it again. The filesystem is used to control how data is stored on the device or provided in a virtual way by network or other services.

The standard form of the **mount** command is:

mount **-t** *type* *device dir*

This tells the kernel to attach the filesystem found on *device* (which is of type *type*) at the directory *dir*. The option **-t** *type* is optional. The **mount** command is usually able to detect a filesystem. The root permissions are necessary to mount a filesystem by default. See section "Non-superuser mounts" below for more details. The previous contents (if any) and owner and mode of *dir* become invisible, and as long as this filesystem remains mounted, the pathname *dir* refers to the root of the filesystem on *device*.

If only the directory or the device is given, for example:

mount */dir*

then **mount** looks for a mountpoint (and if not found then for a device) in the */etc/fstab* file. It's possible to use the **--target** or **--source** options to avoid ambiguous interpretation of the given argument. For example:

mount **--target** */mountpoint*

The same filesystem may be mounted more than once, and in some cases (e.g., network filesystems) the same filesystem may be mounted on the same mountpoint multiple times. The **mount** command does not implement any policy to control this behavior. All behavior is controlled by the kernel and it is usually specific to the filesystem driver. The exception is **--all**, in this case already mounted filesystems are ignored (see **--all** below for more details).

Listing the mounts

The listing mode is maintained for backward compatibility only.

For more robust and customizable output use **findmnt(8)**, especially in your scripts. Note that control characters in the mountpoint name are replaced with '?'.

The following command lists all mounted filesystems (of type *type*):

```
mount [-l] [-t type]
```

The option **-l** adds labels to this listing. See below.

Indicating the device and filesystem

Most devices are indicated by a filename (of a block special device), like */dev/sda1*, but there are other possibilities. For example, in the case of an NFS mount, *device* may look like *knuth.cwi.nl:/dir*.

The device names of disk partitions are unstable; hardware reconfiguration, and adding or removing a device can cause changes in names. This is the reason why it's strongly recommended to use filesystem or partition identifiers like UUID or LABEL. Currently supported identifiers (tags):

LABEL=*label*

Human readable filesystem identifier. See also **-L**.

UUID=*uuid*

Filesystem universally unique identifier. The format of the UUID is usually a series of hex digits separated by hyphens. See also **-U**.

Note that **mount** uses UUIDs as strings. The UUIDs from the command line or from **fstab(5)** are not converted to internal binary representation. The string representation of the UUID should be based on lower case characters.

PARTLABEL=*label*

Human readable partition identifier. This identifier is independent on filesystem and does not change by **mkfs** or **mkswap** operations. It's supported for example for GUID Partition Tables (GPT).

PARTUUID=*uuid*

Partition universally unique identifier. This identifier is independent on filesystem and does not change by **mkfs** or **mkswap** operations. It's supported for example for GUID Partition Tables (GPT).

ID=*id*

Hardware block device ID as generated by udevd. This identifier is usually based on WWN (unique storage identifier) and assigned by the hardware manufacturer. See **ls /dev/disk/by-id** for more details, this directory and running udevd is required. This identifier is not recommended for generic use as the identifier is not strictly defined and it depends on udev, udev rules and hardware.

The command **lsblk --fs** provides an overview of filesystems, LABELs and UUIDs on available block devices. The command **blkid -p <device>** provides details about a filesystem on the specified device.

Don't forget that there is no guarantee that UUIDs and labels are really unique, especially if you move, share or copy the device. Use **lsblk -o +UUID,PARTUUID** to verify that the UUIDs are really unique in your system.

The recommended setup is to use tags (e.g. **UUID=***uuid*) rather than */dev/disk/by-{label,uuid,id,partuuid,partlabel}* udev symlinks in the */etc/fstab* file. Tags are more readable, robust and portable. The **mount(8)** command internally uses udev symlinks, so the use of symlinks in */etc/fstab* has no advantage over tags. For more details see **libblkid(3)**.

The *proc* filesystem is not associated with a special device, and when mounting it, an arbitrary keyword – for example, *proc* – can be used instead of a device specification. (The customary choice *none* is less fortunate: the error message 'none already mounted' from **mount** can be confusing.)

The files /etc/fstab, /etc/mtab and /proc/mounts

The file */etc/fstab* (see **fstab(5)**), may contain lines describing what devices are usually mounted where, using which options. The default location of the **fstab(5)** file can be overridden with the **--fstab path** command-line option (see below for more details).

The command

```
mount -a [-t type] [-O optlist]
```

(usually given in a bootscript) causes all filesystems mentioned in *fstab* (of the proper type and/or having or not having the proper options) to be mounted as indicated, except for those whose line contains the **noauto** keyword. Adding the **-F** option will make **mount** fork, so that the filesystems are mounted in parallel.

When mounting a filesystem mentioned in *fstab* or *mtab*, it suffices to specify on the command line only the device, or only the mount point.

The programs **mount** and **umount(8)** traditionally maintained a list of currently mounted filesystems in the file */etc/mtab*. The support for regular classic */etc/mtab* is completely disabled at compile time by default, because on current Linux systems it is better to make */etc/mtab* a symlink to */proc/mounts* instead. The regular *mtab* file maintained in userspace cannot reliably work with namespaces, containers and other advanced Linux features. If the regular *mtab* support is enabled, then it's possible to use the file as well as the symlink.

If no arguments are given to **mount**, the list of mounted filesystems is printed.

If you want to override mount options from */etc/fstab*, you have to use the **-o** option:

```
mount device|dir -o options
```

and then the mount options from the command line will be appended to the list of options from */etc/fstab*. This default behaviour can be changed using the **--options-mode** command-line option. The usual behavior is that the last option wins if there are conflicting ones.

The **mount** program does not read the */etc/fstab* file if both *device* (or LABEL, UUID, ID, PARTUUID or PARTLABEL) and *dir* are specified. For example, to mount device **foo** at **/dir**:

```
mount /dev/foo /dir
```

This default behaviour can be changed by using the **--options-source-force** command-line option to always read configuration from *fstab*. For non-root users **mount** always reads the *fstab* configuration.

Non-superuser mounts

Normally, only the superuser can mount filesystems. However, when *fstab* contains the **user** option on a line, anybody can mount the corresponding filesystem.

Thus, given a line

```
/dev/cdrom /cd iso9660 ro,user,noauto,unhide
```

any user can mount the iso9660 filesystem found on an inserted CDROM using the command:

```
mount /cd
```

Note that **mount** is very strict about non-root users and all paths specified on command line are verified before *fstab* is parsed or a helper program is executed. It's strongly recommended to use a valid mountpoint

to specify filesystem, otherwise **mount** may fail. For example it's a bad idea to use NFS or CIFS source on command line.

Since util-linux 2.35, **mount** does not exit when user permissions are inadequate according to libmount's internal security rules. Instead, it drops uid permissions and continues as regular non-root user. This behavior supports use-cases where root permissions are not necessary (e.g., fuse filesystems, user namespaces, etc).

For more details, see **fstab(5)**. Only the user that mounted a filesystem can umount it again. If any user should be able to unmount it, then use **users** instead of **user** in the *fstab* line. The **owner** option is similar to the **user** option, with the restriction that the user must be the owner of the special file. This may be useful e.g. for */dev/fd* if a login script makes the console user owner of this device. The **group** option is similar, with the restriction that the user must be a member of the group of the special file.

Bind mount operation

Remount part of the file hierarchy somewhere else. The call is:

```
mount --bind olddir newdir
```

or by using this *fstab* entry:

```
/olddir /newdir none bind
```

After this call the same contents are accessible in two places.

It is important to understand that "bind" does not create any second-class or special node in the kernel VFS. The "bind" is just another operation to attach a filesystem. There is nowhere stored information that the filesystem has been attached by a "bind" operation. The *olddir* and *newdir* are independent and the *olddir* may be unmounted.

One can also remount a single file (on a single file). It's also possible to use a bind mount to create a mountpoint from a regular directory, for example:

```
mount --bind foo foo
```

The bind mount call attaches only (part of) a single filesystem, not possible submounts. The entire file hierarchy including submounts can be attached a second place by using:

```
mount --rbind olddir newdir
```

Note that the filesystem mount options maintained by the kernel will remain the same as those on the original mount point. The userspace mount options (e.g., *_netdev*) will not be copied by **mount** and it's necessary to explicitly specify the options on the **mount** command line.

Since util-linux 2.27 **mount** permits changing the mount options by passing the relevant options along with **--bind**. For example:

```
mount -o bind,ro foo foo
```

This feature is not supported by the Linux kernel; it is implemented in userspace by an additional **mount(2)** remounting system call. This solution is not atomic.

The alternative (classic) way to create a read-only bind mount is to use the remount operation, for example:

```
mount --bind olddir newdir
```

```
mount -o remount,bind,ro olddir newdir
```

Note that a read-only bind will create a read-only mountpoint (VFS entry), but the original filesystem superblock will still be writable, meaning that the *olddir* will be writable, but the *newdir* will be read-only.

It's also possible to change nosuid, nodev, noexec, noatime, nodiratime, relatime and nosymfollow VFS entry flags via a "remount,bind" operation. The other flags (for example filesystem-specific flags) are silently ignored. It's impossible to change mount options recursively (for example with **-o rbind,ro**).

Since util-linux 2.31, **mount** ignores the **bind** flag from */etc/fstab* on a **remount** operation (if **-o remount** is specified on command line). This is necessary to fully control mount options on remount by command line. In previous versions the bind flag has been always applied and it was impossible to re-define mount options without interaction with the bind semantic. This **mount** behavior does not affect situations when "remount,bind" is specified in the */etc/fstab* file.

The move operation

Move a **mounted tree** to another place (atomically). The call is:

```
mount --move olddir newdir
```

This will cause the contents which previously appeared under *olddir* to now be accessible under *newdir*. The physical location of the files is not changed. Note that *olddir* has to be a mountpoint.

Note also that moving a mount residing under a shared mount is invalid and unsupported. Use **findmnt -o TARGET,PROPAGATION** to see the current propagation flags.

Shared subtree operations

Since Linux 2.6.15 it is possible to mark a mount and its submounts as shared, private, slave or unbindable. A shared mount provides the ability to create mirrors of that mount such that mounts and unmounts within any of the mirrors propagate to the other mirror. A slave mount receives propagation from its master, but not vice versa. A private mount carries no propagation abilities. An unbindable mount is a private mount which cannot be cloned through a bind operation. The detailed semantics are documented in *Documentation/filesystems/sharedsubtree.txt* file in the kernel source tree; see also **mount_namespaces(7)**.

Supported operations are:

```
mount --make-shared mountpoint
mount --make-slave mountpoint
mount --make-private mountpoint
mount --make-unbindable mountpoint
```

The following commands allow one to recursively change the type of all the mounts under a given mountpoint.

```
mount --make-rshared mountpoint
mount --make-rslave mountpoint
mount --make-rprivate mountpoint
mount --make-runbindable mountpoint
```

mount does not read **fstab(5)** when a **--make-*** operation is requested. All necessary information has to be specified on the command line.

Note that the Linux kernel does not allow changing multiple propagation flags with a single **mount(2)** system call, and the flags cannot be mixed with other mount options and operations.

Since util-linux 2.23 the **mount** command can be used to do more propagation (topology) changes by one

mount(8) call and do it also together with other mount operations. The propagation flags are applied by additional **mount(2)** system calls when the preceding mount operations were successful. Note that this use case is not atomic. It is possible to specify the propagation flags in **fstab(5)** as mount options (**private**, **slave**, **shared**, **unbindable**, **rprivate**, **rslave**, **rshared**, **runbindable**).

For example:

```
mount --make-private --make-unbindable /dev/sda1 /foo
```

is the same as:

```
mount /dev/sda1 /foo
mount --make-private /foo
mount --make-unbindable /foo
```

COMMAND-LINE OPTIONS

The full set of mount options used by an invocation of **mount** is determined by first extracting the mount options for the filesystem from the *fstab* table, then applying any options specified by the **-o** argument, and finally applying a **-r** or **-w** option, when present.

The **mount** command does not pass all command-line options to the */sbin/mount.suffix* mount helpers. The interface between **mount** and the mount helpers is described below in the **EXTERNAL HELPERS** section.

Command-line options available for the **mount** command are:

-a, --all

Mount all filesystems (of the given types) mentioned in *fstab* (except for those whose line contains the **noauto** keyword). The filesystems are mounted following their order in *fstab*. The **mount** command compares filesystem source, target (and fs root for bind mount or btrfs) to detect already mounted filesystems. The kernel table with already mounted filesystems is cached during **mount --all**. This means that all duplicated *fstab* entries will be mounted.

The correct functionality depends on */proc* (to detect already mounted filesystems) and on */sys* (to evaluate filesystem tags like **UUID=** or **LABEL=**). It's strongly recommended to mount */proc* and */sys* filesystems before **mount -a** is executed, or keep */proc* and */sys* at the beginning of *fstab*.

The option **--all** is possible to use for remount operation too. In this case all filters (**-t** and **-O**) are applied to the table of already mounted filesystems.

Since version 2.35 it is possible to use the command line option **-o** to alter mount options from *fstab* (see also **--options-mode**).

Note that it is a bad practice to use **mount -a** for *fstab* checking. The recommended solution is **findmnt --verify**.

-B, --bind

Remount a subtree somewhere else (so that its contents are available in both places). See above, under **Bind mounts**.

-c, --no-canonicalize

Don't canonicalize paths. The **mount** command canonicalizes all paths (from the command line or *fstab*) by default. This option can be used together with the **-f** flag for already canonicalized absolute paths. The option is designed for mount helpers which call **mount -i**. It is strongly recommended to not use this command-line option for normal mount operations.

Note that **mount** does not pass this option to the */sbin/mount.type* helpers.

-F, --fork

(Used in conjunction with **-a**.) Fork off a new incarnation of **mount** for each device. This will do the mounts on different devices or different NFS servers in parallel. This has the advantage that it is faster; also NFS timeouts proceed in parallel. A disadvantage is that the order of the mount operations is undefined. Thus, you cannot use this option if you want to mount both */usr* and */usr/spool*.

-f, --fake

Causes everything to be done except for the actual system call; if it's not obvious, this "fakes" mounting the filesystem. This option is useful in conjunction with the **-v** flag to determine what the **mount** command is trying to do. It can also be used to add entries for devices that were mounted earlier with the **-n** option. The **-f** option checks for an existing record in */etc/mtab* and fails when the record already exists (with a regular non-fake mount, this check is done by the kernel).

-i, --internal-only

Don't call the */sbin/mount.filesystem* helper even if it exists.

-L, --label *label*

Mount the partition that has the specified *label*.

-l, --show-labels

Add the labels in the mount output. **mount** must have permission to read the disk device (e.g. be set-user-ID root) for this to work. One can set such a label for ext2, ext3 or ext4 using the **e2label(8)** utility, or for XFS using **xfs_admin(8)**, or for reiserfs using **reiserfstune(8)**.

-M, --move

Move a subtree to some other place. See above, the subsection **The move operation**.

-m, --mkdir[=*mode*]

Allow to make a target directory (mountpoint) if it does not exist yet. Alias to "**-o X-mount.mkdir[=*mode*]**", the default mode is 0755. For more details see **X-mount.mkdir** below.

-n, --no-*mtab*

Mount without writing in */etc/mtab*. This is necessary for example when */etc* is on a read-only filesystem.

-N, --namespace *ns*

Perform the mount operation in the mount namespace specified by *ns*. *ns* is either PID of process running in that namespace or special file representing that namespace.

mount switches to the mount namespace when it reads */etc/fstab*, writes */etc/mtab*: (*or writes to /run/mount*) and calls **mount(2)**, otherwise it runs in the original mount namespace. This means that the target namespace does not have to contain any libraries or other requirements necessary to execute the **mount(2)** call.

See **mount_namespaces(7)** for more information.

-O, --test-opts *opts*

Limit the set of filesystems to which the **-a** option applies. In this regard it is like the **-t** option except that **-O** is useless without **-a**. For example, the command

mount -a -O no_netdev

mounts all filesystems except those which have the option *netdev* specified in the options field in the */etc/fstab* file.

It is different from **-t** in that each option is matched exactly; a leading **no** at the beginning of one option does not negate the rest.

The **-t** and **-O** options are cumulative in effect; that is, the command

```
mount -a -t ext2 -O _netdev
```

mounts all ext2 filesystems with the *_netdev* option, not all filesystems that are either ext2 or have the *_netdev* option specified.

-o, --options *opts*

Use the specified mount options. The *opts* argument is a comma-separated list. For example:

```
mount LABEL=mydisk -o noatime,nodev,nosuid
```

For more details, see the **FILESYSTEM-INDEPENDENT MOUNT OPTIONS** and **FILESYSTEM-SPECIFIC MOUNT OPTIONS** sections.

--options-mode *mode*

Controls how to combine options from *fstab/mtab* with options from the command line. *mode* can be one of **ignore**, **append**, **prepend** or **replace**. For example, **append** means that options from *fstab* are appended to options from the command line. The default value is **prepend** — it means command line options are evaluated after *fstab* options. Note that the last option wins if there are conflicting ones.

--options-source *source*

Source of default options. *source* is a comma-separated list of **fstab**, **mtab** and **disable**. **disable** disables **fstab** and **mtab** and enables **--options-source-force**. The default value is **fstab,mtab**.

--options-source-force

Use options from *fstab/mtab* even if both *device* and *dir* are specified.

-R, --rbind

Remount a subtree and all possible submounts somewhere else (so that its contents are available in both places). See above, the subsection **Bind mounts**.

-r, --read-only

Mount the filesystem read-only. A synonym is **-o ro**.

Note that, depending on the filesystem type, state and kernel behavior, the system may still write to the device. For example, ext3 and ext4 will replay the journal if the filesystem is dirty. To prevent this kind of write access, you may want to mount an ext3 or ext4 filesystem with the **ro,noload** mount options or set the block device itself to read-only mode, see the **blockdev(8)** command.

-s

Tolerate sloppy mount options rather than failing. This will ignore mount options not supported by a filesystem type. Not all filesystems support this option. Currently it's supported by the **mount.nfs** mount helper only.

--source *device*

If only one argument for the **mount** command is given, then the argument might be interpreted as the target (mountpoint) or source (device). This option allows you to explicitly define that the argument is

the mount source.

--target *directory*

If only one argument for the mount command is given, then the argument might be interpreted as the target (mountpoint) or source (device). This option allows you to explicitly define that the argument is the mount target.

--target-prefix *directory*

Prepend the specified directory to all mount targets. This option can be used to follow *fstab*, but mount operations are done in another place, for example:

```
mount --all --target-prefix /chroot -o X-mount.mkdir
```

mounts all from system *fstab* to */chroot*, all missing mountpoint are created (due to *X-mount.mkdir*). See also **--fstab** to use an alternative *fstab*.

-T, --fstab *path*

Specifies an alternative *fstab* file. If *path* is a directory, then the files in the directory are sorted by **strverscmp(3)**; files that start with "." or without an *.fstab* extension are ignored. The option can be specified more than once. This option is mostly designed for initramfs or chroot scripts where additional configuration is specified beyond standard system configuration.

Note that **mount** does not pass the option **--fstab** to the **/sbin/mount.type** helpers, meaning that the alternative *fstab* files will be invisible for the helpers. This is no problem for normal mounts, but user (non-root) mounts always require *fstab* to verify the user's rights.

-t, --types *fstype*

The argument following the **-t** is used to indicate the filesystem type. The filesystem types which are currently supported depend on the running kernel. See */proc/filesystems* and */lib/modules/\$(uname -r)/kernel/fs* for a complete list of the filesystems. The most common are ext2, ext3, ext4, xfs, btrfs, vfat, sysfs, proc, nfs and cifs.

The programs **mount** and **umount(8)** support filesystem subtypes. The subtype is defined by a '.subtype' suffix. For example 'fuse.sshfs'. It's recommended to use subtype notation rather than add any prefix to the mount source (for example 'sshfs#example.com' is deprecated).

If no **-t** option is given, or if the **auto** type is specified, **mount** will try to guess the desired type. **mount** uses the **libblkid(3)** library for guessing the filesystem type; if that does not turn up anything that looks familiar, **mount** will try to read the file */etc/filesystems*, or, if that does not exist, */proc/filesystems*. All of the filesystem types listed there will be tried, except for those that are labeled "nodev" (e.g. *devpts*, *proc* and *nfs*). If */etc/filesystems* ends in a line with a single *, mount will read */proc/filesystems* afterwards. While trying, all filesystem types will be mounted with the mount option **silent**.

The **auto** type may be useful for user-mounted floppies. Creating a file */etc/filesystems* can be useful to change the probe order (e.g., to try vfat before msdos or ext3 before ext2) or if you use a kernel module autoloader.

More than one type may be specified in a comma-separated list, for the **-t** option as well as in an */etc/fstab* entry. The list of filesystem types for the **-t** option can be prefixed with **no** to specify the filesystem types on which no action should be taken. The prefix **no** has no effect when specified in an */etc/fstab* entry.

The prefix **no** can be meaningful with the **-a** option. For example, the command

mount -a -t nomsdos,smbfs

mounts all filesystems except those of type *msdos* and *smbfs*.

For most types all the **mount** program has to do is issue a simple **mount(2)** system call, and no detailed knowledge of the filesystem type is required. For a few types however (like nfs, nfs4, cifs, smbfs, ncpfs) an ad hoc code is necessary. The nfs, nfs4, cifs, smbfs, and ncpfs filesystems have a separate mount program. In order to make it possible to treat all types in a uniform way, **mount** will execute the program */sbin/mount.type* (if that exists) when called with type *type*. Since different versions of the **smbmount** program have different calling conventions, */sbin/mount.smbfs* may have to be a shell script that sets up the desired call.

-U, --uuid *uuid*

Mount the partition that has the specified *uuid*.

-v, --verbose

Verbose mode.

-w, --rw, --read-write

Mount the filesystem read/write. Read–write is the kernel default and the **mount** default is to try read–only if the previous **mount(2)** syscall with read–write flags on write–protected devices failed.

A synonym is **-o rw**.

Note that specifying **-w** on the command line forces **mount** to never try read–only mount on write–protected devices or already mounted read–only filesystems.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

FILESYSTEM-INDEPENDENT MOUNT OPTIONS

Some of these options are only useful when they appear in the */etc/fstab* file.

Some of these options could be enabled or disabled by default in the system kernel. To check the current setting see the options in */proc/mounts*. Note that filesystems also have per–filesystem specific default mount options (see for example **tune2fs -l** output for extN filesystems).

The following options apply to any filesystem that is being mounted (but not every filesystem actually honors them – e.g., the **sync** option today has an effect only for ext2, ext3, ext4, fat, vfat, ufs and xfs):

async

All I/O to the filesystem should be done asynchronously. (See also the **sync** option.)

atime

Do not use the **noatime** feature, so the inode access time is controlled by kernel defaults. See also the descriptions of the **relatime** and **strictatime** mount options.

noatime

Do not update inode access times on this filesystem (e.g. for faster access on the news spool to speed up news servers). This works for all inode types (directories too), so it implies **nodiratime**.

auto

Can be mounted with the **-a** option.

noauto

Can only be mounted explicitly (i.e., the **-a** option will not cause the filesystem to be mounted).

context=*context*, **fscontext=***context*, **defcontext=***context*, and **rootcontext=***context*

The **context=** option is useful when mounting filesystems that do not support extended attributes, such as a floppy or hard disk formatted with VFAT, or systems that are not normally running under SELinux, such as an ext3 or ext4 formatted disk from a non-SELinux workstation. You can also use **context=** on filesystems you do not trust, such as a floppy. It also helps in compatibility with xattr-supporting filesystems on earlier 2.4.<x> kernel versions. Even where xattrs are supported, you can save time not having to label every file by assigning the entire disk one security context.

A commonly used option for removable media is **context="system_u:object_r:removable_t"**.

The **fscontext=** option works for all filesystems, regardless of their xattr support. The fscontext option sets the overarching filesystem label to a specific security context. This filesystem label is separate from the individual labels on the files. It represents the entire filesystem for certain kinds of permission checks, such as during mount or file creation. Individual file labels are still obtained from the xattrs on the files themselves. The context option actually sets the aggregate context that fscontext provides, in addition to supplying the same label for individual files.

You can set the default security context for unlabeled files using **defcontext=** option. This overrides the value set for unlabeled files in the policy and requires a filesystem that supports xattr labeling.

The **rootcontext=** option allows you to explicitly label the root inode of a FS being mounted before that FS or inode becomes visible to userspace. This was found to be useful for things like stateless Linux.

Note that the kernel rejects any remount request that includes the context option, **even** when unchanged from the current context.

Warning: the *context* value might contain commas, in which case the value has to be properly quoted, otherwise **mount** will interpret the comma as a separator between mount options. Don't forget that the shell strips off quotes and thus **double quoting is required**. For example:

```
mount -t tmpfs none /mnt -o \'context="system_u:object_r:tmp_t:s0:c127,c456",noexec'
```

For more details, see **selinux(8)**.

defaults

Use the default options: **rw**, **suid**, **dev**, **exec**, **auto**, **nouser**, and **async**.

Note that the real set of all default mount options depends on the kernel and filesystem type. See the beginning of this section for more details.

dev

Interpret character or block special devices on the filesystem.

nodev

Do not interpret character or block special devices on the filesystem.

diratime

Update directory inode access times on this filesystem. This is the default. (This option is ignored

when **noatime** is set.)

nodiratime

Do not update directory inode access times on this filesystem. (This option is implied when **noatime** is set.)

dirsync

All directory updates within the filesystem should be done synchronously. This affects the following system calls: **creat(2)**, **link(2)**, **unlink(2)**, **symlink(2)**, **mkdir(2)**, **rmdir(2)**, **mknod(2)** and **rename(2)**.

exec

Permit execution of binaries and other executable files.

noexec

Do not permit direct execution of any binaries on the mounted filesystem.

group

Allow an ordinary user to mount the filesystem if one of that user's groups matches the group of the device. This option implies the options **nosuid** and **nodev** (unless overridden by subsequent options, as in the option line **group,dev,suid**).

iversion

Every time the inode is modified, the *i_version* field will be incremented.

noiversion

Do not increment the *i_version* inode field.

mand

Allow mandatory locks on this filesystem. See **fctl(2)**. This option was deprecated in Linux 5.15.

nomand

Do not allow mandatory locks on this filesystem.

_netdev

The filesystem resides on a device that requires network access (used to prevent the system from attempting to mount these filesystems until the network has been enabled on the system).

nofail

Do not report errors for this device if it does not exist.

relatime

Update inode access times relative to modify or change time. Access time is only updated if the previous access time was earlier than the current modify or change time. (Similar to **noatime**, but it doesn't break **mutt(1)** or other applications that need to know if a file has been read since the last time it was modified.)

Since Linux 2.6.30, the kernel defaults to the behavior provided by this option (unless **noatime** was specified), and the **strictatime** option is required to obtain traditional semantics. In addition, since Linux 2.6.30, the file's last access time is always updated if it is more than 1 day old.

norelatime

Do not use the **relatime** feature. See also the **strictatime** mount option.

strictatime

Allows to explicitly request full atime updates. This makes it possible for the kernel to default to **relatime** or **noatime** but still allow userspace to override it. For more details about the default system mount options see */proc/mounts*.

nostrictatime

Use the kernel's default behavior for inode access time updates.

lazytime

Only update times (atime, mtime, ctime) on the in-memory version of the file inode.

This mount option significantly reduces writes to the inode table for workloads that perform frequent random writes to preallocated files.

The on-disk timestamps are updated only when:

- the inode needs to be updated for some change unrelated to file timestamps
- the application employs **fsync(2)**, **syncfs(2)**, or **sync(2)**
- an undeleted inode is evicted from memory
- more than 24 hours have passed since the inode was written to disk.

nolazytime

Do not use the lazytime feature.

suid

Honor set-user-ID and set-group-ID bits or file capabilities when executing programs from this filesystem.

nosuid

Do not honor set-user-ID and set-group-ID bits or file capabilities when executing programs from this filesystem. In addition, SELinux domain transitions require permission *nosuid_transition*, which in turn needs also policy capability *nnp_nosuid_transition*.

silent

Turn on the silent flag.

loud

Turn off the silent flag.

owner

Allow an ordinary user to mount the filesystem if that user is the owner of the device. This option implies the options **nosuid** and **nodev** (unless overridden by subsequent options, as in the option line **owner,dev,suid**).

remount

Attempt to remount an already-mounted filesystem. This is commonly used to change the mount flags for a filesystem, especially to make a readonly filesystem writable. It does not change device or mount point.

The remount operation together with the **bind** flag has special semantics. See above, the subsection **Bind mounts**.

The remount functionality follows the standard way the **mount** command works with options from *fstab*. This means that **mount** does not read *fstab* (or *mtab*) only when both *device* and *dir* are

specified.

mount -o remount,rw /dev/foo /dir

After this call all old mount options are replaced and arbitrary stuff from *fstab* (or *mtab*) is ignored, except the **loop=** option which is internally generated and maintained by the **mount** command.

mount -o remount,rw /dir

After this call, **mount** reads *fstab* and merges these options with the options from the command line (**-o**). If no mountpoint is found in *fstab*, then a remount with unspecified source is allowed.

mount allows the use of **--all** to remount all already mounted filesystems which match a specified filter (**-O** and **-t**). For example:

mount --all -o remount,ro -t vfat

remounts all already mounted vfat filesystems in read-only mode. Each of the filesystems is remounted by **mount -o remount,ro /dir** semantic. This means the **mount** command reads *fstab* or *mtab* and merges these options with the options from the command line.

ro

Mount the filesystem read-only.

rw

Mount the filesystem read-write.

sync

All I/O to the filesystem should be done synchronously. In the case of media with a limited number of write cycles (e.g. some flash drives), **sync** may cause life-cycle shortening.

user

Allow an ordinary user to mount the filesystem. The name of the mounting user is written to the *mtab* file (or to the private libmount file in */run/mount* on systems without a regular *mtab*) so that this same user can umount the filesystem again. This option implies the options **noexec**, **nosuid**, and **nodev** (unless overridden by subsequent options, as in the option line **user,exec,dev,suid**).

nouser

Forbid an ordinary user to mount the filesystem. This is the default; it does not imply any other options.

users

Allow any user to mount and to umount the filesystem, even when some other ordinary user mounted it. This option implies the options **noexec**, **nosuid**, and **nodev** (unless overridden by subsequent options, as in the option line **users,exec,dev,suid**).

X-*

All options prefixed with "X-" are interpreted as comments or as userspace application-specific options. These options are not stored in user space (e.g., *mtab* file), nor sent to the *mount.type* helpers nor to the **mount(2)** system call. The suggested format is **X-appname.option**.

x-*

The same as **X-*** options, but stored permanently in user space. This means the options are also available for **umount(8)** or other operations. Note that maintaining mount options in user space is

tricky, because it's necessary use libmount-based tools and there is no guarantee that the options will be always available (for example after a move mount operation or in unshared namespace).

Note that before util-linux v2.30 the x-* options have not been maintained by libmount and stored in user space (functionality was the same as for X-* now), but due to the growing number of use-cases (in initrd, systemd etc.) the functionality has been extended to keep existing *fstab* configurations usable without a change.

X-mount.mkdir[=mode]

Allow to make a target directory (mountpoint) if it does not exist yet. The optional argument *mode* specifies the filesystem access mode used for **mkdir(2)** in octal notation. The default mode is 0755. This functionality is supported only for root users or when **mount** is executed without *suid* permissions. The option is also supported as **x-mount.mkdir**, but this notation is deprecated since v2.30. See also **--mkdir** command line option.

X-mount.subdir=directory

Allow mounting sub-directory from a filesystem instead of the root directory. For now, this feature is implemented by temporary filesystem root directory mount in unshared namespace and then bind the sub-directory to the final mount point and umount the root of the filesystem. The sub-directory mount shows up atomically for the rest of the system although it is implemented by multiple **mount(2)** syscalls. This feature is EXPERIMENTAL.

nosymfollow

Do not follow symlinks when resolving paths. Symlinks can still be created, and **readlink(1)**, **readlink(2)**, **realpath(1)**, and **realpath(3)** all still work properly.

FILESYSTEM-SPECIFIC MOUNT OPTIONS

This section lists options that are specific to particular filesystems. Where possible, you should first consult filesystem-specific manual pages for details. Some of those pages are listed in the following table.

Filesystem(s)	Manual page
btrfs	btrfs(5)
cifs	mount.cifs(8)
ext2, ext3, ext4	ext4(5)
fuse	fuse(8)
nfs	nfs(5)
tmpfs	tmpfs(5)
xfs	xfs(5)

Note that some of the pages listed above might be available only after you install the respective userland tools.

The following options apply only to certain filesystems. We sort them by filesystem. All options follow the **-o** flag.

What options are supported depends a bit on the running kernel. Further information may be available in filesystem-specific files in the kernel source subdirectory *Documentation/filesystems*.

Mount options for adfs

uid=value and **gid=value**

Set the owner and group of the files in the filesystem (default: uid=gid=0).

ownmask=value and **othmask=value**

Set the permission mask for ADFS 'owner' permissions and 'other' permissions, respectively (default: 0700 and 0077, respectively). See also */usr/src/linux/Documentation/filesystems/adfs.rst*.

Mount options for affs

uid=value and **gid=value**

Set the owner and group of the root of the filesystem (default: uid=gid=0, but with option **uid** or **gid** without specified value, the UID and GID of the current process are taken).

setuid=value and **setgid=value**

Set the owner and group of all files.

mode=value

Set the mode of all files to *value* & 0777 disregarding the original permissions. Add search permission to directories that have read permission. The value is given in octal.

protect

Do not allow any changes to the protection bits on the filesystem.

usemp

Set UID and GID of the root of the filesystem to the UID and GID of the mount point upon the first sync or umount, and then clear this option. Strange...

verbose

Print an informational message for each successful mount.

prefix=string

Prefix used before volume name, when following a link.

volume=string

Prefix (of length at most 30) used before '/' when following a symbolic link.

reserved=value

(Default: 2.) Number of unused blocks at the start of the device.

root=value

Give explicitly the location of the root block.

bs=value

Give blocksize. Allowed values are 512, 1024, 2048, 4096.

grpquota|noquota|quota|usrquota

These options are accepted but ignored. (However, quota utilities may react to such strings in */etc/fstab*.)

Mount options for debugfs

The debugfs filesystem is a pseudo filesystem, traditionally mounted on */sys/kernel/debug*. As of kernel version 3.4, debugfs has the following options:

uid=n, gid=n

Set the owner and group of the mountpoint.

mode=value

Sets the mode of the mountpoint.

Mount options for devpts

The devpts filesystem is a pseudo filesystem, traditionally mounted on */dev/pts*. In order to acquire a pseudo terminal, a process opens */dev/ptmx*; the number of the pseudo terminal is then made available to the process and the pseudo terminal slave can be accessed as */dev/pts/<number>*.

uid=value and gid=value

This sets the owner or the group of newly created pseudo terminals to the specified values. When nothing is specified, they will be set to the UID and GID of the creating process. For example, if there is a tty group with GID 5, then **gid=5** will cause newly created pseudo terminals to belong to the tty group.

mode=value

Set the mode of newly created pseudo terminals to the specified value. The default is 0600. A value of **mode=620** and **gid=5** makes "mesg y" the default on newly created pseudo terminals.

newinstance

Create a private instance of the devpts filesystem, such that indices of pseudo terminals allocated in this new instance are independent of indices created in other instances of devpts.

All mounts of devpts without this **newinstance** option share the same set of pseudo terminal indices (i.e., legacy mode). Each mount of devpts with the **newinstance** option has a private set of pseudo terminal indices.

This option is mainly used to support containers in the Linux kernel. It is implemented in Linux kernel versions starting with 2.6.29. Further, this mount option is valid only if **CONFIG_DEVPTS_MULTIPLE_INSTANCES** is enabled in the kernel configuration.

To use this option effectively, */dev/ptmx* must be a symbolic link to *pts/ptmx*. See *Documentation/filesystems/devpts.txt* in the Linux kernel source tree for details.

ptmxmode=value

Set the mode for the new *ptmx* device node in the devpts filesystem.

With the support for multiple instances of devpts (see **newinstance** option above), each instance has a private *ptmx* node in the root of the devpts filesystem (typically */dev/pts/ptmx*).

For compatibility with older versions of the kernel, the default mode of the new *ptmx* node is 0000. **ptmxmode=value** specifies a more useful mode for the *ptmx* node and is highly recommended when the **newinstance** option is specified.

This option is only implemented in Linux kernel versions starting with 2.6.29. Further, this option is valid only if **CONFIG_DEVPTS_MULTIPLE_INSTANCES** is enabled in the kernel configuration.

Mount options for fat

(Note: *fat* is not a separate filesystem, but a common part of the *msdos*, *umsdos* and *vfat* filesystems.)

blocksize={512|1024|2048}

Set blocksize (default 512). This option is obsolete.

uid=value and gid=value

Set the owner and group of all files. (Default: the UID and GID of the current process.)

umask=value

Set the umask (the bitmask of the permissions that are **not** present). The default is the umask of the current process. The value is given in octal.

dmask=value

Set the umask applied to directories only. The default is the umask of the current process. The value is given in octal.

fmask=value

Set the umask applied to regular files only. The default is the umask of the current process. The value is given in octal.

allow_utime=value

This option controls the permission check of mtime/atime.

20

If current process is in group of file's group ID, you can change timestamp.

2

Other users can change timestamp.

The default is set from 'dmask' option. (If the directory is writable, **utime**(2) is also allowed. I.e. ~dmask & 022)

Normally **utime**(2) checks that the current process is owner of the file, or that it has the **CAP_FOWNER** capability. But FAT filesystems don't have UID/GID on disk, so the normal check is too inflexible. With this option you can relax it.

check=value

Three different levels of pickiness can be chosen:

r[elaxed]

Upper and lower case are accepted and equivalent, long name parts are truncated (e.g. *verylongname.foobar* becomes *verylong.foo*), leading and embedded spaces are accepted in each name part (name and extension).

n[ormal]

Like "relaxed", but many special characters (*, ?, <, spaces, etc.) are rejected. This is the default.

s[trict]

Like "normal", but names that contain long parts or special characters that are sometimes used on Linux but are not accepted by MS-DOS (+, =, etc.) are rejected.

codepage=value

Sets the codepage for converting to shortname characters on FAT and VFAT filesystems. By default, codepage 437 is used.

conv=mode

This option is obsolete and may fail or be ignored.

cvf_format=module

Forces the driver to use the CVF (Compressed Volume File) module *cvf_module* instead of

auto-detection. If the kernel supports **kmod**, the **cvf_format=xxx** option also controls on-demand CVF module loading. This option is obsolete.

cvf_option=option

Option passed to the CVF module. This option is obsolete.

debug

Turn on the *debug* flag. A version string and a list of filesystem parameters will be printed (these data are also printed if the parameters appear to be inconsistent).

discard

If set, causes discard/TRIM commands to be issued to the block device when blocks are freed. This is useful for SSD devices and sparse/thinly-provisioned LUNs.

dos1xfloppy

If set, use a fallback default BIOS Parameter Block configuration, determined by backing device size. These static parameters match defaults assumed by DOS 1.x for 160 kiB, 180 kiB, 320 kiB, and 360 kiB floppies and floppy images.

errors={panic|continue|remount-ro}

Specify FAT behavior on critical errors: panic, continue without doing anything, or remount the partition in read-only mode (default behavior).

fat={12|16|32}

Specify a 12, 16 or 32 bit fat. This overrides the automatic FAT type detection routine. Use with caution!

iocharset=value

Character set to use for converting between 8 bit characters and 16 bit Unicode characters. The default is iso8859-1. Long filenames are stored on disk in Unicode format.

nfs={stale_rw|nostale_ro}

Enable this only if you want to export the FAT filesystem over NFS.

stale_rw: This option maintains an index (cache) of directory inodes which is used by the nfs-related code to improve look-ups. Full file operations (read/write) over NFS are supported but with cache eviction at NFS server, this could result in spurious **ESTALE** errors.

nostale_ro: This option bases the inode number and file handle on the on-disk location of a file in the FAT directory entry. This ensures that **ESTALE** will not be returned after a file is evicted from the inode cache. However, it means that operations such as rename, create and unlink could cause file handles that previously pointed at one file to point at a different file, potentially causing data corruption. For this reason, this option also mounts the filesystem readonly.

To maintain backward compatibility, **-o nfs** is also accepted, defaulting to **stale_rw**.

tz=UTC

This option disables the conversion of timestamps between local time (as used by Windows on FAT) and UTC (which Linux uses internally). This is particularly useful when mounting devices (like digital cameras) that are set to UTC in order to avoid the pitfalls of local time.

time_offset=minutes

Set offset for conversion of timestamps from local time used by FAT to UTC. I.e., *minutes* will be subtracted from each timestamp to convert it to UTC used internally by Linux. This is useful when the

time zone set in the kernel via **settimeofday**(2) is not the time zone used by the filesystem. Note that this option still does not provide correct time stamps in all cases in presence of DST – time stamps in a different DST setting will be off by one hour.

quiet

Turn on the *quiet* flag. Attempts to chown or chmod files do not return errors, although they fail. Use with caution!

rodir

FAT has the **ATTR_RO** (read-only) attribute. On Windows, the **ATTR_RO** of the directory will just be ignored, and is used only by applications as a flag (e.g. it's set for the customized folder).

If you want to use **ATTR_RO** as read-only flag even for the directory, set this option.

showexec

If set, the execute permission bits of the file will be allowed only if the extension part of the name is .EXE, .COM, or .BAT. Not set by default.

sys_immutable

If set, **ATTR_SYS** attribute on FAT is handled as **IMMUTABLE** flag on Linux. Not set by default.

flush

If set, the filesystem will try to flush to disk more early than normal. Not set by default.

usefree

Use the "free clusters" value stored on **FSINFO**. It'll be used to determine number of free clusters without scanning disk. But it's not used by default, because recent Windows don't update it correctly in some case. If you are sure the "free clusters" on **FSINFO** is correct, by this option you can avoid scanning disk.

dots, nodots, dotsOK=[yes|no]

Various misguided attempts to force Unix or DOS conventions onto a FAT filesystem.

Mount options for hfs**creator=cccc, type=cccc**

Set the creator/type values as shown by the MacOS finder used for creating new files. Default values: '????'.

uid=n, gid=n

Set the owner and group of all files. (Default: the UID and GID of the current process.)

dir_umask=n, file_umask=n, umask=n

Set the umask used for all directories, all regular files, or all files and directories. Defaults to the umask of the current process.

session=n

Select the CDROM session to mount. Defaults to leaving that decision to the CDROM driver. This option will fail with anything but a CDROM as underlying device.

part=n

Select partition number n from the device. Only makes sense for CDROMs. Defaults to not parsing the partition table at all.

quiet

Don't complain about invalid mount options.

Mount options for hpfs**uid=value** and **gid=value**

Set the owner and group of all files. (Default: the UID and GID of the current process.)

umask=value

Set the umask (the bitmask of the permissions that are **not** present). The default is the umask of the current process. The value is given in octal.

case={lower|asis}

Convert all files names to lower case, or leave them. (Default: **case=lower**.)

conv=mode

This option is obsolete and may fail or being ignored.

nocheck

Do not abort mounting when certain consistency checks fail.

Mount options for iso9660

ISO 9660 is a standard describing a filesystem structure to be used on CD-ROMs. (This filesystem type is also seen on some DVDs. See also the *udf* filesystem.)

Normal *iso9660* filenames appear in an 8.3 format (i.e., DOS-like restrictions on filename length), and in addition all characters are in upper case. Also there is no field for file ownership, protection, number of links, provision for block/character devices, etc.

Rock Ridge is an extension to iso9660 that provides all of these UNIX-like features. Basically there are extensions to each directory record that supply all of the additional information, and when Rock Ridge is in use, the filesystem is indistinguishable from a normal UNIX filesystem (except that it is read-only, of course).

norock

Disable the use of Rock Ridge extensions, even if available. Cf. **map**.

nojoliet

Disable the use of Microsoft Joliet extensions, even if available. Cf. **map**.

check={r[elaxed]|s[trict]}

With **check=relaxed**, a filename is first converted to lower case before doing the lookup. This is probably only meaningful together with **norock** and **map=normal**. (Default: **check=strict**.)

uid=value and **gid=value**

Give all files in the filesystem the indicated user or group id, possibly overriding the information found in the Rock Ridge extensions. (Default: **uid=0,gid=0**.)

map={n[ormal]|o[ff]|a[corn]}

For non-Rock Ridge volumes, normal name translation maps upper to lower case ASCII, drops a trailing ';', and converts ';' to '!'. With **map=off** no name translation is done. See **norock**. (Default: **map=normal**.) **map=acorn** is like **map=normal** but also apply Acorn extensions if present.

mode=value

For non-Rock Ridge volumes, give all files the indicated mode. (Default: read and execute permission for everybody.) Octal mode values require a leading 0.

unhide

Also show hidden and associated files. (If the ordinary files and the associated or hidden files have the

same filenames, this may make the ordinary files inaccessible.)

block={512|1024|2048}

Set the block size to the indicated value. (Default: **block=1024**.)

conv=mode

This option is obsolete and may fail or being ignored.

cruft

If the high byte of the file length contains other garbage, set this mount option to ignore the high order bits of the file length. This implies that a file cannot be larger than 16 MB.

session=x

Select number of session on a multisession CD.

sbsector=xxx

Session begins from sector xxx.

The following options are the same as for vfat and specifying them only makes sense when using discs encoded using Microsoft's Joliet extensions.

iocharset=value

Character set to use for converting 16 bit Unicode characters on CD to 8 bit characters. The default is iso8859-1.

utf8

Convert 16 bit Unicode characters on CD to UTF-8.

Mount options for jfs
iocharset=name

Character set to use for converting from Unicode to ASCII. The default is to do no conversion. Use **iocharset=utf8** for UTF8 translations. This requires **CONFIG_NLS_UTF8** to be set in the kernel .config file.

resize=value

Resize the volume to *value* blocks. JFS only supports growing a volume, not shrinking it. This option is only valid during a remount, when the volume is mounted read-write. The **resize** keyword with no value will grow the volume to the full size of the partition.

nointegrity

Do not write to the journal. The primary use of this option is to allow for higher performance when restoring a volume from backup media. The integrity of the volume is not guaranteed if the system abnormally ends.

integrity

Default. Commit metadata changes to the journal. Use this option to remount a volume where the **nointegrity** option was previously specified in order to restore normal behavior.

errors={continue|remount-ro|panic}

Define the behavior when an error is encountered. (Either ignore errors and just mark the filesystem erroneous and continue, or remount the filesystem read-only, or panic and halt the system.)

noquota|quota|usrquota|grpquota

These options are accepted but ignored.

Mount options for msdos

See mount options for fat. If the *msdos* filesystem detects an inconsistency, it reports an error and sets the file system read-only. The filesystem can be made writable again by remounting it.

Mount options for ncpfs

Just like *nfs*, the *ncpfs* implementation expects a binary argument (a *struct ncp_mount_data*) to the **mount**(2) system call. This argument is constructed by **ncpmount**(8) and the current version of **mount** (2.12) does not know anything about *ncpfs*.

Mount options for ntfs**iocharset=name**

Character set to use when returning file names. Unlike VFAT, NTFS suppresses names that contain nonconvertible characters. Deprecated.

nls=name

New name for the option earlier called *iocharset*.

utf8

Use UTF-8 for converting file names.

uni_xlate={0|1|2}

For 0 (or 'no' or 'false'), do not use escape sequences for unknown Unicode characters. For 1 (or 'yes' or 'true') or 2, use vfat-style 4-byte escape sequences starting with ":". Here 2 gives a little-endian encoding and 1 a byteswapped bigendian encoding.

posix=[0|1]

If enabled (posix=1), the filesystem distinguishes between upper and lower case. The 8.3 alias names are presented as hard links instead of being suppressed. This option is obsolete.

uid=value, gid=value and umask=value

Set the file permission on the filesystem. The umask value is given in octal. By default, the files are owned by root and not readable by somebody else.

Mount options for overlay

Since Linux 3.18 the overlay pseudo filesystem implements a union mount for other filesystems.

An overlay filesystem combines two filesystems – an **upper** filesystem and a **lower** filesystem. When a name exists in both filesystems, the object in the upper filesystem is visible while the object in the lower filesystem is either hidden or, in the case of directories, merged with the upper object.

The lower filesystem can be any filesystem supported by Linux and does not need to be writable. The lower filesystem can even be another overlayfs. The upper filesystem will normally be writable and if it is it must support the creation of trusted.* extended attributes, and must provide a valid d_type in readdir responses, so NFS is not suitable.

A read-only overlay of two read-only filesystems may use any filesystem type. The options **lowerdir** and **upperdir** are combined into a merged directory by using:

```
mount -t overlay overlay \
    -olowerdir=/lower,upperdir=/upper,workdir=/work /merged
```

lowerdir=directory

Any filesystem, does not need to be on a writable filesystem.

upperdir=directory

The upperdir is normally on a writable filesystem.

workdir=directory

The workdir needs to be an empty directory on the same filesystem as upperdir.

userxattr

Use the "**user.overlay.**" xattr namespace instead of "**trusted.overlay.**". This is useful for unprivileged mounting of overlays.

redirect_dir={on|off|follow|nofollow}

If the *redirect_dir* feature is enabled, then the directory will be copied up (but not the contents). Then the "**{trusted|user}.overlay.redirect**" extended attribute is set to the path of the original location from the root of the overlay. Finally the directory is moved to the new location.

on

Redirects are enabled.

off

Redirects are not created and only followed if "redirect_always_follow" feature is enabled in the kernel/module config.

follow

Redirects are not created, but followed.

nofollow

Redirects are not created and not followed (equivalent to "redirect_dir=off" if "redirect_always_follow" feature is not enabled).

index={on|off}

Inode index. If this feature is disabled and a file with multiple hard links is copied up, then this will "break" the link. Changes will not be propagated to other names referring to the same inode.

uuid={on|off}

Can be used to replace UUID of the underlying filesystem in file handles with null, and effectively disable UUID checks. This can be useful in case the underlying disk is copied and the UUID of this copy is changed. This is only applicable if all lower/upper/work directories are on the same filesystem, otherwise it will fallback to normal behaviour.

nfs_export={on|off}

When the underlying filesystem supports NFS export and the "nfs_export" feature is enabled, an overlay filesystem may be exported to NFS.

With the "nfs_export" feature, on copy_up of any lower object, an index entry is created under the index directory. The index entry name is the hexadecimal representation of the copy up origin file handle. For a non-directory object, the index entry is a hard link to the upper inode. For a directory object, the index entry has an extended attribute "**{trusted|user}.overlay.upper**" with an encoded file handle of the upper directory inode.

When encoding a file handle from an overlay filesystem object, the following rules apply

- For a non-upper object, encode a lower file handle from lower inode
- For an indexed object, encode a lower file handle from copy_up origin
- For a pure-upper object and for an existing non-indexed upper object, encode an upper file handle from upper inode

The encoded overlay file handle includes

- Header including path type information (e.g. lower/upper)
- UUID of the underlying filesystem
- Underlying filesystem encoding of underlying inode

This encoding format is identical to the encoding format of file handles that are stored in extended attribute "`{trusted|user}.overlay.origin`". When decoding an overlay file handle, the following steps are followed

- Find underlying layer by UUID and path type information.
- Decode the underlying filesystem file handle to underlying dentry.
- For a lower file handle, lookup the handle in index directory by name.
- If a whiteout is found in index, return **ESTALE**. This represents an overlay object that was deleted after its file handle was encoded.
- For a non-directory, instantiate a disconnected overlay dentry from the decoded underlying dentry, the path type and index inode, if found.
- For a directory, use the connected underlying decoded dentry, path type and index, to lookup a connected overlay dentry.

Decoding a non-directory file handle may return a disconnected dentry. `copy_up` of that disconnected dentry will create an upper index entry with no upper alias.

When overlay filesystem has multiple lower layers, a middle layer directory may have a "redirect" to lower directory. Because middle layer "redirects" are not indexed, a lower file handle that was encoded from the "redirect" origin directory, cannot be used to find the middle or upper layer directory. Similarly, a lower file handle that was encoded from a descendant of the "redirect" origin directory, cannot be used to reconstruct a connected overlay path. To mitigate the cases of directories that cannot be decoded from a lower file handle, these directories are copied up on encode and encoded as an upper file handle. On an overlay filesystem with no upper layer this mitigation cannot be used NFS export in this setup requires turning off redirect follow (e.g. `"redirect_dir=nofollow"`).

The overlay filesystem does not support non-directory connectable file handles, so exporting with the `subtree_check` exportfs configuration will cause failures to lookup files over NFS.

When the NFS export feature is enabled, all directory index entries are verified on mount time to check that upper file handles are not stale. This verification may cause significant overhead in some cases.

Note: the mount options `index=off,nfs_export=on` are conflicting for a read-write mount and will result in an error.

xino={on|off|auto}

The "xino" feature composes a unique object identifier from the real object `st_ino` and an underlying `fsid` index. The "xino" feature uses the high inode number bits for `fsid`, because the underlying filesystems rarely use the high inode number bits. In case the underlying inode number does overflow into the high xino bits, overlay filesystem will fall back to the non xino behavior for that inode.

For a detailed description of the effect of this option please refer to
<https://www.kernel.org/doc/html/latest/filesystems/overlayfs.html?highlight=overlayfs>

metacopy={on|off}

When metadata only copy up feature is enabled, `overlayfs` will only copy up metadata (as opposed to whole file), when a metadata specific operation like `chown/chmod` is performed. Full file will be

copied up later when file is opened for WRITE operation.

In other words, this is delayed data copy up operation and data is copied up when there is a need to actually modify data.

volatile

Volatile mounts are not guaranteed to survive a crash. It is strongly recommended that volatile mounts are only used if data written to the overlay can be recreated without significant effort.

The advantage of mounting with the "volatile" option is that all forms of sync calls to the upper filesystem are omitted.

In order to avoid giving a false sense of safety, the syncfs (and fsync) semantics of volatile mounts are slightly different than that of the rest of VFS. If any writeback error occurs on the upperdir's filesystem after a volatile mount takes place, all sync functions will return an error. Once this condition is reached, the filesystem will not recover, and every subsequent sync call will return an error, even if the upperdir has not experienced a new error since the last sync call.

When overlay is mounted with "volatile" option, the directory "\$workdir/work/incompat/volatile" is created. During next mount, overlay checks for this directory and refuses to mount if present. This is a strong indicator that user should throw away upper and work directories and create fresh one. In very limited cases where the user knows that the system has not crashed and contents of upperdir are intact, the "volatile" directory can be removed.

Mount options for reiserfs

Reiserfs is a journaling filesystem.

conv

Instructs version 3.6 reiserfs software to mount a version 3.5 filesystem, using the 3.6 format for newly created objects. This filesystem will no longer be compatible with reiserfs 3.5 tools.

hash={rupasov|tea|r5|detect}

Choose which hash function reiserfs will use to find files within directories.

rupasov

A hash invented by Yury Yu. Rupasov. It is fast and preserves locality, mapping lexicographically close file names to close hash values. This option should not be used, as it causes a high probability of hash collisions.

tea

A Davis–Meyer function implemented by Jeremy Fitzhardinge. It uses hash permuting bits in the name. It gets high randomness and, therefore, low probability of hash collisions at some CPU cost. This may be used if **EHASHCOLLISION** errors are experienced with the r5 hash.

r5

A modified version of the rupasov hash. It is used by default and is the best choice unless the filesystem has huge directories and unusual file-name patterns.

detect

Instructs **mount** to detect which hash function is in use by examining the filesystem being mounted, and to write this information into the reiserfs superblock. This is only useful on the first mount of an old format filesystem.

hashed_relocation

Tunes the block allocator. This may provide performance improvements in some situations.

no_unhashed_relocation

Tunes the block allocator. This may provide performance improvements in some situations.

noborder

Disable the border allocator algorithm invented by Yury Yu. Rupasov. This may provide performance improvements in some situations.

nolog

Disable journaling. This will provide slight performance improvements in some situations at the cost of losing reiserfs's fast recovery from crashes. Even with this option turned on, reiserfs still performs all journaling operations, save for actual writes into its journaling area. Implementation of *nolog* is a work in progress.

notail

By default, reiserfs stores small files and 'file tails' directly into its tree. This confuses some utilities such as **lilo(8)**. This option is used to disable packing of files into the tree.

replayonly

Replay the transactions which are in the journal, but do not actually mount the filesystem. Mainly used by *reiserfsck*.

resize=number

A remount option which permits online expansion of reiserfs partitions. Instructs reiserfs to assume that the device has *number* blocks. This option is designed for use with devices which are under logical volume management (LVM). There is a special *resizer* utility which can be obtained from [ftp://ftp.namesys.com/pub/reiserfsprogs](http://ftp.namesys.com/pub/reiserfsprogs).

user_xattr

Enable Extended User Attributes. See the **attr(1)** manual page.

acl

Enable POSIX Access Control Lists. See the **acl(5)** manual page.

barrier=none / barrier=flush

This disables / enables the use of write barriers in the journaling code. **barrier=none** disables, **barrier=flush** enables (default). This also requires an IO stack which can support barriers, and if reiserfs gets an error on a barrier write, it will disable barriers again with a warning. Write barriers enforce proper on-disk ordering of journal commits, making volatile disk write caches safe to use, at some performance penalty. If your disks are battery-backed in one way or another, disabling barriers may safely improve performance.

Mount options for ubifs

UBIFS is a flash filesystem which works on top of UBI volumes. Note that **atime** is not supported and is always turned off.

The device name may be specified as

ubiX_Y

UBI device number **X**, volume number **Y**

ubiY

UBI device number **0**, volume number **Y**

ubiX:NAME

UBI device number **X**, volume with name **NAME**

ubi:NAME

UBI device number **0**, volume with name **NAME**

Alternative ! separator may be used instead of ::

The following mount options are available:

bulk_read

Enable bulk-read. VFS read-ahead is disabled because it slows down the filesystem. Bulk-Read is an internal optimization. Some flashes may read faster if the data are read at one go, rather than at several read requests. For example, OneNAND can do "read-while-load" if it reads more than one NAND page.

no_bulk_read

Do not bulk-read. This is the default.

chk_data_crc

Check data CRC-32 checksums. This is the default.

no_chk_data_crc

Do not check data CRC-32 checksums. With this option, the filesystem does not check CRC-32 checksum for data, but it does check it for the internal indexing information. This option only affects reading, not writing. CRC-32 is always calculated when writing the data.

compr={none|lzo|zlib}

Select the default compressor which is used when new files are written. It is still possible to read compressed files if mounted with the **none** option.

Mount options for udf

UDF is the "Universal Disk Format" filesystem defined by OSTA, the Optical Storage Technology Association, and is often used for DVD-ROM, frequently in the form of a hybrid UDF/ISO-9660 filesystem. It is, however, perfectly usable by itself on disk drives, flash drives and other block devices. See also *iso9660*.

uid=

Make all files in the filesystem belong to the given user. **uid=forget** can be specified independently of (or usually in addition to) **uid=<user>** and results in UDF not storing uids to the media. In fact the recorded uid is the 32-bit overflow uid -1 as defined by the UDF standard. The value is given as either **<user>** which is a valid user name or the corresponding decimal user id, or the special string "forget".

gid=

Make all files in the filesystem belong to the given group. **gid=forget** can be specified independently of (or usually in addition to) **gid=<group>** and results in UDF not storing gids to the media. In fact the recorded gid is the 32-bit overflow gid -1 as defined by the UDF standard. The value is given as either **<group>** which is a valid group name or the corresponding decimal group id, or the special string "forget".

umask=

Mask out the given permissions from all inodes read from the filesystem. The value is given in octal.

mode=

If **mode=** is set the permissions of all non-directory inodes read from the filesystem will be set to the given mode. The value is given in octal.

dmode=

If **dmode**= is set the permissions of all directory inodes read from the filesystem will be set to the given dmode. The value is given in octal.

bs=

Set the block size. Default value prior to kernel version 2.6.30 was 2048. Since 2.6.30 and prior to 4.11 it was logical device block size with fallback to 2048. Since 4.11 it is logical block size with fallback to any valid block size between logical device block size and 4096.

For other details see the **mkudffs(8)** 2.0+ manpage, see the **COMPATIBILITY** and **BLOCK SIZE** sections.

unhide

Show otherwise hidden files.

undelete

Show deleted files in lists.

adinicb

Embed data in the inode. (default)

noadinicb

Don't embed data in the inode.

shortad

Use short UDF address descriptors.

longad

Use long UDF address descriptors. (default)

nostrict

Unset strict conformance.

ioccharset=

Set the NLS character set. This requires kernel compiled with **CONFIG_UDF_NLS** option.

utf8

Set the UTF-8 character set.

Mount options for debugging and disaster recovery**novrs**

Ignore the Volume Recognition Sequence and attempt to mount anyway.

session=

Select the session number for multi-session recorded optical media. (default= last session)

anchor=

Override standard anchor location. (default= 256)

lastblock=

Set the last block of the filesystem.

Unused historical mount options that may be encountered and should be removed**uid=ignore**

Ignored, use uid=<user> instead.

gid=ignore

Ignored, use `gid=<group>` instead.

volume=

Unimplemented and ignored.

partition=

Unimplemented and ignored.

fileset=

Unimplemented and ignored.

rootdir=

Unimplemented and ignored.

Mount options for ufs**ufs_{type}=*value***

UFS is a filesystem widely used in different operating systems. The problem are differences among implementations. Features of some implementations are undocumented, so its hard to recognize the type of ufs automatically. That's why the user must specify the type of ufs by mount option. Possible values are:

old

Old format of ufs, this is the default, read only. (Don't forget to give the `-r` option.)

44bsd

For filesystems created by a BSD-like system (NetBSD, FreeBSD, OpenBSD).

ufs2

Used in FreeBSD 5.x supported as read-write.

5xbsd

Synonym for ufs2.

sun

For filesystems created by SunOS or Solaris on Sparc.

sunx86

For filesystems created by Solaris on x86.

hp

For filesystems created by HP-UX, read-only.

nextstep

For filesystems created by NeXTStep (on NeXT station) (currently read only).

nextstep-cd

For NextStep CDROMs (`block_size == 2048`), read-only.

openstep

For filesystems created by OpenStep (currently read only). The same filesystem type is also used by macOS.

onerror=*value*

Set behavior on error:

panic

If an error is encountered, cause a kernel panic.

[lock|umount|repair]

These mount options don't do anything at present; when an error is encountered only a console message is printed.

Mount options for umsdos

See mount options for msdos. The **dotsOK** option is explicitly killed by *umsdos*.

Mount options for vfat

First of all, the mount options for *fat* are recognized. The **dotsOK** option is explicitly killed by *vfat*. Furthermore, there are

uni_xlate

Translate unhandled Unicode characters to special escaped sequences. This lets you backup and restore filenames that are created with any Unicode characters. Without this option, a '?' is used when no translation is possible. The escape character is ':' because it is otherwise invalid on the vfat filesystem. The escape sequence that gets used, where u is the Unicode character, is: ':', (u & 0x3f), ((u>>6) & 0x3f), (u>>12).

posix

Allow two files with names that only differ in case. This option is obsolete.

nonumtail

First try to make a short name without sequence number, before trying *name~num.ext*.

utf8

UTF8 is the filesystem safe 8-bit encoding of Unicode that is used by the console. It can be enabled for the filesystem with this option or disabled with utf8=0, utf8=no or utf8=false. If *uni_xlate* gets set, UTF8 gets disabled.

shortname=*mode*

Defines the behavior for creation and display of filenames which fit into 8.3 characters. If a long name for a file exists, it will always be the preferred one for display. There are four *modes*:

lower

Force the short name to lower case upon display; store a long name when the short name is not all upper case.

win95

Force the short name to upper case upon display; store a long name when the short name is not all upper case.

winnt

Display the short name as is; store a long name when the short name is not all lower case or all upper case.

mixed

Display the short name as is; store a long name when the short name is not all upper case. This mode is the default since Linux 2.6.32.

Mount options for usbfs**devuid=*uid* and devgid=*gid* and devmode=*mode***

Set the owner and group and mode of the device files in the usbfs filesystem (default: uid=gid=0, mode=0644). The mode is given in octal.

busuid=uid and **busgid=gid** and **busmode=mode**

Set the owner and group and mode of the bus directories in the usbfss filesystem (default: uid=gid=0, mode=0555). The mode is given in octal.

listuid=uid and **listgid=gid** and **listmode=mode**

Set the owner and group and mode of the file *devices* (default: uid=gid=0, mode=0444). The mode is given in octal.

DM-VERITY SUPPORT

The device-mapper verity target provides read-only transparent integrity checking of block devices using kernel crypto API. The **mount** command can open the dm-verity device and do the integrity verification before the device filesystem is mounted. Requires libcryptsetup with in libmount (optionally via **dlopen(3)**). If libcryptsetup supports extracting the root hash of an already mounted device, existing devices will be automatically reused in case of a match. Mount options for dm-verity:

verity.hashdevice=path

Path to the hash tree device associated with the source volume to pass to dm-verity.

verity.roothash=hex

Hex-encoded hash of the root of *verity.hashdevice*. Mutually exclusive with *verity.roothashfile*.

verity.roothashfile=path

Path to file containing the hex-encoded hash of the root of *verity.hashdevice*. Mutually exclusive with *verity.roothash*.

verity.hashoffset=offset

If the hash tree device is embedded in the source volume, *offset* (default: 0) is used by dm-verity to get to the tree.

verity.fecdevice=path

Path to the Forward Error Correction (FEC) device associated with the source volume to pass to dm-verity. Optional. Requires kernel built with **CONFIG_DM_VERITY_FEC**.

verity.fecoffset=offset

If the FEC device is embedded in the source volume, *offset* (default: 0) is used by dm-verity to get to the FEC area. Optional.

verity.fecroots=value

Parity bytes for FEC (default: 2). Optional.

verity.roothashsig=path

Path to **pkes7(1ssl)** signature of root hash hex string. Requires **crypt_activate_by_signed_key()** from cryptsetup and kernel built with **CONFIG_DM_VERITY_VERIFY_ROOTHASH_SIG**. For device reuse, signatures have to be either used by all mounts of a device or by none. Optional.

verity.oncorruption=ignore|restart|panic

Instruct the kernel to ignore, reboot or panic when corruption is detected. By default the I/O operation simply fails. Requires Linux 4.1 or newer, and libcryptsetup 2.3.4 or newer. Optional.

Supported since util-linux v2.35.

For example commands:

```
mksquashfs /etc /tmp/etc.squashfs
dd if=/dev/zero of=/tmp/etc.hash bs=1M count=10
```

```
veritysetup format /tmp/etc.squashfs /tmp/etc.hash
openssl smime -sign -in <hash> -nocerts -inkey private.key \
-signer private.crt -noattr -binary -outform der -out /tmp/etc.roothash.p7s
mount -o verity.hashdevice=/tmp/etc.hash,verity.roothash=<hash>, \
verity.roothashsig=/tmp/etc.roothash.p7s /tmp/etc.squashfs /mnt
```

create squashfs image from */etc* directory, verity hash device and mount verified filesystem image to */mnt*. The kernel will verify that the root hash is signed by a key from the kernel keyring if roothashsig is used.

LOOP-DEVICE SUPPORT

One further possible type is a mount via the loop device. For example, the command

```
mount /tmp/disk.img /mnt -t vfat -o loop=dev/loop3
```

will set up the loop device */dev/loop3* to correspond to the file */tmp/disk.img*, and then mount this device on */mnt*.

If no explicit loop device is mentioned (but just an option '**-o loop**' is given), then **mount** will try to find some unused loop device and use that, for example

```
mount /tmp/disk.img /mnt -o loop
```

The **mount** command **automatically** creates a loop device from a regular file if a filesystem type is not specified or the filesystem is known for libblkid, for example:

```
mount /tmp/disk.img /mnt
```

```
mount -t ext4 /tmp/disk.img /mnt
```

This type of mount knows about three options, namely **loop**, **offset** and **sizelimit**, that are really options to **losetup(8)**. (These options can be used in addition to those specific to the filesystem type.)

Since Linux 2.6.25 auto-destruction of loop devices is supported, meaning that any loop device allocated by **mount** will be freed by **umount** independently of */etc/mtab*.

You can also free a loop device by hand, using **losetup -d** or **umount -d**.

Since util-linux v2.29, **mount** re-uses the loop device rather than initializing a new device if the same backing file is already used for some loop device with the same offset and sizelimit. This is necessary to avoid a filesystem corruption.

EXIT STATUS

mount has the following exit status values (the bits can be ORed):

0
success

1
incorrect invocation or permissions

2
system error (out of memory, cannot fork, no more loop devices)

4
internal **mount** bug

8

user interrupt

16problems writing or locking */etc/mtab***32**

mount failure

64

some mount succeeded

The command **mount -a** returns 0 (all succeeded), 32 (all failed), or 64 (some failed, some succeeded).

EXTERNAL HELPERS

The syntax of external mount helpers is:

/sbin/mount.*suffix* *spec dir* [−sfnv**] [−**N namespace**] [−**o options**] [−**t type.subtype**]**

where the *suffix* is the filesystem type and the **−sfnvN** options have the same meaning as the normal mount options. The **−t** option is used for filesystems with subtypes support (for example **/sbin/mount.fuse −t fuse.sshfs**).

The command **mount** does not pass the mount options **unbindable**, **runbindable**, **private**, **rprivate**, **slave**, **rslave**, **shared**, **rshared**, **auto**, **noauto**, **comment**, **x−***, **loop**, **offset** and **sizelimit** to the mount.<*suffix*> helpers. All other options are used in a comma-separated list as an argument to the **−o** option.

ENVIRONMENT

LIBMOUNT_FSTAB=<path>

overrides the default location of the *fstab* file (ignored for suid)

LIBMOUNT_MTAB=<path>

overrides the default location of the *mtab* file (ignored for suid)

LIBMOUNT_DEBUG=all

enables libmount debug output

LIBBLKID_DEBUG=all

enables libblkid debug output

LOOPDEV_DEBUG=all

enables loop device setup debug output

FILES

See also "The files */etc/fstab*, */etc/mtab* and */proc/mounts*" section above.

/etc/fstab

filesystem table

/run/mount

libmount private runtime directory

/etc/mtab

table of mounted filesystems or symlink to */proc/mounts*

/etc/mtab~

lock file (unused on systems with *mtab* symlink)

/etc/mtab.tmp

temporary file (unused on systems with *mtab* symlink)

/etc/filesystems

a list of filesystem types to try

HISTORY

A **mount** command existed in Version 5 AT&T UNIX.

BUGS

It is possible for a corrupted filesystem to cause a crash.

Some Linux filesystems don't support **-o sync** and **-o dirsync** (the ext2, ext3, ext4, fat and vfat filesystems do support synchronous updates (a la BSD) when mounted with the **sync** option).

The **-o remount** may not be able to change mount parameters (all *ext2fs*-specific parameters, except **sb**, are changeable with a remount, for example, but you can't change **gid** or **umask** for the *fatfs*).

It is possible that the files */etc/mtab* and */proc/mounts* don't match on systems with a regular *mtab* file. The first file is based only on the **mount** command options, but the content of the second file also depends on the kernel and others settings (e.g. on a remote NFS server — in certain cases the **mount** command may report unreliable information about an NFS mount point and the */proc/mount* file usually contains more reliable information.) This is another reason to replace the *mtab* file with a symlink to the */proc/mounts* file.

Checking files on NFS filesystems referenced by file descriptors (i.e. the **fcntl** and **ioctl** families of functions) may lead to inconsistent results due to the lack of a consistency check in the kernel even if the **noac** mount option is used.

The **loop** option with the **offset** or **sizelimit** options used may fail when using older kernels if the **mount** command can't confirm that the size of the block device has been configured as requested. This situation can be worked around by using the **losetup(8)** command manually before calling **mount** with the configured loop device.

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **mount** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

fuse – configuration and mount options for FUSE file systems

DESCRIPTION

FUSE (Filesystem in Userspace) is a simple interface for userspace programs to export a virtual filesystem to the Linux kernel. FUSE also aims to provide a secure method for non privileged users to create and mount their own filesystem implementations.

DEFINITIONS

FUSE The in-kernel filesystem that forwards requests to a user-space process.

filesystem

The user-space process that responds to requests received from the kernel.

libfuse The shared library that most (user-space) filesystems use to communicate with FUSE (the kernel filesystem). libfuse also provides the **fusermount3** (or **fusermount** if you have older version of libfuse) helper to allow non-privileged users to mount filesystems.

filesystem owner

The user that starts the filesystem and instructs the kernel to associate it with a particular mount-point. The latter is typically done by the filesystem itself on start-up. When using libfuse, this is done by calling the **fusermount3** utility.

client Any process that interacts with the mountpoint.

CONFIGURATION

Some options regarding mount policy can be set in the file */etc/fuse.conf*. Currently these options are:

mount_max = NNN

Set the maximum number of FUSE mounts allowed to non-root users. The default is 1000.

user_allow_other

Allow non-root users to specify the **allow_other** or **allow_root** mount options (see below).

These limits are enforced by the **fusermount3** helper, so they can be avoided by filesystems that run as root.

OPTIONS

Most of the generic mount options described in **mount** are supported (**ro**, **rw**, **suid**, **nosuid**, **dev**, **nodev**, **exec**, **noexec**, **atime**, **noatime**, **sync**, **async**, **dirsync**). Filesystems are mounted with **nodev,nosuid** by default, which can only be overridden by a privileged user.

General mount options:

These are FUSE specific mount options that can be specified for all filesystems:

default_permissions

This option instructs the kernel to perform its own permission check instead of deferring all permission checking to the filesystem. The check by the kernel is done in addition to any permission checks by the filesystem, and both have to succeed for an operation to be allowed. The kernel performs a standard UNIX permission check (based on mode bits and ownership of the directory entry, and uid/gid of the client).

This mount option is activated implicitly if the filesystem enables ACL support during the initial feature negotiation when opening the device fd. In this case, the kernel performs both ACL and standard unix permission checking.

Filesystems that do not implement any permission checking should generally add this option internally.

allow_other

This option overrides the security measure restricting file access to the filesystem owner, so that all users (including root) can access the files.

rootmode=M

Specifies the file mode of the filesystem's root (in octal representation).

blkdev Mount a filesystem backed by a block device. This is a privileged option. The device must be specified with the **fsname=NAME** option.

blksize=N

Set the block size for the filesystem. This option is only valid for 'fuseblk' type mounts. The default is 512.

In most cases, this option should not be specified by the filesystem owner but set internally by the filesystem.

max_read=N

With this option the maximum size of read operations can be set. The default is infinite, but typically the kernel enforces its own limit in addition to this one. A value of zero corresponds to no limit.

This option should not be specified by the filesystem owner. The correct (or optimum) value depends on the filesystem implementation and should thus be set by the filesystem internally.

This mount option is deprecated in favor of direct negotiation over the device fd (as done for e.g. the maximum size of write operations). For the time being, libfuse-using filesystems that want to limit the read size must therefore use this mount option *and* set the same value again in the init() handler.

fd=N The file descriptor to use for communication between the userspace filesystem and the kernel. The file descriptor must have been obtained by opening the FUSE device (/dev/fuse).

This option should not be specified by the filesystem owner. It is set by libfuse (or, if libfuse is not used, must be set by the filesystem itself).

user_id=N

group_id=N Specifies the numeric uid/gid of the mount owner.

This option should not be specified by the filesystem owner. It is set by libfuse (or, if libfuse is not used, must be set by the filesystem itself).

fsname=NAME

Sets the filesystem source (first field in /etc/mtab). The default is the name of the filesystem process.

subtype=TYPE

Sets the filesystem type (third field in /etc/mtab). The default is the name of the filesystem process. If the kernel supports it, /etc/mtab and /proc/mounts will show the filesystem type as **fuse.TYPE**

If the kernel doesn't support subtypes, the source field will be **TYPE#NAME**, or if **fsname** option is not specified, just **TYPE**.

libfuse-specific mount options:

These following options are not actually passed to the kernel but interpreted by libfuse. They can be specified for all filesystems that use libfuse:

allow_root

This option is similar to **allow_other** but file access is limited to the filesystem owner and root. This option and **allow_other** are mutually exclusive.

auto_unmount

This option enables automatic release of the mountpoint if filesystem terminates for any reason. Normally the filesystem is responsible for releasing the mountpoint, which means that the mountpoint becomes inaccessible if the filesystem terminates without first unmounting.

At the moment, this option implies that the filesystem will also be mounted with **nodev** and **nosuid** (even when mounted by root). This restriction may be lifted in the future.

High-level mount options:

These following options are not actually passed to the kernel but interpreted by libfuse. They can only be specified for filesystems that use the high-level libfuse API:

kernel_cache

This option disables flushing the cache of the file contents on every **open(2)**. This should only be enabled on filesystems, where the file data is never changed externally (not through the mounted FUSE filesystem). Thus it is not suitable for network filesystems and other "intermediate" filesystems.

NOTE: if this option is not specified (and neither **direct_io**) data is still cached after the **open(2)**, so a **read(2)** system call will not always initiate a read operation.

auto_cache

This option is an alternative to **kernel_cache**. Instead of unconditionally keeping cached data, the cached data is invalidated on **open(2)** if the modification time or the size of the file has changed since it was last opened.

umask=M

Override the permission bits in *st_mode* set by the filesystem. The resulting permission bits are the ones missing from the given umask value. The value is given in octal representation.

uid=N Override the *st_uid* field set by the filesystem (N is numeric).

gid=N Override the *st_gid* field set by the filesystem (N is numeric).

entry_timeout=T

The timeout in seconds for which name lookups will be cached. The default is 1.0 second. For all the timeout options, it is possible to give fractions of a second as well (e.g. **entry_timeout=2.8**)

negative_timeout=T

The timeout in seconds for which a negative lookup will be cached. This means, that if file did not exist (lookup returned **ENOENT**), the lookup will only be redone after the timeout, and the file/directory will be assumed to not exist until then. The default is 0.0 second, meaning that caching negative lookups are disabled.

attr_timeout=T

The timeout in seconds for which file/directory attributes are cached. The default is 1.0 second.

ac_attr_timeout=T

The timeout in seconds for which file attributes are cached for the purpose of checking if **auto_cache** should flush the file data on **open**. The default is the value of **attr_timeout**

noforget**remember=T**

Normally, libfuse assigns inodes to paths only for as long as the kernel is aware of them. With this option inodes are instead assigned for at least T seconds (or, in the case of **noforget**, the life-time of the filesystem). This will require more memory, but may be necessary when using applications that make use of inode numbers.

modules=M1[:M2...]

Add modules to the filesystem stack. Modules are pushed in the order they are specified, with the original filesystem being on the bottom of the stack.

mount.fuse3 options:

These options are interpreted by **mount.fuse3** and are thus only available when mounting a file system via **mount.fuse3** (such as when mounting via the generic **mount(1)** command or **/etc/fstab**). Supported options are:

setuid=USER

Switch to **USER** and its primary group before launching the FUSE file system process. **mount.fuse3** must be run as root or with **CAP_SETUID** and **CAP_SETGID** for this to work.

drop_privileges

Perform setup of the FUSE file descriptor and mounting the file system before launching the FUSE file system process. **mount.fuse3** requires privilege to do so, i.e. must be run as root or at least with **CAP_SYS_ADMIN** and **CAP_SETPCAP**. It will launch the file system process fully unprivileged, i.e. without **capabilities(7)** and **prctl(2)** flags set up such that privileges can't be reacquired (e.g. via setuid or fscaps binaries). This reduces risk in the event of the FUSE file system process getting compromised by malicious file system data.

FUSE MODULES (STACKING)

Modules are filesystem stacking support to high level API. Filesystem modules can be built into libfuse or loaded from shared object

iconv

Perform file name character set conversion. Options are:

from_code=CHARSET

Character set to convert from (see **iconv -l** for a list of possible values). Default is **UTF-8**.

to_code=CHARSET

Character set to convert to. Default is determined by the current locale.

subdir

Prepend a given directory to each path. Options are:

subdir=DIR

Directory to prepend to all paths. This option is *mandatory*.

rellinks

Transform absolute symlinks into relative

norellinks

Do not transform absolute symlinks into relative. This is the default.

SECURITY

The fusermount3 program is installed set-user-gid to fuse. This is done to allow users from fuse group to mount their own filesystem implementations. There must however be some limitations, in order to prevent Bad User from doing nasty things. Currently those limitations are:

1. The user can only mount on a mountpoint, for which it has write permission
2. The mountpoint is not a sticky directory which isn't owned by the user (like **/tmp** usually is)
3. No other user (including root) can access the contents of the mounted filesystem.

NOTE

FUSE filesystems are unmounted using the **fusermount3(1)** command (**fusermount3 -u mountpoint**).

AUTHORS

FUSE is currently maintained by Nikolaus Rath <Nikolaus@rath.org>

The original author of FUSE is Miklos Szeredi <mszteredi@inf.bme.hu>.

This man page was originally written by Bastien Roucaries <roucaries.bastien+debian@gmail.com> for the Debian GNU/Linux distribution.

SEE ALSO

mount.nfs(8) - Linux man page

Name

mount.nfs, mount.nfs4 - mount a Network File System

Synopsis

mount.nfs *remotetarget dir [-rvVwfnsH] [-o options]*

Description

mount.nfs is a part of [**nfs**\(5\)](#) utilities package, which provides NFS client functionality.

mount.nfs is meant to be used by the [**mount**\(8\)](#) command for mounting NFS shares. This subcommand, however, can also be used as a standalone command with limited functionality.

mount.nfs4 is used for mounting NFSv4 file system, while **mount.nfs** is used to mount NFS file systems versions 3 or 2. *remotetarget* is a server share usually in the form of **servername:/path/to/share**. *dir* is the directory on which the file system is to be mounted.

Options

-r

Mount file system readonly.

-v

Be verbose.

-V

Print version.

-w

Mount file system read-write.

-f

Fake mount. Don't actually call the mount system call.

-n

Do not update */etc/mtab*. By default, an entry is created in */etc/mtab* for every mounted file system. Use this option to skip making an entry.

-s

Tolerate sloppy mount options rather than fail.

-h

Print help message.

nfsoptions

Refer to [nfs\(5\)](#) or [mount\(8\)](#) manual pages.

Note

For further information please refer [nfs\(5\)](#) and [mount\(8\)](#) manual pages.

NAME

ntfs-3g – Third Generation Read/Write NTFS Driver

SYNOPSIS

```
ntfs-3g [-o option[,...]] volume mount_point
mount -t ntfs-3g [-o option[,...]] volume mount_point
lowntfs-3g [-o option[,...]] volume mount_point
mount -t lowntfs-3g [-o option[,...]] volume mount_point
```

DESCRIPTION

ntfs-3g is an NTFS driver, which can create, remove, rename, move files, directories, hard links, and streams; it can read and write files, including streams, sparse files and transparently compressed files; it can handle special files like symbolic links, devices, and FIFOs; moreover it provides standard management of file ownership and permissions, including POSIX ACLs.

It comes in two variants **ntfs-3g** and **lowntfs-3g** with a few differences mentioned below in relevant options descriptions.

The *volume* to be mounted can be either a block device or an image file, either by using the *mount* command or starting the drive.

Windows hibernation and fast restarting

On computers which can be dual-booted into Windows or Linux, Windows has to be fully shut down before booting into Linux, otherwise the NTFS file systems on internal disks may be left in an inconsistent state and changes made by Linux may be ignored by Windows.

So, Windows may not be left in hibernation when starting Linux, in order to avoid inconsistencies. Moreover, the fast restart feature available on recent Windows systems has to be disabled. This can be achieved by issuing as an Administrator the Windows command which disables both hibernation and fast restarting :

```
powercfg /h off
```

If either Windows is hibernated or its fast restart is enabled, partitions on internal disks are forced to be mounted in read-only mode.

Access Handling and Security

By default, files and directories are owned by the effective user and group of the mounting process, and everybody has full read, write, execution and directory browsing permissions. You can also assign permissions to a single user by using the **uid** and/or the **gid** options together with the **umask**, or **fmask** and **dmask** options.

Doing so, all Windows users have full access to the files created by **ntfs-3g**.

But, by setting the **permissions** option, you can benefit from the full ownership and permissions features as defined by POSIX. Moreover, by defining a Windows-to-Linux user mapping, the ownerships and permissions are even applied to Windows users and conversely.

If **ntfs-3g** is set setuid-root then non-root users will be also able to mount volumes.

Windows Filename Compatibility

NTFS supports several filename namespaces: DOS, Win32 and POSIX. While the **ntfs-3g** driver handles all of them, it always creates new files in the POSIX namespace for maximum portability and interoperability reasons. This means that filenames are case sensitive and all characters are allowed except '/' and '\0'. This is perfectly legal on Windows, though some application may get confused. The option **windows_names** may be used to apply Windows restrictions to new file names.

Alternate Data Streams (ADS)

NTFS stores all data in streams. Every file has exactly one unnamed data stream and can have many named data streams. The size of a file is the size of its unnamed data stream. By default, **ntfs-3g** will only read the unnamed data stream.

By using the option **streams_interface=windows**, with the ntfs-3g driver (not possible with lowntfs-3g),

you will be able to read any named data streams, simply by specifying the stream name after a colon. For example:

```
cat some.mp3:artist
```

Named data streams act like normal files, so you can read from them, write to them and even delete them (using rm). You can list all the named data streams a file has by getting the **ntfs.streams.list** extended attribute.

OPTIONS

Below is a summary of the options that **ntfs-3g** accepts.

acl Enable setting Posix ACLs on created files and use them for access control. This option is only available on specific builds. It is set by default when a user mapping file is present and the **permissions** mount option is not set.

allow_other

This option overrides the security measure restricting file access to the user mounting the filesystem. This option is only allowed to root, but this restriction can be overridden by the **user_allow_other** option in the /etc/fuse.conf file.

atime, noatime, relatime

The **atime** option updates inode access time for each access.

The **noatime** option disables inode access time updates, which can speed up file operations and prevent sleeping (notebook) disks spinning up too often thus saving energy and disk lifetime.

The **relatime** option is very similar to **noatime**. It updates inode access times relative to modify or change time. The access time is only updated if the previous access time was earlier than the current modify or change time. Unlike **noatime** this option doesn't break applications that need to know if a file has been read since the last time it was modified. This is the default behaviour.

big_writes

This option prevents fuse from splitting write buffers into 4K chunks, enabling big write buffers to be transferred from the application in a single step (up to some system limit, generally 128K bytes).

compression

This option enables creating new transparently compressed files in directories marked for compression. A directory is marked for compression by setting the bit 11 (value 0x00000800) in its Windows attribute. In such a directory, new files are created compressed and new subdirectories are themselves marked for compression. The option and the flag have no effect on existing files. Currently this is the default option.

debug Makes ntfs-3g (or lowntfs-3g) to print a lot of debug output from libntfs-3g and FUSE.

delay_mtime[= value]

Only update the file modification time and the file change time of a file when it is closed or when the indicated delay since the previous update has elapsed. The argument is a number of seconds, with a default value of 60. This is mainly useful for big files which are kept open for a long time and written to without changing their size, such as databases or file system images mounted as loop.

dmask=value

Set the bitmask of the directory permissions that are not present. The value is given in octal. The default value is 0 which means full access to everybody.

efs_raw

This option should only be used in backup or restore situation. It changes the apparent size of files and the behavior of read and write operation so that encrypted files can be saved and restored

without being decrypted. The **user.ntfs.efsinfo** extended attribute has also to be saved and restored for the file to be decrypted.

fmask=value

Set the bitmask of the file permissions that are not present. The value is given in octal. The default value is 0 which means full access to everybody.

force This option is obsolete. It has been superseded by the **recover** and **norecover** options.

hide_dot_files

Set the hidden flag in the NTFS attribute for created files and directories whose first character of the name is a dot. Such files and directories normally do not appear in directory listings, and when the flag is set they do not appear in Windows directory displays either. When a file is renamed or linked with a new name, the hidden flag is adjusted to the latest name.

hide_hid_files

Hide the hidden files and directories in directory listings, the hidden files and directories being the ones whose NTFS attribute have the hidden flag set. The hidden files will not be selected when using wildcards in commands, but all files and directories remain accessible by full name, for example you can always display the Windows trash bin directory by : "ls -ld '\$RECYCLE.BIN'".

ignore_case (only with lowntfs-3g)

Ignore character case when accessing a file (**FOO**, **Foo**, **foo**, etc. designate the same file). All files are displayed with lower case in directory listings.

inherit When creating a new file, set its initial protections according to inheritance rules defined in parent directory. These rules deviate from Posix specifications, but yield a better Windows compatibility. The **permissions** (or ****acl****) option or a valid user mapping file is required for this option to be effective.

locale=value

This option can be useful when wanting a language specific locale environment. It is however discouraged as it leads to files with untranslatable characters to not be visible.

max_read=value

With this option the maximum size of read operations can be set. The default is infinite. Note that the size of read requests is limited anyway by the system (usually to 128kbyte).

no_def_opts

By default ntfs-3g acts as if **silent** (ignore permission errors when permissions are not enabled), **allow_other** (allow any user to access files) and **nonempty** (allow mounting on non-empty directories) were set, and **no_def_opts** cancels these default options.

no_detach

Makes ntfs-3g to not detach from terminal and print some debug output.

nocompression

This option disables creating new transparently compressed files in directories marked for compression. Existing compressed files can still be read and updated.

norecover

Do not try to mount a partition which was not unmounted properly by Windows.

permissions

Set standard permissions on created files and use standard access control. This option is set by default when a user mapping file is present.

posix_nlink

Compute the count of hard links of a file or directory according to the POSIX specifications. When this option is not set, a count of 1 is set for directories, and the short name of files is accounted for. Using the option entails some penalty as the count is not stored and has to be computed.

recover

Recover and try to mount a partition which was not unmounted properly by Windows. The Windows logfile is cleared, which may cause inconsistencies. Currently this is the default option.

remove_hiberfile

When the NTFS volume is hibernated, a read-write mount is denied and a read-only mount is forced. One needs either to resume Windows and shutdown it properly, or use this option which will remove the Windows hibernation file. Please note, this means that the saved Windows session will be completely lost. Use this option under your own responsibility.

- ro** Mount the filesystem read-only. Useful if Windows is hibernated or the NTFS journal file is unclean.

show_sys_files

Show the metafiles in directory listings. Otherwise the default behaviour is to hide the metafiles, which are special files used to store the NTFS structure. Please note that even when this option is specified, "\$MFT" may not be visible due to a glibc bug. Furthermore, irrespectively of **show_sys_files**, all files are accessible by name, for example you can always do "ls -l '\$UpCase'".

- silent** Do nothing, without returning any error, on chmod and chown operations and on permission checking errors, when the **permissions** option is not set and no user mapping file is defined. This option is on by default, and when set off (through option **no_def_opts**) ownership and permissions parameters have to be set.

special_files=mode

This option selects a mode for representing a special file to be created (symbolic link, socket, fifo, character or block device). The *mode* can be **interix** or **wsl**, and existing files in either mode are recognized irrespective of the selected mode. Interix is the traditional mode, used by default, and wsl is interoperable with Windows WSL, but it is not compatible with Windows versions earlier than Windows 10. Neither mode are interoperable with Windows.

streams_interface=mode

This option controls how the user can access Alternate Data Streams (ADS) or in other words, named data streams. The *mode* can be set to one of **none**, **windows** or **xattr**. If the option is set to **none**, the user will have no access to the named data streams. If it is set to **windows** (not possible with lowntfs-3g), then the user can access them just like in Windows (eg. cat file:stream). If it's set to **xattr**, then the named data streams are mapped to extended attributes and a user can manipulate them using {get,set}fattr utilities. The default is **xattr**.

uid=value and gid=value

Set the owner and the group of files and directories. The values are numerical. The defaults are the uid and gid of the current process.

umask=value

Set the bitmask of the file and directory permissions that are not present. The value is given in octal. The default value is 0 which means full access to everybody.

usermapping=file-name

Use file *file-name* as the user mapping file instead of the default **.NTFS-3G/UserMapping**. If *file-name* defines a full path, the file must be located on a partition previously mounted. If it defines a relative path, it is interpreted relative to the root of NTFS partition being mounted.

When a user mapping file is defined, the options **uid=**, **gid=**, **umask=**, **fmask=**, **dmask=** and **silent** are ignored.

user_xattr

Same as **streams_interface=xattr**.

windows_names

This option prevents files, directories and extended attributes to be created with a name not allowed by windows, because

- it contains some not allowed character,
- or the last character is a space or a dot,
- or the name is reserved.

The forbidden characters are the nine characters " * / : < > ? \ | and those whose code is less than 0x20, and the reserved names are CON, PRN, AUX, NUL, COM1..COM9, LPT1..LPT9, with no suffix or followed by a dot.

Existing such files can still be read (and renamed).

USER MAPPING

NTFS uses specific ids to record the ownership of files instead of the **uid** (user id) and **gid** (group id) used by Linux. As a consequence a mapping between the ids has to be defined for ownerships to be recorded into NTFS files and recognized.

By default, this mapping is fetched from the file **.NTFS-3G/UserMapping** located in the NTFS partition. The option **usermapping=** may be used to define another location. When the option **permissions** is set and no mapping file is found, a default mapping is used.

Each line in the user mapping file defines a mapping. It is organized in three fields separated by colons. The first field identifies a **uid**, the second field identifies a **gid** and the third one identifies the corresponding NTFS id, known as a **SID**. The **uid** and the **gid** are optional and defining both of them for the same **SID** is not recommended.

If no interoperation with Windows is needed, you can use the option **permissions** to define a standard mapping. Alternately, you may define your own mapping by setting a single default mapping with no uid and gid. In both cases, files created on Linux will appear to Windows as owned by a foreign user, and files created on Windows will appear to Linux as owned by root. Just copy the example below and replace the 9 and 10-digit numbers by any number not greater than 4294967295. The resulting behavior is the same as the one with the option **permission** set with no ownership option and no user mapping file available.

```
::S-1-5-21-3141592653-589793238-462643383-10000
```

If a strong interoperation with Windows is needed, the mapping has to be defined for each user and group known to both system, and the **SIDs** used by Windows has to be collected. This will lead to a user mapping file like :

```
john::S-1-5-21-3141592653-589793238-462643383-1008
mary::S-1-5-21-3141592653-589793238-462643383-1009
smith::S-1-5-21-3141592653-589793238-462643383-513
::S-1-5-21-3141592653-589793238-462643383-10000
```

The utility **ntfsusermap** may be used to create such a user mapping file.

EXAMPLES

Mount /dev/sda1 to /mnt/windows:

```
ntfs-3g /dev/sda1 /mnt/windows
```

or

```
mount -t ntfs-3g /dev/sda1 /mnt/windows
```

Mount the ntfs data partition /dev/sda3 to /mnt/data with standard Linux permissions applied :

```
ntfs-3g -o permissions /dev/sda3 /mnt/data
```

or

```
mount -t ntfs-3g -o permissions /dev/sda3 /mnt/data
```

Read-only mount /dev/sda5 to /home/user/mnt and make user with uid 1000 to be the owner of all files:

```
ntfs-3g /dev/sda5 /home/user/mnt -o ro,uid=1000
```

/etc/fstab entry for the above (the sixth and last field has to be zero to avoid a file system check at boot time) :

```
/dev/sda5 /home/user/mnt ntfs-3g ro,uid=1000 0 0
```

Unmount /mnt/windows:

```
umount /mnt/windows
```

EXIT CODES

To facilitate the use of the **ntfs-3g** driver in scripts, an exit code is returned to give an indication of the mountability status of a volume. Value 0 means success, and all other ones mean an error. The unique error codes are documented in the **ntfs-3g.probe(8)** manual page.

KNOWN ISSUES

Please see

<https://github.com/tuxera/ntfs-3g/wiki/NTFS-3G-FAQ>

for common questions and known issues. If you would find a new one in the latest release of the software then please post an ntfs-3g issue describing it in detail so that the development team can be aware of the issue and take care of it:

<https://github.com/tuxera/ntfs-3g/issues>

AUTHORS

ntfs-3g was based on and a major improvement to ntfsmount and libntfs which were written by Yura Pakhuchiy and the Linux-NTFS team. The improvements were made, the ntfs-3g project was initiated and currently led by long time Linux-NTFS team developer Szabolcs Szakacsits (szaka@tuxera.com).

THANKS

Several people made heroic efforts, often over five or more years which resulted the ntfs-3g driver. Most importantly they are Anton Altaparmakov, Jean-Pierre André, Erik Larsson, Richard Russon, Szabolcs Szakacsits, Yura Pakhuchiy, Yuval Fledel, and the author of the groundbreaking FUSE filesystem development framework, Miklos Szeredi.

mountd(8) - Linux man page

Name

rpc.mountd - NFS mount daemon

Synopsis

/usr/sbin/rpc.mountd [options]

Description

The **rpc.mountd** daemon implements the server side of the NFS MOUNT protocol, an NFS side protocol used by NFS version 2 [RFC1094] and NFS version 3 [RFC1813].

An NFS server maintains a table of local physical file systems that are accessible to NFS clients. Each file system in this table is referred to as an *exported file system*, or *export*, for short.

Each file system in the export table has an access control list. **rpc.mountd** uses these access control lists to determine whether an NFS client is permitted to access a given file system. For details on how to manage your NFS server's export table, see the **exports(5)** and **exportfs(8)** man pages.

Mounting exported NFS File Systems

The NFS MOUNT protocol has several procedures. The most important of these are MNT (mount an export) and UMNT (unmount an export).

A MNT request has two arguments: an explicit argument that contains the pathname of the root directory of the export to be mounted, and an implicit argument that is the sender's IP address.

When receiving a MNT request from an NFS client, **rpc.mountd** checks both the pathname and the sender's IP address against its export table. If the sender is permitted to access the requested export, **rpc.mountd** returns an NFS file handle for the export's root directory to the client. The client can then use the root file handle and NFS LOOKUP requests to navigate the directory structure of the export.

The rmtab File

The **rpc.mountd** daemon registers every successful MNT request by adding an entry to the `/var/lib/nfs/rmtab` file. When receiving a UMNT request from an NFS client, **rpc.mountd** simply removes the matching entry from `/var/lib/nfs/rmtab`, as long as the access control list for that export allows that sender to access the export.

Clients can discover the list of file systems an NFS server is currently exporting, or the list of other clients that have mounted its exports, by using the **showmount**(8) command. **showmount**(8) uses other procedures in the NFS MOUNT protocol to report information about the server's exported file systems.

Note, however, that there is little to guarantee that the contents of */var/lib/nfs/rmtab* are accurate. A client may continue accessing an export even after invoking UMNT. If the client reboots without sending a UMNT request, stale entries remain for that client in */var/lib/nfs/rmtab*.

Options

-d kind or --debug kind

Turn on debugging. Valid kinds are: all, auth, call, general and parse.

-F or --foreground

Run in foreground (do not daemonize)

-f or --exports-file

This option specifies the exports file, listing the clients that this server is prepared to serve and parameters to apply to each such mount (see **exports**(5)). By default, export information is read from */etc(exports*.

-h or --help

Display usage message.

-o num or --descriptors num

Set the limit of the number of open file descriptors to num. The default is to leave the limit unchanged.

-N or --no-nfs-version

This option can be used to request that **rpc.mountd** do not offer certain versions of NFS. The current version of **rpc.mountd** can support both NFS version 2, 3 and 4. If either one of these version should not be offered, **rpc.mountd** must be invoked with the option **--no-nfs-version <vers>** .

-n or --no-tcp

Don't advertise TCP for mount.

-P

Ignored (compatibility with unfsd??).

-p or --port num

Specifies the port number used for RPC listener sockets. If this option is not specified, **rpc.mountd** chooses a random ephemeral port for each listener socket.

This option can be used to fix the port value of **rpc.mountd**'s listeners when NFS MOUNT requests must traverse a firewall between clients and servers.

-H or --ha-callout prog

Specify a high availability callout program. This program receives callouts for all MOUNT and UNMOUNT requests. This allows **rpc.mountd** to be used in a High

Availability NFS (HA-NFS) environment.

The callout program is run with 4 arguments. The first is **mount** or **umount** depending on the reason for the callout. The second will be the name of the client performing the mount. The third will be the path that the client is mounting. The last is the number of concurrent mounts that we believe the client has of that path.

This callout is not needed with 2.6 and later kernels. Instead, mount the nfsd filesystem on `/proc/fs/nfsd`.

-s, --state-directory-path *directory*

Specify a directory in which to place statd state information. If this option is not specified the default of `/var/lib/nfs` is used.

-r, --reverse-lookup

rpc.mountd tracks IP addresses in the `rmtab` file. When a DUMP request is made (by someone running **showmount -a**, for instance), it returns IP addresses instead of hostnames by default. This option causes **rpc.mountd** to perform a reverse lookup on each IP address and return that hostname instead. Enabling this can have a substantial negative effect on performance in some situations.

-t N or **--num-threads=N**

This option specifies the number of worker threads that **rpc.mountd** spawns. The default is 1 thread, which is probably enough. More threads are usually only needed for NFS servers which need to handle mount storms of hundreds of NFS mounts in a few seconds, or when your DNS server is slow or unreliable.

-V or **--nfs-version**

This option can be used to request that **rpc.mountd** offer certain versions of NFS. The current version of **rpc.mountd** can support both NFS version 2 and the newer version 3.

-v or **--version**

Print the version of **rpc.mountd** and exit.

-g or **--manage-gids**

Accept requests from the kernel to map user id numbers into lists of group id numbers for use in access control. An NFS request will normally (except when using Kerberos or other cryptographic authentication) contains a user-id and a list of group-ids. Due to a limitation in the NFS protocol, at most 16 groups ids can be listed. If you use the **-g** flag, then the list of group ids received from the client will be replaced by a list of group ids determined by an appropriate lookup on the server. Note that the 'primary' group id is not affected so a **newgroup** command on the client will still be effective. This function requires a Linux Kernel with version at least 2.6.21.

TCP_WRAPPERS SUPPORT

You can protect your **rpc.mountd** listeners using the **tcp_wrapper** library or **iptables**(8).

Note that the **tcp_wrapper** library supports only IPv4 networking.

Add the hostnames of NFS peers that are allowed to access **rpc.mountd** to */etc/hosts.allow*. Use the daemon name **mountd** even if the **rpc.mountd** binary has a different name.

Hostnames used in either access file will be ignored when they can not be resolved into IP addresses. For further information see the **tcpd**(8) and **hosts_access**(5) man pages.

IPv6 and TI-RPC support

TI-RPC is a pre-requisite for supporting NFS on IPv6. If TI-RPC support is built into **rpc.mountd**, it attempts to start listeners on network transports marked 'visible' in */etc/netconfig*. As long as at least one network transport listener starts successfully, **rpc.mountd** will operate.

Files

/etc/exports

input file for **exportfs**, listing exports, export options, and access control lists

/var/lib/nfs/rmtab

table of clients accessing server's exports

Name

`mshowfat` - shows FAT clusters allocated to file

Note of warning

This manpage has been automatically generated from mtools's texinfo documentation, and may not be entirely accurate or complete. See the end of this man page for details.

Description

The `mshowfat` command is used to display the FAT entries for a file. Syntax:

`mshowfat [-o offset] files`

If no offset is given, a list of all clusters occupied by the file is printed. If an offset is given, only the number of the cluster containing that offset is printed.

Mtools' texinfo doc

Viewing the texi doc

This manpage has been automatically generated from mtools's texinfo documentation. However, this process is only approximative, and some items, such as crossreferences, footnotes and indices are lost in this translation process. Indeed, these items have no appropriate representation in the manpage format. Moreover, not all information has been translated into the manpage version. Thus I strongly advise you to use the original texinfo doc. See the end of this manpage for instructions how to view the texinfo doc.

- * To generate a printable copy from the texinfo doc, run the following commands:

`./configure; make dvi; dvips mtools.dvi`

- * To generate a html copy, run:

`./configure; make html`

A premade html can be found at '<http://www.gnu.org/software/mtools/manual/mtools.html>'

- * To generate an info copy (browsable using emacs' info mode), run:

`./configure; make info`

The texinfo doc looks most pretty when printed or as html. Indeed, in the info version certain examples are difficult to read due to the quoting conventions used in info.

NAME

mv – move (rename) files

SYNOPSIS

```
mv [OPTION]... [-T] SOURCE DEST
mv [OPTION]... SOURCE... DIRECTORY
mv [OPTION]... -t DIRECTORY SOURCE...
```

DESCRIPTION

Rename *SOURCE* to *DEST*, or move *SOURCE*(s) to *DIRECTORY*.

Mandatory arguments to long options are mandatory for short options too.

--backup[=CONTROL]

make a backup of each existing destination file

-b like **--backup** but does not accept an argument

-f, --force

do not prompt before overwriting

-i, --interactive

prompt before overwrite

-n, --no-clobber

do not overwrite an existing file

If you specify more than one of **-i**, **-f**, **-n**, only the final one takes effect.

--strip-trailing-slashes

remove any trailing slashes from each *SOURCE* argument

-S, --suffix=SUFFIX

override the usual backup suffix

-t, --target-directory=DIRECTORY

move all *SOURCE* arguments into *DIRECTORY*

-T, --no-target-directory

treat *DEST* as a normal file

-u, --update

move only when the *SOURCE* file is newer than the destination file or when the destination file is missing

-v, --verbose

explain what is being done

-Z, --context

set SELinux security context of destination file to default type

--help display this help and exit

--version

output version information and exit

The backup suffix is ‘`~’’, unless set with **--suffix** or **SIMPLE_BACKUP_SUFFIX**. The version control method may be selected via the **--backup** option or through the **VERSION_CONTROL** environment variable. Here are the values:

none, off

never make backups (even if **--backup** is given)

numbered, t

make numbered backups

existing, nil
numbered if numbered backups exist, simple otherwise
simple, never
always make simple backups

NAME

nano – Nano’s ANOther editor, inspired by Pico

SYNOPSIS

nano [*options*] [[+*line[,column]*] *file*]...

nano [*options*] [[+[**crCR**](/|?)*string*] *file*]...

DESCRIPTION

nano is a small and friendly editor. It copies the look and feel of Pico, but is free software, and implements several features that Pico lacks, such as: opening multiple files, scrolling per line, undo/redo, syntax coloring, line numbering, and soft-wrapping overlong lines.

When giving a filename on the command line, the cursor can be put on a specific line by adding the line number with a plus sign (+) before the filename, and even in a specific column by adding it with a comma. (Negative numbers count from the end of the file or line.) The cursor can be put on the first or last occurrence of a specific string by specifying that string after +/ or +? before the filename. The string can be made case sensitive and/or caused to be interpreted as a regular expression by inserting **c** and/or **r** after the + sign. These search modes can be explicitly disabled by using the uppercase variant of those letters: **C** and/or **R**. When the string contains spaces, it needs to be enclosed in quotes. To give an example: to open a file at the first occurrence of the word "Foo", you would do:

nano +c/Foo file

As a special case: if instead of a filename a dash (–) is given, **nano** will read data from standard input.

EDITING

Entering text and moving around in a file is straightforward: typing the letters and using the normal cursor movement keys. Commands are entered by using the Control (^) and the Alt or Meta (M-) keys. Typing ^K deletes the current line and puts it in the cutbuffer. Consecutive ^Ks will put all deleted lines together in the cutbuffer. Any cursor movement or executing any other command will cause the next ^K to overwrite the cutbuffer. A^U will paste the current contents of the cutb uffer at the current cursor position.

When a more precise piece of text needs to be cut or copied, you can mark its start with ^G, move the cursor to its end (the marked text will be highlighted), and then use ^K to cut it, or M-6 to copy it to the cutbuffer. You can also save the marked text to a file with ^O, or spell check it with ^T^T.

On some terminals, text can be selected also by holding down Shift while using the arrow keys. Holding down the Ctrl or Alt key too will increase the stride. Any cursor movement without Shift being held will cancel such a selection.

The two lines at the bottom of the screen show some important commands; the built-in help (^G) lists all the available ones. The default key bindings can be changed via a *nanorc* file -- see **nanorc**(5).

NOTICE

Since version 4.0, **nano** by default:

- does not automatically hard-wrap lines that become overlong,
- includes the line below the title bar in the editing area,
- does linewise (smooth) scrolling.

If you want the old, Pico behavior back, you can use **--breaklonglines**, **--emptyline**, and **--jumppyscrolling** (or **-bej** for short).

OPTIONS**-A, --smarthome**

Make the Home key smarter. When Home is pressed anywhere but at the very beginning of non-whitespace characters on a line, the cursor will jump to that beginning (either forwards or backwards). If the cursor is already at that position, it will jump to the true beginning of the line.

-B, --backup

When saving a file, back up the previous version of it, using the current filename suffixed with a tilde (~).

-C directory, --backupdir=directory

Make and keep not just one backup file, but make and keep a uniquely numbered one every time a file is saved -- when backups are enabled (-B). The uniquely numbered files are stored in the specified *directory*.

-D, --boldtext

For the interface, use bold instead of reverse video. This will be overridden by setting the options **titlecolor**, **statuscolor**, **keycolor**, **functioncolor**, **numbercolor**, and/or **selectedcolor** in your *nanorc*(5). See **nanorc**(5).

-E, --tabstospaces

Convert each typed tab to spaces -- to the number of spaces that a tab at that position would take up.

-F, --multibuffer

Read a file into a new buffer by default.

-G, --locking

Use vim-style file locking when editing files.

-H, --historylog

Save the last hundred search strings and replacement strings and executed commands, so they can be easily reused in later sessions.

-I, --ignorercfiles

Don't look at the system's *nanorc* nor at the user's *nanorc*.

-J number, --guidestripe=number

Draw a vertical stripe at the given column, to help judge the width of the text. (The color of the stripe can be changed with **set stripecolor** in your *nanorc* file.)

-K, --rawsequences

Interpret escape sequences directly, instead of asking **ncurses** to translate them. (If you need this option to get some keys to work properly, it means that the terminfo terminal description that is used does not fully match the actual behavior of your terminal. This can happen when you ssh into a BSD machine, for example.) Using this option disables **nano**'s mouse support.

-L, --nonewlines

Don't automatically add a newline when a text does not end with one. (This can cause you to save non-POSIX text files.)

-M, --trimblanks

Snip trailing whitespace from the wrapped line when automatic hard-wrapping occurs or when text is justified.

-N, --noconvert

Disable automatic conversion of files from DOS/Mac format.

-O, --bookstyle

When justifying, treat any line that starts with whitespace as the beginning of a paragraph (unless auto-indenting is on).

-P, --positionlog

For the 200 most recent files, log the last position of the cursor, and place it at that position again upon reopening such a file.

-Q "regex", --quotestr="regex"

Set the regular expression for matching the quoting part of a line. The default value is `"^([\t]*([!#%:;>|{}]|//))+"`. (Note that `\t` stands for an actual T ab.) This makes it possible to rejustify blocks of quoted text when composing email, and to rewrap blocks of line comments when writing source code.

-R, --restricted

Restricted mode: don't read or write to any file not specified on the command line. This means: don't read or write history files; don't allow suspending; don't allow spell checking; don't allow a file to be appended to, prepended to, or saved under a different name if it already has one; and don't make backup files. Restricted mode can also be activated by invoking **nano** with any name beginning with 'r' (e.g. "rnano").

-S, --softwrap

Display over multiple screen rows lines that exceed the screen's width. (You can make this soft-wrapping occur at whitespace instead of rudely at the screen's edge, by using also **--atblanks**.) (The old short option, **-\$**, is deprecated.)

-T number, --tabsize=number

Set the size (width) of a tab to *number* columns. The value of *number* must be greater than 0. The default value is **8**.

-U, --quickblank

Make status-bar messages disappear after 1 keystroke instead of after 20. Note that option **-c** (**--constantshow**) overrides this. When option **--minibar** or **--zero** is in effect, **--quickblank** makes a message disappear after 0.8 seconds instead of after the default 1.5 seconds.

-V, --version

Show the current version number and exit.

-W, --wordbounds

Detect word boundaries differently by treating punctuation characters as part of a word.

-X "characters", --wordchars="characters"

Specify which other characters (besides the normal alphanumeric ones) should be considered as part of a word. When using this option, you probably want to omit **-W** (**--wordbounds**).

-Y name, --syntax=name

Specify the name of the syntax highlighting to use from among the ones defined in the *nanorc* files.

-Z, --zap

Let an unmodified Backspace or Delete erase the marked region (instead of a single character, and without affecting the cutbuffer).

-a, --atblanks

When doing soft line wrapping, wrap lines at whitespace instead of always at the edge of the screen.

-b, --breaklonglines

Automatically hard-wrap the current line when it becomes overlong. (This option is the opposite of **-w** (**--nowrap**) -- the last one given takes effect.)

-c, --constantshow

Constantly show the cursor position on the status bar. Note that this overrides option **-U** (**--quickblank**).

-d, --rebinddelete

Interpret the Delete and Backspace keys differently so that both Backspace and Delete work properly. You should only use this option when on your system either Backspace acts like Delete or Delete acts like Backspace.

-e, --emptyline

Do not use the line below the title bar, leaving it entirely blank.

-f file, --rcfile=file

Read only this *file* for setting nano's options, instead of reading both the system-wide and the user's nanorc files.

-g, --showcursor

Make the cursor visible in the file browser (putting it on the highlighted item) and in the help viewer. Useful for braille users and people with poor vision.

-h, --help

Show a summary of the available command-line options and exit.

-i, --autoindent

Automatically indent a newly created line to the same number of tabs and/or spaces as the previous line (or as the next line if the previous line is the beginning of a paragraph).

-j, --jumpyscrolling

Scroll the buffer contents per half-screen instead of per line.

-k, --cutfromcursor

Make the 'Cut Text' command (normally ^K) cut from the current cursor position to the end of the line, instead of cutting the entire line.

-l, --linenumbers

Display line numbers to the left of the text area. (Any line with an anchor additionally gets a mark in the margin.)

-m, --mouse

Enable mouse support, if available for your system. When enabled, mouse clicks can be used to place the cursor, set the mark (with a double click), and execute shortcuts. The mouse will work in the X Window System, and on the console when gpm is running. Text can still be selected through dragging by holding down the Shift key.

-n, --noread

Treat any name given on the command line as a new file. This allows **nano** to write to named pipes: it will start with a blank buffer, and will write to the pipe when the user saves the "file". This way **nano** can be used as an editor in combination with for instance **gpg** without having to write sensitive data to disk first.

-o directory, --operatingdir=directory

Set the operating directory. This makes **nano** set up something similar to a chroot.

-p, --preserve

Preserve the XON and XOFF sequences (^Q and ^S) so they will be caught by the terminal.

-q, --indicator

Display a "scrollbar" on the righthand side of the edit window. It shows the position of the viewport in the buffer and how much of the buffer is covered by the viewport.

-r number, --fill=number

Set the target width for justifying and automatic hard-wrapping at this *number* of columns. If the value is 0 or less, wrapping will occur at the width of the screen minus *number* columns, allowing the wrap point to vary along with the width of the screen if the screen is resized. The default value is -8.

-s "program [argument ...]", --spell="program [argument ...]"

Use this command to perform spell checking and correcting, instead of using the built-in corrector that calls **hunspell(1)** or **spell(1)**.

-t, --saveonexit

Save a changed buffer without prompting (when exiting with **^X**). (The old form of the long option, **--tempfile**, is deprecated.)

-u, --unix

Save a file by default in Unix format. This overrides nano's default behavior of saving a file in the format that it had. (This option has no effect when you also use **--noconvert**.)

-v, --view

Just view the file and disallow editing: read-only mode. This mode allows the user to open also other files for viewing, unless **--restricted** is given too.

-w, --nowrap

Do not automatically hard-wrap the current line when it becomes overlong. This is the default. (This option is the opposite of **-b (--breaklonglines)** -- the last one given takes effect.)

-x, --nohelp

Don't show the two help lines at the bottom of the screen.

-y, --afterends

Make Ctrl+Right and Ctrl+Delete stop at word ends instead of beginnings.

-z, --suspendable

Obsolete option; ignored. Suspension is enabled by default, reachable via **^T^Z**. (If you want a plain **^Z** to suspend nano, add **bind ^Z suspend main** to your nanorc.)

-%, --stateflags

Use the top-right corner of the screen for showing some state flags: **I** when auto-indenting, **M** when the mark is on, **L** when hard-wrapping (breaking long lines), **R** when recording a macro, and **S** when soft-wrapping. When the buffer is modified, a star (*) is shown after the filename in the center of the title bar.

-_, --minibar

Suppress the title bar and instead show information about the current buffer at the bottom of the screen, in the space for the status bar. In this "minibar" the filename is shown on the left, followed by an asterisk if the buffer has been modified. On the right are displayed the current line and column number, the code of the character under the cursor (in Unicode format: U+xxxx), the same flags as are shown by **--stateflags**, and a percentage that expresses how far the cursor is into the file (linewise). When a file is loaded or saved, and also when switching between buffers, the number of lines in the buffer is displayed after the filename. This number is cleared upon the next keystroke, or replaced with an [i/n] counter when multiple buffers are open. The line plus column numbers and the character code are displayed only when **--constantshow** is used, and can be toggled on and off with **M-C**. The state flags are displayed only when **--stateflags** is used.

-0, --zero

Hide all elements of the interface (title bar, status bar, and help lines) and use all rows of the terminal for showing the contents of the buffer. The status bar appears only when there is a significant message, and disappears after 1.5 seconds or upon the next keystroke. With **M-Z** the title bar plus status bar can be toggled. With **M-X** the help lines.

-!, --magic

When neither the file's name nor its first line give a clue, try using libmagic to determine the applicable syntax.

TOGGLERS

Several of the above options can be switched on and off also while **nano** is running. For example, **M-L** toggles the hard-wrapping of long lines, **M-S** toggles soft-wrapping, **M-N** toggles line numbers, **M-M**

toggles the mouse, **M-I** auto-indentation, and **M-X** the help lines. See at the end of the **^G** help text for a complete list.

The **M-X** toggle is special: it works in all menus except the help viewer and the linter. All other toggles work in the main menu only.

FILES

When **--rcfile** is given, **nano** will read just the specified file for setting its options and syntaxes and key bindings. Without that option, **nano** will read two configuration files: first the system's *nanorc* (if it exists), and then the user's *nanorc* (if it exists), either *~.nanorc* or *\$XDG_CONFIG_HOME/nano/nanorc* or *~.config/nano/nanorc*, whichever is encountered first. See **nanorc(5)** for more information on the possible contents of those files.

See */usr/share/nano/* and */usr/share/nano/extral/* for available syntax-coloring definitions.

NOTES

If no alternative spell checker command is specified on the command line nor in one of the *nanorc* files, **nano** will check the **SPELL** environment variable for one.

In some cases **nano** will try to dump the buffer into an emergency file. This will happen mainly if **nano** receives a SIGHUP or SIGTERM or runs out of memory. It will write the buffer into a file named *nano.save* if the buffer didn't have a name already, or will add a ".save" suffix to the current filename. If an emergency file with that name already exists in the current directory, it will add ".save" plus a number (e.g. ".save.1") to the current filename in order to make it unique. In multibuffer mode, **nano** will write all the open buffers to their respective emergency files.

BUGS

The recording and playback of keyboard macros works correctly only on a terminal emulator, not on a Linux console (VT), because the latter does not by default distinguish modified from unmodified arrow keys.

Please report any other bugs that you encounter via:
<https://savannah.gnu.org/bugs/?group=nano>.

When nano crashes, it will save any modified buffers to emergency .save files. If you are able to reproduce the crash and you want to get a backtrace, define the environment variable **NANO_NOCATCH**.

SEE ALSO

nanorc(5)

/usr/share/doc/nano/ (or equivalent on your system)

NAME

nanorc – GNU nano’s configuration file

DESCRIPTION

The *nanorc* files contain the default settings for **nano**, a small and friendly editor. During startup, if **--rcfile** is not given, **nano** will read two files: first the system-wide settings, from */etc/nanorc* (the exact path might be different on your system), and then the user-specific settings, either from *~/.nanorc* or from *\$XDG_CONFIG_HOME/nano/nanorc* or from *~/.config/nano/nanorc*, whichever is encountered first. If **--rcfile** is given, **nano** will read just the specified settings file.

NOTICE

Since version 4.0, **nano** by default:

- does not automatically hard-wrap lines that become overlong,
- includes the line below the title bar in the editing area,
- does linewise (smooth) scrolling.

To get the old, Pico behavior back, you can use **set breaklonglines**, **set emptyline**, and **set jumpyscrolling**.

OPTIONS

The configuration file accepts a series of **set** and **unset** commands, which can be used to configure nano on startup without using command-line options. Additionally, there are some commands to define syntax highlighting and to rebind keys -- see the two separate sections on those. **nano** reads one command per line. All commands and keywords should be written in lowercase.

Options in *nanorc* files take precedence over nano’s defaults, and command-line options override *nanorc* settings. Also, options that do not take an argument are unset by default. So using the **unset** command is only needed when wanting to override a setting of the system’s *nanorc* file in your own *nanorc*. Options that take an argument cannot be unset.

Quotes inside the *characters* parameters below should not be escaped. The last double quote on the line will be seen as the closing quote.

The supported commands and arguments are:

set afterends

Make Ctrl+Right and Ctrl+Delete stop at word ends instead of beginnings.

set allow_insecure_backup

When backing up files, allow the backup to succeed even if its permissions can’t be (re)set due to special OS considerations. You should NOT enable this option unless you are sure you need it.

set atblanks

When soft line wrapping is enabled, make it wrap lines at blank characters (tabs and spaces) instead of always at the edge of the screen.

set autoindent

Automatically indent a newly created line to the same number of tabs and/or spaces as the previous line (or as the next line if the previous line is the beginning of a paragraph).

set backup

When saving a file, create a backup file by adding a tilde (~) to the file’s name.

set backupdir *directory*

Make and keep not just one backup file, but make and keep a uniquely numbered one every time a file is saved -- when backups are enabled with **set backup** or **--backup** or **-B**. The uniquely numbered files

are stored in the specified *directory*.

set boldtext

Use bold instead of reverse video for the title bar, status bar, key combos, function tags, line numbers, and selected text. This can be overridden by setting the options **titlecolor**, **statuscolor**, **keycolor**, **functioncolor**, **numbercolor**, and **selectedcolor**.

set bookstyle

When justifying, treat any line that starts with whitespace as the beginning of a paragraph (unless auto-indenting is on).

set brackets "characters"

Set the characters treated as closing brackets when justifying paragraphs. This may not include blank characters. Only closing punctuation (seeset **punct**), optionally followed by the specified closing brackets, can end sentences. The default value is """)>}".

set breaklonglines

Automatically hard-wrap the current line when it becomes overlong.

set casesensitive

Do case-sensitive searches by default.

set constantshow

Constantly display the cursor position in the status bar. This overrides the option **quickblank**.

set cutfromcursor

Use cut-from-cursor-to-end-of-line by default, instead of cutting the whole line.

set emptyline

Do not use the line below the title bar, leaving it entirely blank.

set errorcolor [bold,][italic,]fgcolor,bgcolor

Use this color combination for the status bar when an error message is displayed. The default value is **bold,white,red**. Seeset **titlecolor** for valid color names.

set fill number

Set the target width for justifying and automatic hard-wrapping at this *number* of columns. If the value is 0 or less, wrapping will occur at the width of the screen minus *number* columns, allowing the wrap point to vary along with the width of the screen if the screen is resized. The default value is **-8**.

set functioncolor [bold,][italic,]fgcolor,bgcolor

Use this color combination for the concise function descriptions in the two help lines at the bottom of the screen. See set **titlecolor** for more details.

set guidestripe number

Draw a vertical stripe at the given column, to help judge the width of the text. (The color of the stripe can be changed with set **stripecolor**.)

set historylog

Save the last hundred search strings and replacement strings and executed commands, so they can be easily reused in later sessions.

set indicator

Display a "scrollbar" on the righthand side of the edit window. It shows the position of the viewport in the buffer and how much of the buffer is covered by the viewport.

set jumpyscrolling

Scroll the buffer contents per half-screen instead of per line.

set keycolor [bold,][italic,]fgcolor,bgcolor

Use this color combination for the shortcut key combos in the two help lines at the bottom of the screen. See set **titlecolor** for more details.

set linenumbers

Display line numbers to the left of the text area. (Any line with an anchor additionally gets a mark in the margin.)

set locking

Enable vim-style lock-files for when editing files.

set magic

When neither the file's name nor its first line give a clue, try using libmagic to determine the applicable syntax. (Calling libmagic can be relatively time consuming. It is therefore not done by default.)

set matchbrackets "*characters*"

Specify the opening and closing brackets that can be found by bracket searches. This may not include blank characters. The opening set must come before the closing set, and the two sets must be in the same order. The default value is "<[{}]>".

set minibar

Suppress the title bar and instead show information about the current buffer at the bottom of the screen, in the space for the status bar. In this "minibar" the filename is shown on the left, followed by an asterisk if the buffer has been modified. On the right are displayed the current line and column number, the code of the character under the cursor (in Unicode format: U+xxxx), the same flags as are shown by **set stateflags**, and a percentage that expresses how far the cursor is into the file (linewise). When a file is loaded or saved, and also when switching between buffers, the number of lines in the buffer is displayed after the filename. This number is cleared upon the next keystroke, or replaced with an [i/n] counter when multiple buffers are open. The line plus column numbers and the character code are displayed only when **set constantshow** is used, and can be toggled on and off with **M-C**. The state flags are displayed only when **set stateflags** is used.

set minicolor [bold**,][**italic**,]*fgcolor,bgcolor***

Use this color combination for the minibar. (When this option is not specified, the colors of the title bar are used.) See **set titlecolor** for more details.

set mouse

Enable mouse support, if available for your system. When enabled, mouse clicks can be used to place the cursor, set the mark (with a double click), and execute shortcuts. The mouse will work in the X Window System, and on the console when gpm is running. Text can still be selected through dragging by holding down the Shift key.

set multibuffer

When reading in a file with **^R**, insert it into a new buffer by default.

set noconvert

Don't convert files from DOS/Mac format.

set nohelp

Don't display the two help lines at the bottom of the screen.

set nonewlines

Don't automatically add a newline when a text does not end with one. (This can cause you to save non-POSIX text files.)

set nowrap

Deprecated option since it has become the default setting. When needed, use **unset breaklonglines** instead.

set numbercolor [bold**,][**italic**,]*fgcolor,bgcolor***

Use this color combination for line numbers. See **set titlecolor** for more details.

set operatingdir *directory*

nano will only read and write files inside *directory* and its subdirectories. Also, the current directory is changed to here, so files are inserted from this directory. By default, the operating directory feature is turned off.

set positionlog

Save the cursor position of files between editing sessions. The cursor position is remembered for the 200 most-recently edited files.

set preserve

Preserve the XON and XOFF keys (^Q and ^S).

set promptcolor [bold,][italic,]*fgcolor,bgcolor*

Use this color combination for the prompt bar. (When this option is not specified, the colors of the title bar are used.) See **set titlecolor** for more details.

set punct "characters"

Set the characters treated as closing punctuation when justifying paragraphs. This may not include blank characters. Only the specified closing punctuation, optionally followed by closing brackets (see **brackets**), can end sentences. The default value is ".?".

set quickblank

Make status-bar messages disappear after 1 keystroke instead of after 20. Note that option **constantshow** overrides this. When option **minibar** or **zero** is in effect, **quickblank** makes a message disappear after 0.8 seconds instead of after the default 1.5 seconds.

set quotestr "regex"

Set the regular expression for matching the quoting part of a line. The default value is `^([\t]*([!#%:;:>|])]+` . (Note that \t stands for an actual Tab character.) This makes it possible to rejustify blocks of quoted text when composing email, and to rewrap blocks of line comments when writing source code.

set rawsequences

Interpret escape sequences directly, instead of asking **ncurses** to translate them. (If you need this option to get some keys to work properly, it means that the terminfo terminal description that is used does not fully match the actual behavior of your terminal. This can happen when you ssh into a BSD machine, for example.) Using this option disables **nano**'s mouse support.

set rebinddelete

Interpret the Delete and Backspace keys differently so that both Backspace and Delete work properly. You should only use this option when on your system either Backspace acts like Delete or Delete acts like Backspace.

set regexp

Do regular-expression searches by default. Regular expressions in **nano** are of the extended type (ERE).

set saveonexit

Save a changed buffer automatically on exit (^X); don't prompt. (The old form of this option, **set tempfile**, is deprecated.)

set scrollercolor *fgcolor,bgcolor*

Use this color combination for the indicator alias "scrollbar". (On terminal emulators that link to a libvte older than version 0.55, using a background color here does not work correctly.) See **set titlecolor** for more details.

set selectedcolor [bold,][italic,]*fgcolor,bgcolor*

Use this color combination for selected text. See **set titlecolor** for more details.

set showcursor

Put the cursor on the highlighted item in the file browser, and show the cursor in the help viewer, to aid braille users and people with poor vision.

set smarthome

Make the Home key smarter. When Home is pressed anywhere but at the very beginning of non-white-space characters on a line, the cursor will jump to that beginning (either forwards or backwards). If the cursor is already at that position, it will jump to the true beginning of the line.

set softwrap

Display lines that exceed the screen's width over multiple screen lines. (You can make this soft-wrappping occur at whitespace instead of rudely at the screen's edge, by using also **set atblanks**.)

set speller "program [argument ...]"

Use the given *program* to do spell checking and correcting, instead of using the built-in corrector that calls **hunspell(1)** or **spell(1)**.

set spotlightcolor [bold,][italic,]*fgcolor*,*bgcolor*

Use this color combination for highlighting a search match. The default value is **black,lightyellow**.

See **set titlecolor** for valid color names.

set stateflags

Use the top-right corner of the screen for showing some state flags: **I** when auto-indenting, **M** when the mark is on, **L** when hard-wrapping (breaking long lines), **R** when recording a macro, and **S** when soft-wrapping. When the buffer is modified, a star (*) is shown after the filename in the center of the title bar.

set statuscolor [bold,][italic,]*fgcolor*,*bgcolor*

Use this color combination for the status bar. See **set titlecolor** for more details.

set stripecolor [bold,][italic,]*fgcolor*,*bgcolor*

Use this color combination for the vertical guiding stripe. See **set titlecolor** for more details.

set suspendable

Obsolete option; ignored. Suspension is enabled by default, reachable via **^T^Z**. (If you want a plain **Z** to suspend nano, add **bind 'Z suspend main** to your nanorc.)

set tabsize *number*

Use a tab size of *number* columns. The value of *number* must be greater than 0. The default value is **8**.

set tabstospaces

Convert each typed tab to spaces -- to the number of spaces that a tab at that position would take up.

set titlecolor [bold,][italic,]*fgcolor*,*bgcolor*

Use this color combination for the title bar. Valid names for the foreground and background colors are: **red**, **green**, **blue**, **magenta**, **yellow**, **cyan**, **white**, and **black**. Each of these eight names may be pre-fixed with the word **light** to get a brighter version of that color. The word **grey** or **gray** may be used as a synonym for **lightblack**. On terminal emulators that can do at least 256 colors, other valid (but unprefixable) color names are: **pink**, **purple**, **mauve**, **lagoon**, **mint**, **lime**, **peach**, **orange**, **latte**, **rosy**, **beet**, **plum**, **sea**, **sky**, **slate**, **teal**, **sage**, **brown**, **ocher**, **sand**, **tawny**, **brick**, **crimson**, and **normal** -- where **normal** means the default foreground or background color. On such emulators, the color may also be specified as a three-digit hexadecimal number prefixed with #, with the digits representing the amounts of red, green, and blue, respectively. This tellsnano to select from the available palette the color that approximates the given values.

Either "*fgcolor*" or ",*bgcolor*" may be left out, and the pair may be preceded by **bold** and/or **italic** (separated by commas) to get a bold and/or slanting typeface, if your terminal can do those.

set trimblanks

Remove trailing whitespace from wrapped lines when automatic hard-wrapping occurs or when text is justified.

set unix

Save a file by default in Unix format. This overrides nano's default behavior of saving a file in the format that it had. (This option has no effect when you also use **set noconvert**.)

set whitespace "*characters*"

Set the two characters used to indicate the presence of tabs and spaces. They must be single-column characters. The default pair for a UTF-8 locale is "».", and for other locales ">.".

set wordbounds

Detect word boundaries differently by treating punctuation characters as parts of words.

set wordchars "characters"

Specify which other characters (besides the normal alphanumeric ones) should be considered as parts of words. When using this option, you probably want to unset **wordbounds**.

set zap

Let an unmodified Backspace or Delete erase the marked region (instead of a single character, and without affecting the cutbuffer).

set zero

Hide all elements of the interface (title bar, status bar, and help lines) and use all rows of the terminal for showing the contents of the buffer. The status bar appears only when there is a significant message, and disappears after 1.5 seconds or upon the next keystroke. With **M-Z** the title bar plus status bar can be toggled. With **M-X** the help lines.

SYNTAX HIGHLIGHTING

Coloring the different syntactic elements of a file is done via regular expressions (see the **color** command below). This is inherently imperfect, because regular expressions are not powerful enough to fully parse a file. Nevertheless, regular expressions can do a lot and are easy to make, so they are a good fit for a small editor like **nano**.

All regular expressions in **nano** are POSIX extended regular expressions. This means that., ?, *, +, ^, \$, and several other characters are special. The period . matches any single character, ? means the preceding item is optional, * means the preceding item may be matched zero or more times, + means the preceding item must be matched one or more times, ^ matches the beginning of a line, and \$ the end, \< matches the start of a word, and \> the end, and \s matches a blank. It also means that lookahead and lookbehind are not possible. A complete explanation can be found in the manual page of GNU grep: **man grep**.

For each kind of file a separate syntax can be defined via the following commands:

syntax name ["fileregex" ...]

Start the definition of a syntax with this *name*. All subsequent **color** and other such commands will be added to this syntax, until a new **syntax** command is encountered.

When **nano** is run, this syntax will be automatically activated if the current filename matches the extended regular expression *fileregex*. Or the syntax can be explicitly activated by using the **-Y** or **--syntax** command-line option followed by the *name*.

The syntax **default** is special: it takes no *fileregex*, and applies to files that don't match any syntax's regexes. The **syntaxnone** is reserved; specifying it on the command line is the same as not having a syntax at all.

header "regex" ...

If from all defined syntaxes no *fileregex* matched, then compare this *regex* (or regexes) against the first line of the current file, to determine whether this syntax should be used for it.

magic "regex" ...

If no *fileregex* matched and no **header** regex matched either, then compare this *regex* (or regexes) against the result of querying the **magic** database about the current file, to determine whether this syntax should be used for it. (This functionality only works when **libmagic** is installed on the system and will be silently ignored otherwise.)

formatter program [argument ...]

Run the given *program* on the full contents of the current buffer. (The current buffer is written out to a temporary file, the program is run on it, and then the temporary file is read back in, replacing the contents of the buffer.)

linter *program [argument ...]*

Use the given *program* to run a syntax check on the current buffer.

comment "string"

Use the given *string* for commenting and uncommenting lines. If the string contains a vertical bar or pipe character (|), this designates bracket-style comments; for example, "/*|*/" for CSS files. The characters before the pipe are prepended to the line and the characters after the pipe are appended at the end of the line. If no pipe character is present, the full string is prepended; for example, "#" for Python files. If empty double quotes are specified, the comment/uncomment function is disabled; for example, "" for JSON. The default value is "#".

tabgives "string"

Make the <Tab> key produce the given *string*. Useful for languages like Python that want to see only spaces for indentation. This overrides the setting of the **tabstospaces** option.

color [**bold**,][**italic**,]*fgcolor,bgcolor "regex"* ...

Paint all pieces of text that match the extended regular expression *regex* with the given foreground and background colors, at least one of which must be specified. Valid color names are: **red**, **green**, **blue**, **magenta**, **yellow**, **cyan**, **white**, and **black**. Each of these eight names may be prefixed with the word **light** to get a brighter version of that color. The word **grey** or **gray** may be used as a synonym for **lightblack**. On terminal emulators that can do at least 256 colors, other valid (but unprefixable) color names are: **pink**, **purple**, **mauve**, **lagoon**, **mint**, **lime**, **peach**, **orange**, **latte**, **rosy**, **beet**, **plum**, **sea**, **sky**, **slate**, **teal**, **sage**, **brown**, **ocher**, **sand**, **tawny**, **brick**, **crimson**, and **normal** -- where **normal** means the default foreground or background color. On such emulators, the color may also be specified as a three-digit hexadecimal number prefixed with #, with the digits representing the amounts of red, green, and blue, respectively. This tells nano to select from the available palette the color that approximates the given values.

The color pair may be preceded by **bold** and/or **italic** (separated by commas) to get a bold and/or slanting typeface, if your terminal can do those.

All coloring commands are applied in the order in which they are specified, which means that later commands can recolor stuff that was colored earlier.

icolor [**bold**,][**italic**,]*fgcolor,bgcolor "regex"* ...

Same as above, except that the matching is case insensitive.

color [**bold**,][**italic**,]*fgcolor,bgcolor start="fromrx" end="torx"*

Paint all pieces of text whose start matches extended regular expression *fromrx* and whose end matches extended regular expression *torx* with the given foreground and background colors, at least one of which must be specified. This means that, after an initial instance of *fromrx*, all text until the first instance of *torx* will be colored. This allows syntax highlighting to span multiple lines.

icolor [**bold**,][**italic**,]*fgcolor,bgcolor start="fromrx" end="torx"*

Same as above, except that the matching is case insensitive.

include "*syntaxfile*"

Read in self-contained color syntaxes from *syntaxfile*. Note that *syntaxfile* may contain only the above commands, from **syntax** to **icolor**.

extendsyntax *name command argument* ...

Extend the syntax previously defined as *name* with another *command*. This allows adding a new **color**, **icolor**, **header**, **magic**, **formatter**, **linter**, **comment**, or **tabgives** command to an already defined syntax -- useful when you want to slightly improve a syntax defined in one of the system-installed files (which normally are not writable).

REBINDING KEYS

Key bindings can be changed via the following three commands:

bind *key function menu*

Rebinds the given *key* to the given *function* in the given *menu* (or in all menus where the function exists when **all** is used).

bind *key "string" menu*

Makes the given *key* produce the given *string* in the given *menu* (or in all menus where the key exists when **all** is used). The *string* can consist of text or commands or a mix of them. (To enter a command into the *string*, precede its keystroke with **M-V**.)

unbind *key menu*

Unbinds the given *key* from the given *menu* (or from all menus where the key exists when **all** is used).

The format of *key* should be one of:

^X where *X* is a Latin letter, or one of several ASCII characters (@,], \, ^, _), or the word "Space".
Example: **^C**.

M-X where *X* is any ASCII character except [, or the word "Space". Example: **M-8**.

Sh-M-X

where *X* is a Latin letter. Example: **Sh-M-U**. By default, each Meta+letter keystroke does the same as the corresponding Shift+Meta+letter. But when any Shift+Meta bind is made, that will no longer be the case, for all letters.

FN where *N* is a numeric value from 1 to 24. Example: **F10**. (Often, **F13** to **F24** can be typed as **F1** to **F12** with Shift.)

Ins or **Del**.

Rebinding **^M** (Enter) or **^T** (Tab) is probably not a good idea. Rebinding **^L** (Esc) is not possible, because its keycode is the starter byte of Meta keystrokes and escape sequences. Rebinding any of the dedicated cursor-moving keys (the arrows, Home, End, PageUp and PageDown) is not possible. On some terminals it's not possible to rebind **^H** (unless **--raw** is used) because its keycode is identical to that of the Backspace key.

Valid *function* names to be bound are:

help

Invokes the help viewer.

cancel

Cancels the current command.

exit

Exits from the program (or from the help viewer or file browser).

writeout

Writes the current buffer to disk, asking for a name.

savefile

Writes the current file to disk without prompting.

insert

Inserts a file into the current buffer (at the current cursor position), or into a new buffer when option **multibuffer** is set.

whereis

Starts a forward search for text in the current buffer -- or for filenames matching a string in the current list in the file browser.

wherewas

Starts a backward search for text in the current buffer -- or for filenames matching a string in the current list in the file browser.

findprevious

Searches the next occurrence in the backward direction.

findnext

Searches the next occurrence in the forward direction.

replace

Interactively replaces text within the current buffer.

cut

Cuts and stores the current line (or the marked region).

copy

Copies the current line (or the marked region) without deleting it.

paste

Pastes the currently stored text into the current buffer at the current cursor position.

zap

Throws away the current line (or the marked region). (This function is bound by default to <Meta+Delete>.)

chopwordleft

Deletes from the cursor position to the beginning of the preceding word. (This function is bound by default to <Shift+Ctrl+Delete>. If your terminal produces **H** for <Ctrl+Backspace>, you can make <Ctrl+Backspace> delete the word to the left of the cursor by rebinding **H** to this function.)

chopwordright

Deletes from the cursor position to the beginning of the next word. (This function is bound by default to <Ctrl+Delete>.)

cutrestoffile

Cuts all text from the cursor position till the end of the buffer.

mark

Sets the mark at the current position, to start selecting text. Or, when it is set, unsets the mark.

location

Reports the current position of the cursor in the buffer: the line, column, and character positions. (The old name of this function, 'curpos', is deprecated.)

wordcount

Counts and reports on the status bar the number of lines, words, and characters in the current buffer (or in the marked region).

execute

Prompts for a program to execute. The program's output will be inserted into the current buffer (or into a new buffer when **M-F** is toggled).

speller

Invokes a spell-checking program, either the default **hunspell(1)** or GNU **spell(1)**, or the one defined by **--speller** or **set speller**.

formatter

Invokes a full-buffer-processing program (if the active syntax defines one).

linter

Invokes a syntax-checking program (if the active syntax defines one).

justify

Justifies the current paragraph (or the marked region). A paragraph is a group of contiguous lines that, apart from possibly the first line, all have the same indentation. The beginning of a paragraph is detected by either this lone line with a differing indentation or by a preceding blank line.

fulljustify

Justifies the entire current buffer (or the marked region).

indent

Indents (shifts to the right) the current line or the marked lines.

unindent

Unindents (shifts to the left) the current line or the marked lines.

comment

Comments or uncomments the current line or the marked lines, using the comment style specified in the active syntax.

complete

Completes (when possible) the fragment before the cursor to a full word found elsewhere in the current buffer.

left

Goes left one position (in the editor or browser).

right

Goes right one position (in the editor or browser).

up

Goes one line up (in the editor or browser).

down

Goes one line down (in the editor or browser).

scrollup

Scrolls the viewport up one row (meaning that the text slides down) while keeping the cursor in the same text position, if possible. (This function is bound by default to <Alt+Up>. If <Alt+Up> does nothing on your Linux console, see the FAQ: <https://nano-editor.org/dist/latest/faq.html#4.1>.)

scrolldown

Scrolls the viewport down one row (meaning that the text slides up) while keeping the cursor in the same text position, if possible. (This function is bound by default to <Alt+Down>.)

center

Scrolls the line with the cursor to the middle of the screen.

prevword

Moves the cursor to the beginning of the previous word.

nextword

Moves the cursor to the beginning of the next word.

home

Moves the cursor to the beginning of the current line.

end

Moves the cursor to the end of the current line.

beginpara

Moves the cursor to the beginning of the current paragraph.

endpara

Moves the cursor to the end of the current paragraph.

prevblock

Moves the cursor to the beginning of the current or preceding block of text. (Blocks are separated by one or more blank lines.)

nextblock

Moves the cursor to the beginning of the next block of text.

pageup

Goes up one screenful.

pagedown

Goes down one screenful.

firstline

Goes to the first line of the file.

lastline

Goes to the last line of the file.

gotoline

Goes to a specific line (and column if specified). Negative numbers count from the end of the file (and end of the line).

findbracket

Moves the cursor to the bracket (or brace or parenthesis, etc.) that matches (pairs) with the one under the cursor. Seeset **matchbrack ets**.

anchor

Places an anchor at the current line, or removes it when already present. (An anchor is visible when line numbers are activated.)

prevanchor

Goes to the first anchor before the current line.

nextanchor

Goes to the first anchor after the current line.

prevbuf

Switches to editing/viewing the previous buffer when multiple buffers are open.

nextbuf

Switches to editing/viewing the next buffer when multiple buffers are open.

verbatim

Inserts the next keystroke verbatim into the file.

tab

Inserts a tab at the current cursor location.

enter

Inserts a new line below the current one.

delete

Deletes the character under the cursor.

backspace

Deletes the character before the cursor.

recordmacro

Starts the recording of keystrokes -- the keystrokes are stored as a macro. When already recording, the recording is stopped.

runmacro

Replays the keystrokes of the last recorded macro.

undo

Undoes the last performed text action (add text, delete text, etc).

redo

Redoes the last undone action (i.e., it undoes an undo).

refresh

Refreshes the screen.

suspend

Suspends the editor and returns control to the shell (until you tell the process to resume execution with **fg**).

casesens

Toggles whether searching/replacing ignores or respects the case of the given characters.

regexp

Toggles whether searching/replacing uses literal strings or regular expressions.

backwards

Toggles whether searching/replacing goes forward or backward.

older

Retrieves the previous (earlier) entry at a prompt.

newer

Retrieves the next (later) entry at a prompt.

flipreplace

Toggles between searching for something and replacing something.

flipgoto

Toggles between searching for text and targeting a line number.

flipexecute

Toggles between inserting a file and executing a command.

flippipe

When executing a command, toggles whether the current buffer (or marked region) is piped to the command.

flipnewbuffer

Toggles between inserting into the current buffer and into a new empty buffer.

flipconvert

When reading in a file, toggles between converting and not converting it from DOS/Mac format. Converting is the default.

dosformat

When writing a file, switches to writing a DOS format (CR/LF).

macformat

When writing a file, switches to writing a Mac format.

append

When writing a file, appends to the end instead of overwriting.

prepend

When writing a file, 'prepends' (writes at the beginning) instead of overwriting.

backup

When writing a file, creates a backup of the current file.

discardbuffer

When about to write a file, discard the current buffer without saving. (This function is bound by default only when option **--saveonexit** is in effect.)

browser

Starts the file browser (in the Read File and Write Out menus), allowing to select a file from a list.

gotodir

Goes to a directory to be specified, allowing to browse anywhere in the filesystem.

firstfile

Goes to the first file in the list when using the file browser.

lastfile

Goes to the last file in the list when using the file browser.

nohelp

Toggles the presence of the two-line list of key bindings at the bottom of the screen. (This toggle is special: it is available in all menus except the help viewer and the linter. All further toggles are available in the main menu only.)

zero

Toggles the presence of title bar and status bar.

constantshow

Toggles the constant display of the current line, column, and character positions.

softwrap

Toggles the displaying of overlong lines on multiple screen lines.

linenumbers

Toggles the display of line numbers in front of the text.

whitespacedisplay

Toggles the showing of whitespace.

nosyntax

Toggles syntax highlighting.

smarthome

Toggles the smartness of the Home key.

autoindent

Toggles whether a newly created line will contain the same amount of leading whitespace as the preceding line -- or as the next line if the preceding line is the beginning of a paragraph.

cutfromcursor

Toggles whether cutting text will cut the whole line or just from the current cursor position to the end of the line.

breaklonglines

Toggles whether long lines will be hard-wrapped to the next line. (The old name of this function, 'nowrap', is deprecated.)

tabstospaces

Toggles whether typed tabs will be converted to spaces.

mouse

Toggles mouse support.

Valid *menu* sections are:

main

The main editor window where text is entered and edited.

help

The help-viewer menu.

search

The search menu (AKA whereis).

replace

The 'search to replace' menu.

replacewith

The 'replace with' menu, which comes up after 'search to replace'.

yesno

The 'yesno' menu, where the Yes/No/All/Cancel question is asked.

gotoline

The 'goto line (and column)' menu.

writeout

The 'write file' menu.

insert

The 'insert file' menu.

browser

The 'file browser' menu, for selecting a file to be opened or inserted or written to.

whereisfile

The 'search for a file' menu in the file browser.

gotodir

The 'go to directory' menu in the file browser.

execute

The menu for inserting the output from an external command, or for filtering the buffer (or the marked region) through an external command, or for executing one of several tools. (The old form of this menu name, 'extcmd', is deprecated.)

spell

The menu of the integrated spell checker where the user can edit a misspelled word.

linter

The linter menu, which allows jumping through the linting messages.

all

A special name that encompasses all menus. For **bind** it means all menus where the specified *function* exists; for **unbind** it means all menus where the specified *key* exists.

FILES

/etc/nanorc

System-wide configuration file.

/.nanorc or *\$XDG_CONFIG_HOME/nano/nanorc* or *~/.config/nano/nanorc*

Per-user configuration file.

*/usr/share/nano/**

Syntax definitions for the syntax coloring of common file types (and for less common file types in the *extra/* subdirectory).

NAME

netstat – Print network connections, routing tables, interface statistics, masquerade connections, and multi-cast memberships

SYNOPSIS

```
netstat [address_family_options] [--tcp|-t] [--udp|-u] [--udplite|-U] [--sctp|-S] [--raw|-w]
[--l2cap|-2] [--rfcomm|-f] [--listening|-l] [--all|-a] [--numeric|-n] [--numeric-hosts] [--numeric-ports]
[--numeric-users] [--symbolic|-N] [--extend|-e|--extend|-e] [--timers|-o] [--program|-p]
[--verbose|-v] [--continuous|-c] [--wide|-W]

netstat {--route|-r} [address_family_options] [--extend|-e|--extend|-e] [--verbose|-v] [--numeric|-n]
[--numeric-hosts] [--numeric-ports] [--numeric-users] [--continuous|-c]

netstat {--interfaces|-i} [--all|-a] [--extend|-e|--extend|-e] [--verbose|-v] [--program|-p]
[--numeric|-n] [--numeric-hosts] [--numeric-ports] [--numeric-users] [--continuous|-c]

netstat {--groups|-g} [--numeric|-n] [--numeric-hosts] [--numeric-ports] [--numeric-users]
[--continuous|-c]

netstat {--masquerade|-M} [--extend|-e] [--numeric|-n] [--numeric-hosts] [--numeric-ports]
[--numeric-users] [--continuous|-c]

netstat {--statistics|-s} [--tcp|-t] [--udp|-u] [--udplite|-U] [--sctp|-S] [--raw|-w]

netstat {--version|-V}

netstat {--help|-h}

address_family_options:
[-4|--inet] [-6|--inet6] [--protocol={inet,inet6,unix,ipx,ax25,netrom,ddp,bluetooth,...}] 
[--unix|-x] [--inet|--ip|--tcpip] [--ax25] [--x25] [--rose] [--ash] [--bluetooth] [--ipx]
[--netrom] [--ddp|--appletalk] [--econet|--ec]
```

NOTES

This program is mostly obsolete. Replacement for **netstat** is **ss**. Replacement for **netstat -r** is **ip route**. Replacement for **netstat -i** is **ip -s link**. Replacement for **netstat -g** is **ip maddr**.

DESCRIPTION

Netstat prints information about the Linux networking subsystem. The type of information printed is controlled by the first argument, as follows:

(none)

By default, **netstat** displays a list of open sockets. If you don't specify any address families, then the active sockets of all configured address families will be printed.

--route, -r

Display the kernel routing tables. See the description in **route(8)** for details. **netstat -r** and **r oute** produce the same output.

--groups, -g

Display multicast group membership information for IPv4 and IPv6.

--interfaces, -i

Display a table of all network interfaces.

--masquerade, -M

Display a list of masqueraded connections.

--statistics, -s

Display summary statistics for each protocol.

OPTIONS

--verbose, -v

Tell the user what is going on by being verbose. Especially print some useful information about unconfigured address families.

--wide, -W

Do not truncate IP addresses by using output as wide as needed. This is optional for now to not break existing scripts.

--numeric, -n

Show numerical addresses instead of trying to determine symbolic host, port or user names.

--numeric-hosts

shows numerical host addresses but does not affect the resolution of port or user names.

--numeric-ports

shows numerical port numbers but does not affect the resolution of host or user names.

--numeric-users

shows numerical user IDs but does not affect the resolution of host or port names.

--protocol=family, -A

Specifies the address families (perhaps better described as low level protocols) for which connections are to be shown. *family* is a comma (',') separated list of address family keywords like **inet**, **inet6**, **unix**, **ipx**, **ax25**, **netrom**, **econet**, **ddp**, and **bluetooth**. This has the same effect as using the **--inet|-4**, **--inet6|-6**, **--unix|-x**, **--ipx**, **--ax25**, **--netrom**, **--ddp**, and **--bluetooth** options.

The address family **inet** (Iv4) includes raw, udp, udplite and tcp protocol sockets.

The address family **bluetooth** (Iv4) includes l2cap and rfcomm protocol sockets.

-c, --continuous

This will cause **netstat** to print the selected information every second continuously.

-e, --extend

Display additional information. Use this option twice for maximum detail.

-o, --timers

Include information related to networking timers.

-p, --program

Show the PID and name of the program to which each socket belongs.

-l, --listening

Show only listening sockets. (These are omitted by default.)

-a, --all

Show both listening and non-listening sockets. With the **--interfaces** option, show interfaces that are not up

-F

Print routing information from the FIB. (This is the default.)

-C

Print routing information from the route cache.

OUTPUT

Active Internet connections (TCP, UDP, UDPLite, raw)**Proto**

The protocol (tcp, udp, udpl, raw) used by the socket.

Recv-Q

Established: The count of bytes not copied by the user program connected to this socket. Listening: Since Kernel 2.6.18 this column contains the current syn backlog.

Send-Q

Established: The count of bytes not acknowledged by the remote host. Listening: Since Kernel 2.6.18 this column contains the maximum size of the syn backlog.

Local Address

Address and port number of the local end of the socket. Unless the **--numeric (-n)** option is specified, the socket address is resolved to its canonical host name (FQDN), and the port number is translated into the corresponding service name.

Foreign Address

Address and port number of the remote end of the socket. Analogous to "Local Address".

State

The state of the socket. Since there are no states in raw mode and usually no states used in UDP and UDPLite, this column may be left blank. Normally this can be one of several values:

ESTABLISHED

The socket has an established connection.

SYN_SENT

The socket is actively attempting to establish a connection.

SYN_RECV

A connection request has been received from the network.

FIN_WAIT1

The socket is closed, and the connection is shutting down.

FIN_WAIT2

Connection is closed, and the socket is waiting for a shutdown from the remote end.

TIME_WAIT

The socket is waiting after close to handle packets still in the network.

CLOSE

The socket is not being used.

CLOSE_WAIT

The remote end has shut down, waiting for the socket to close.

LAST_ACK

The remote end has shut down, and the socket is closed. Waiting for acknowledgement.

LISTEN

The socket is listening for incoming connections. Such sockets are not included in the output unless you specify the **--listening (-l)** or **--all (-a)** option.

CLOSING

Both sockets are shut down but we still don't have all our data sent.

UNKNOWN

The state of the socket is unknown.

User

The username or the user id (UID) of the owner of the socket.

PID/Program name

Slash-separated pair of the process id (PID) and process name of the process that owns the socket. **--program** causes this column to be included. You will also need *superuser* privileges to see this information on sockets you don't own. This identification information is not yet available for IPX sockets.

Timer

(this needs to be written)

Active UNIX domain Sockets

Proto

The protocol (usually unix) used by the socket.

RefCnt

The reference count (i.e. attached processes via this socket).

Flags

The flags displayed is SO_ACCEPTON (displayed as **ACC**), SO_WAITDATA (**W**) or SO_NOSPACE (**N**). SO_ACCECPTON is used on unconnected sockets if their corresponding processes are waiting for a connect request. The other flags are not of normal interest.

Type

There are several types of socket access:

SOCK_DGRAM

The socket is used in Datagram (connectionless) mode.

SOCK_STREAM

This is a stream (connection) socket.

SOCK_RAW

The socket is used as a raw socket.

SOCK_RDM

This one serves reliably-delivered messages.

SOCK_SEQPACKET

This is a sequential packet socket.

SOCK_PACKET

Raw interface access socket.

UNKNOWN

Who ever knows what the future will bring us - just fill in here :-)

State

This field will contain one of the following Keywords:

FREE

The socket is not allocated

LISTENING

The socket is listening for a connection request. Such sockets are only included in the output if you specify the **--listening (-l)** or **--all (-a)** option.

CONNECTING

The socket is about to establish a connection.

CONNECTED

The socket is connected.

DISCONNECTING

The socket is disconnecting.

(empty) The socket is not connected to another one.

UNKNOWN

This state should never happen.

PID/Program name

Process ID (PID) and process name of the process that has the socket open. More info available in **Active Internet connections** section written above.

Path

This is the path name as which the corresponding processes attached to the socket.

Active IPX sockets

(this needs to be done by somebody who knows it)

Active NET/ROM sockets

(this needs to be done by somebody who knows it)

Active AX.25 sockets

(this needs to be done by somebody who knows it)

FILES

/etc/services -- The services translation file

/proc -- Mount point for the proc filesystem, which gives access to kernel status information via the following files.

/proc/net/dev -- device information

/proc/net/raw -- raw socket information

/proc/net/tcp -- TCP socket information

/proc/net/udp -- UDP socket information

/proc/net/udplite -- UDPLite socket information

/proc/net/igmp -- IGMP multicast information

/proc/net/unix -- Unix domain socket information

/proc/net/ipx -- IPX socket information

/proc/net/ax25 -- AX25 socket information

/proc/net/appletalk -- DDP (appletalk) socket information

/proc/net/nr -- NET/ROM socket information

/proc/net/route -- IP routing information

/proc/net/ax25_route -- AX25 routing information

/proc/net/px_route -- IPX routing information

/proc/net/nr_nodes -- NET/ROM nodelist

/proc/net/nr_neigh -- NET/ROM neighbours

/proc/net/ip_masquerade -- masqueraded connections

/sys/kernel/debug/bluetooth/l2cap -- Bluetooth L2CAP information

/sys/kernel/debug/bluetooth/rfcomm -- Bluetooth serial connections

/proc/net/snmp -- statistics

SEE ALSO

BUGS

Occasionally strange information may appear if a socket changes as it is viewed. This is unlikely to occur.

AUTHORS

The netstat user interface was written by Fred Baumgarten <dc6iq@insu1.etec.uni-karlsruhe.de>, the man page basically by Matt Welsh <mdw@tc.cornell.edu>. It was updated by Alan Cox <Alan.Cox@linux.org>, updated again by Tuan Hoang <tqhoang@bigfoot.com>. The man page and the command included in the net-tools package is totally rewritten by Bernd Eckenfels <ecki@linux.de>. UDPLite options were added by Brian Micek <bmicek@gmail.com>

nfsmount.conf(5) - Linux man page

Name

nfsmount.conf - Configuration file for NFS mounts

Synopsis

Configuration file for NFS mounts that allows options to be set globally, per server or per mount point.

Description

The configuration file is made up of multiple sections followed by variables associated with that section. A section is defined by a string enclosed by [and] branches. Variables are assignment statements that assign values to particular variables using the = operator, as in **Proto=Tcp**. Sections are broken up into three basic categories: Global options, Server options and Mount Point options.

[NFSMount_Global_Options] - This statically named section defines all of the global mount options that can be applied to every NFS mount.

[Server "Server_Name"] - This section defines all the mount options that should be used on mounts to a particular NFS server. The "Server_Name" strings needs to be surrounded by "" and be an exact match of the server name used in the **mount** command.

[MountPoint "Mount_Point"] - This section defines all the mount options that should be used on a particular mount point. The "Mount_Point" string needs to be surrounded by "" and be an exact match of the mount point used in the **mount** command.

Examples

These are some example lines of how sections and variables are defined in the configuration file.

```
[ NFSMount_Global_Options ]
Proto=Tcp
```

The TCP protocol will be used on every NFS mount.

```
[ Server "nfsserver.foo.com" ]
rsize=32k
wsize=32k
```

A 33k (32768 bytes) block size will be used as the read and write size on all mounts to the 'nfsserver.foo.com' server.

```
[ MountPoint "/export/home" ]
Background=True
```

All mounts to the '/export/home' export will be performed in the background (i.e. done asynchronously).

Files

/etc/nfsmount.conf

Default NFS mount configuration file

See Also

[nfs\(5\)](#), [mount\(8\)](#),

nfsstat(8) - Linux man page

Name

nfsstat - list NFS statistics

Synopsis

nfsstat [*OPTION*]...

Description

The **nfsstat** displays statistics kept about NFS client and server activity.

Options

-s, --server

Print only server-side statistics. The default is to print both server and client statistics.

-c, --client

Print only client-side statistics.

-n, --nfs

Print only NFS statistics. The default is to print both NFS and RPC information.

-2

Print only NFS v2 statistics. The default is to only print information about the versions of **NFS** that have non-zero counts.

-3

Print only NFS v3 statistics. The default is to only print information about the versions of **NFS** that have non-zero counts.

-4

Print only NFS v4 statistics. The default is to only print information about the versions of **NFS** that have non-zero counts.

-m, --mounts

Print information about each of the mounted **NFS** file systems.

If this option is used, all other options are ignored.

-r, --rpc

Print only RPC statistics.

-o *facility*

Display statistics for the specified facility, which must be one of:

nfs

NFS protocol information, split up by RPC call.

rpc

General RPC information.

net

Network layer statistics, such as the number of received packets, number of TCP connections, etc.

fh

Usage information on the server's file handle cache, including the total number of lookups, and the number of hits and misses.

rc

Usage information on the server's request reply cache, including the total number of lookups, and the number of hits and misses.

all

Display all of the above facilities.

-v, --verbose

This is equivalent to **-o all**.

-l, --list

Print information in list form.

-S, --since file

Instead of printing current statistics, **nfsstat** imports statistics from *file* and displays the difference between those and the current statistics. Valid input *files* may be in the form of **/proc/net/rpc/nfs** (raw client stats), **/proc/net/rpc/nfsd** (raw server stats), or saved output from **nfsstat** itself (client and/or server stats). Any statistics missing from a saved **nfsstat** output *file* are treated as zeroes.

-Z[interval], --sleep=[interval]

Instead of printing current statistics and immediately exiting, **nfsstat** takes a snapshot of the current statistics and pauses until it receives **SIGINT** (typically from **Ctrl-C**), at which point it takes another snapshot and displays the difference between the two. If *interval* is specified, **nfsstat** will print the number of **NFS** calls made since the previous report. Stats will be printed repeatedly every *interval* seconds.

Examples

nfsstat -o all -234

Show all information about all versions of **NFS**.

nfsstat --verbose -234

Same as above.

nfsstat -o all

Show all information about active versions of **NFS**.

nfsstat --nfs --server -3

Show statistics for **NFS** version 3 server.

nfsstat -m

Show information about mounted **NFS** filesystems.

Display

The **Flags** output from the **-m** option is the same as the flags give to the **mount** command.

Files

/proc/net/rpc/nfsd

procfs-based interface to kernel NFS server statistics.

/proc/net/rpc/nfs

procfs-based interface to kernel NFS client statistics.

/proc/mounts

procfs-based interface to the mounted filesystems.

See Also

[rpc.nfsd\(8\)](#). [nfs\(5\)](#).

Bugs

The default output has been changed. To get the old default output you must run **nfsstat -auto -2**.

The function of the **-v** and **-a** options have changed. The **-a** option is now reserved for future use. The **-v** does what the **-a** option used to do, and the new **-[234]** options replace the **-v** option.

The **Display** section should be more complete.

Further bugs can be found or reported at <http://nfs.sf.net/>.

NAME

nice – run a program with modified scheduling priority

SYNOPSIS

nice [*OPTION*] [*COMMAND* [*ARG*]...]

DESCRIPTION

Run *COMMAND* with an adjusted niceness, which affects process scheduling. With no *COMMAND*, print the current niceness. Niceness values range from **-20** (most favorable to the process) to 19 (least favorable to the process).

Mandatory arguments to long options are mandatory for short options too.

-n, --adjustment=N

add integer N to the niceness (default 10)

--help display this help and exit

--version

output version information and exit

NOTE: your shell may have its own version of nice, which usually supersedes the version described here. Please refer to your shell's documentation for details about the options it supports.

NAME

nice – change process priority

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <unistd.h>
int nice(int inc);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
nice():
_XOPEN_SOURCE
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _BSD_SOURCE || _SVID_SOURCE
```

DESCRIPTION

nice() adds *inc* to the nice value for the calling thread. (A higher nice value means a lower priority.)

The range of the nice value is +19 (low priority) to -20 (high priority). Attempts to set a nice value outside the range are clamped to the range.

Traditionally, only a privileged process could lower the nice value (i.e., set a higher priority). However, since Linux 2.6.12, an unprivileged process can decrease the nice value of a target process that has a suitable **RLIMIT_NICE** soft limit; see **getrlimit(2)** for details.

RETURN VALUE

On success, the new nice value is returned (but see NOTES below). On error, -1 is returned, and *errno* is set to indicate the error.

A successful call can legitimately return -1. To detect an error, set *errno* to 0 before the call, and check whether it is nonzero after **nice()** returns -1.

ERRORS

EPERM

The calling process attempted to increase its priority by supplying a negative *inc* but has insufficient privileges. Under Linux, the**CAP_SYS_NICE** capability is required. (But see the discussion of the **RLIMIT_NICE** resource limit in **setrlimit(2)**.)

STANDARDS

POSIX.1-2001, POSIX.1-2008, SVr4, 4.3BSD. However, the raw system call and (g)libc (earlier than glibc 2.2.4) return value is nonstandard, see below.

NOTES

For further details on the nice value, see **sched(7)**.

Note: the addition of the "autogroup" feature in Linux 2.6.38 means that the nice value no longer has its traditional effect in many circumstances. For details, see **sched(7)**.

C library/kernel differences

POSIX.1 specifies that **nice()** should return the new nice value. However, the raw Linux system call returns 0 on success. Likewise, the **nice()** wrapper function provided in glibc 2.2.3 and earlier returns 0 on success.

Since glibc 2.2.4, the **nice()** wrapper function provided by glibc provides conformance to POSIX.1 by calling **getpriority(2)** to obtain the new nice value, which is then returned to the caller.

NAME

nm-settings-nmcli – Description of settings and properties of NetworkManager connection profiles for nmcli

DESCRIPTION

NetworkManager is based on a concept of connection profiles, sometimes referred to as connections only. These connection profiles contain a network configuration. When NetworkManager activates a connection profile on a network device the configuration will be applied and an active network connection will be established. Users are free to create as many connection profiles as they see fit. Thus they are flexible in having various network configurations for different networking needs.

NetworkManager provides an API for configuring connection profiles, for activating them to configure the network, and inspecting the current network configuration. The command line tool *nmcli* is a client application to NetworkManager that uses this API. See **nmcli(1)** for details.

With commands like *nmcli connection add*, *nmcli connection modify* and *nmcli connection show*, connection profiles can be created, modified and inspected. A profile consists of properties. On D-Bus this follows the format as described by **nm-settings-dbus(5)**, while this manual page describes the settings format how they are expected by *nmcli*.

The settings and properties shown in tables below list all available connection configuration options. However, note that not all settings are applicable to all connection types. *nmcli* connection editor has also a built-in *describe* command that can display description of particular settings and properties of this page.

The *setting* and *property* can be abbreviated provided they are unique. The list below also shows aliases that can be used unqualified instead of the full name. For example *connection.interface-name* and *ifname* refer to the same property.

connection setting

General Connection Profile Settings.

Properties:

auth-retries

The number of retries for the authentication. Zero means to try indefinitely; -1 means to use a global default. If the global default is not set, the authentication retries for 3 times before failing the connection. Currently, this only applies to 802-1x authentication.

Format: int32

autoconnect

Alias: autoconnect

Whether or not the connection should be automatically connected by NetworkManager when the resources for the connection are available. TRUE to automatically activate the connection, FALSE to require manual intervention to activate the connection. Autoconnect happens when the circumstances are suitable. That means for example that the device is currently managed and not active. Autoconnect thus never replaces or competes with an already active profile. Note that autoconnect is not implemented for VPN profiles. See "secondaries" as an alternative to automatically connect VPN profiles.

Format: boolean

autoconnect-priority

The autoconnect priority in range -999 to 999. If the connection is set to autoconnect, connections with higher priority will be preferred. The higher number means higher priority. Defaults to 0. Note that this property only matters if there are more than one candidate profile to select for autoconnect. In case of equal priority, the profile used most recently is chosen.

Format: int32

autoconnect-retries

The number of times a connection should be tried when autoactivating before giving up. Zero means forever, -1 means the global default (4 times if not overridden). Setting this to 1 means to try activation only once before blocking autoconnect. Note that after a timeout, NetworkManager will try to autoconnect again.

Format: int32

autoconnect-slaves

Whether or not slaves of this connection should be automatically brought up when NetworkManager activates this connection. This only has a real effect for master connections. The properties "autoconnect", "autoconnect-priority" and "autoconnect-retries" are unrelated to this setting. The permitted values are: 0: leave slave connections untouched, 1: activate all the slave connections with this connection, -1: default. If -1 (default) is set, global connection.autoconnect-slaves is read to determine the real value. If it is default as well, this falls back to 0.

Format: NMSettingConnectionAutoconnectSlaves (int32)

dns-over-tls

Whether DNSOverTls (dns-over-tls) is enabled for the connection. DNSOverTls is a technology which uses TLS to encrypt dns traffic. The permitted values are: "yes" (2) use DNSOverTls and disabled fallback, "opportunistic" (1) use DNSOverTls but allow fallback to unencrypted resolution, "no" (0) don't ever use DNSOverTls. If unspecified "default" depends on the plugin used. Systemd-resolved uses global setting. This feature requires a plugin which supports DNSOverTls. Otherwise, the setting has no effect. One such plugin is dns-systemd-resolved.

Format: int32

gateway-ping-timeout

If greater than zero, delay success of IP addressing until either the timeout is reached, or an IP gateway replies to a ping.

Format: uint32

id

Alias: con-name

A human readable unique identifier for the connection, like "Work Wi-Fi" or "T-Mobile 3G".

Format: string

interface-name

Alias: ifname

The name of the network interface this connection is bound to. If not set, then the connection can be attached to any interface of the appropriate type (subject to restrictions imposed by other settings). For software devices this specifies the name of the created device. For connection types where interface names cannot easily be made persistent (e.g. mobile broadband or USB Ethernet), this property should not be used. Setting this property restricts the interfaces a connection can be used with, and if interface names change or are reordered the connection may be applied to the wrong interface.

Format: string

lldp

Whether LLDP is enabled for the connection.

Format: int32

llmnr

Whether Link–Local Multicast Name Resolution (LLMNR) is enabled for the connection. LLMNR is a protocol based on the Domain Name System (DNS) packet format that allows both IPv4 and IPv6 hosts to perform name resolution for hosts on the same local link. The permitted values are: "yes" (2) register hostname and resolving for the connection, "no" (0) disable LLMNR for the interface, "resolve" (1) do not register hostname but allow resolving of LLMNR host names If unspecified, "default" ultimately depends on the DNS plugin (which for systemd–resolved currently means "yes"). This feature requires a plugin which supports LLMNR. Otherwise, the setting has no effect. One such plugin is dns–systemd–resolved.

Format: int32

master

Alias: master

Interface name of the master device or UUID of the master connection.

Format: string

mdns

Whether mDNS is enabled for the connection. The permitted values are: "yes" (2) register hostname and resolving for the connection, "no" (0) disable mDNS for the interface, "resolve" (1) do not register hostname but allow resolving of mDNS host names and "default" (-1) to allow lookup of a global default in NetworkManager.conf. If unspecified, "default" ultimately depends on the DNS plugin (which for systemd–resolved currently means "no"). This feature requires a plugin which supports mDNS. Otherwise, the setting has no effect. One such plugin is dns–systemd–resolved.

Format: int32

metered

Whether the connection is metered. When updating this property on a currently activated connection, the change takes effect immediately.

Format: NMMetered (int32)

mud–url

If configured, set to a Manufacturer Usage Description (MUD) URL that points to manufacturer–recommended network policies for IoT devices. It is transmitted as a DHCPv4 or DHCPv6 option. The value must be a valid URL starting with "https://". The special value "none" is allowed to indicate that no MUD URL is used. If the per–profile value is unspecified (the default), a global connection default gets consulted. If still unspecified, the ultimate default is "none".

Format: string

multi–connect

Specifies whether the profile can be active multiple times at a particular moment. The value is of type NMConnectionMultiConnect.

Format: int32

permissions

An array of strings defining what access a given user has to this connection. If this is NULL or empty, all users are allowed to access this connection; otherwise users are allowed if and only if they are in this list. When this is not empty, the connection can be active only when one of the specified users is logged into an active session. Each entry is of the form "[type]:[id]:[reserved]"; for example, "user:dcbw:blah". At this time only the "user" [type] is allowed. Any other values are ignored and reserved for future use. [id] is the username that this permission refers to, which may not contain the ":" character. Any [reserved] information present must be ignored and is reserved for future use. All of [type], [id], and [reserved] must be valid UTF–8.

Format: array of string

read-only

FALSE if the connection can be modified using the provided settings service's D-Bus interface with the right privileges, or TRUE if the connection is read-only and cannot be modified.

Format: boolean

secondaries

List of connection UUIDs that should be activated when the base connection itself is activated. Currently, only VPN connections are supported.

Format: array of string

slave-type

Alias: slave-type

Setting name of the device type of this slave's master connection (eg, "bond"), or NULL if this connection is not a slave.

Format: string

stable-id

This represents the identity of the connection used for various purposes. It allows to configure multiple profiles to share the identity. Also, the stable-id can contain placeholders that are substituted dynamically and deterministically depending on the context. The stable-id is used for generating IPv6 stable private addresses with ipv6.addr-gen-mode=stable-privacy. It is also used to seed the generated cloned MAC address for ethernet.cloned-mac-address=stable and wifi.cloned-mac-address=stable. It is also used as DHCP client identifier with ipv4.dhcp-client-id=stable and to derive the DHCP DUID with ipv6.dhcp-duid=stable-[llt, ll, uuid]. Note that depending on the context where it is used, other parameters are also seeded into the generation algorithm. For example, a per-host key is commonly also included, so that different systems end up generating different IDs. Or with ipv6.addr-gen-mode=stable-privacy, also the device's name is included, so that different interfaces yield different addresses. The per-host key is the identity of your machine and stored in /var/lib/NetworkManager/secret-key. The '\$' character is treated special to perform dynamic substitutions at runtime. Currently, supported are "\${CONNECTION}", "\${DEVICE}", "\${MAC}", "\${BOOT}", "\${RANDOM}". These effectively create unique IDs per-connection, per-device, per-boot, or every time. Note that "\${DEVICE}" corresponds to the interface name of the device and "\${MAC}" is the permanent MAC address of the device. Any unrecognized patterns following '\$' are treated verbatim, however are reserved for future use. You are thus advised to avoid '\$' or escape it as "\$\$". For example, set it to "\${CONNECTION}-\${BOOT}-\${DEVICE}" to create a unique id for this connection that changes with every reboot and differs depending on the interface where the profile activates. If the value is unset, a global connection default is consulted. If the value is still unset, the default is similar to "\${CONNECTION}" and uses a unique, fixed ID for the connection.

Format: string

timestamp

The time, in seconds since the Unix Epoch, that the connection was last _successfully_ fully activated. NetworkManager updates the connection timestamp periodically when the connection is active to ensure that an active connection has the latest timestamp. The property is only meant for reading (changes to this property will not be preserved).

Format: uint64

type

Alias: type

Base type of the connection. For hardware-dependent connections, should contain the setting name of the hardware-type specific setting (ie, "802-3-ethernet" or "802-11-wireless" or "bluetooth", etc), and for non-hardware dependent connections like VPN or otherwise, should contain the setting name of that setting type (ie, "vpn" or "bridge", etc).

Format: string

uuid

A universally unique identifier for the connection, for example generated with libuuid. It should be assigned when the connection is created, and never changed as long as the connection still applies to the same network. For example, it should not be changed when the "id" property or NMSettingIP4Config changes, but might need to be re-created when the Wi-Fi SSID, mobile broadband network provider, or "type" property changes. The UUID must be in the format "2815492f-7e56-435e-b2e9-246bd7cdc664" (ie, contains only hexadecimal characters and "-").

Format: string

wait-device-timeout

Timeout in milliseconds to wait for device at startup. During boot, devices may take a while to be detected by the driver. This property will cause NetworkManager-wait-online.service and nm-online to give the device a chance to appear. This works by waiting for the given timeout until a compatible device for the profile is available and managed. The value 0 means no wait time. The default value is -1, which currently has the same meaning as no wait time.

Format: int32

zone

The trust level of a the connection. Free form case-insensitive string (for example "Home", "Work", "Public"). NULL or unspecified zone means the connection will be placed in the default zone as defined by the firewall. When updating this property on a currently activated connection, the change takes effect immediately.

Format: string

6lowpan setting

6LoWPAN Settings.

Properties:

parent

Alias: dev

If given, specifies the parent interface name or parent connection UUID from which this 6LowPAN interface should be created.

Format: string

802-1x setting

IEEE 802.1x Authentication Settings.

Properties:

altsubject-matches

List of strings to be matched against the altSubjectName of the certificate presented by the authentication server. If the list is empty, no verification of the server certificate's altSubjectName is performed.

Format: array of string

anonymous-identity

Anonymous identity string for EAP authentication methods. Used as the unencrypted identity with EAP types that support different tunneled identity like EAP-TTLS.

Format: string

auth-timeout

A timeout for the authentication. Zero means the global default; if the global default is not set, the authentication timeout is 25 seconds.

Format: int32

ca-cert

Contains the CA certificate if used by the EAP method specified in the "eap" property. Certificate data is specified using a "scheme"; three are currently supported: blob, path and pkcs#11 URL. When using the blob scheme this property should be set to the certificate's DER encoded data. When using the path scheme, this property should be set to the full UTF-8 encoded path of the certificate, prefixed with the string "file://" and ending with a terminating NUL byte. This property can be unset even if the EAP method supports CA certificates, but this allows man-in-the-middle attacks and is NOT recommended. Note that enabling NMSetting8021x:system-ca-certs will override this setting to use the built-in path, if the built-in path is not a directory.

Format: byte array

ca-cert-password

The password used to access the CA certificate stored in "ca-cert" property. Only makes sense if the certificate is stored on a PKCS#11 token that requires a login.

Format: string

ca-cert-password-flags

Flags indicating how to handle the "ca-cert-password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

ca-path

UTF-8 encoded path to a directory containing PEM or DER formatted certificates to be added to the verification chain in addition to the certificate specified in the "ca-cert" property. If NMSetting8021x:system-ca-certs is enabled and the built-in CA path is an existing directory, then this setting is ignored.

Format: string

client-cert

Contains the client certificate if used by the EAP method specified in the "eap" property. Certificate data is specified using a "scheme"; two are currently supported: blob and path. When using the blob scheme (which is backwards compatible with NM 0.7.x) this property should be set to the certificate's DER encoded data. When using the path scheme, this property should be set to the full UTF-8 encoded path of the certificate, prefixed with the string "file://" and ending with a terminating NUL byte.

Format: byte array

client-cert-password

The password used to access the client certificate stored in "client-cert" property. Only makes sense if the certificate is stored on a PKCS#11 token that requires a login.

Format: string

client-cert-password-flags

Flags indicating how to handle the "client-cert-password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

domain-match

Constraint for server domain name. If set, this list of FQDNs is used as a match requirement for dNSName element(s) of the certificate presented by the authentication server. If a matching dNSName is found, this constraint is met. If no dNSName values are present, this constraint is matched against SubjectName CN using the same comparison. Multiple valid FQDNs can be passed as a ";" delimited list.

Format: string

domain-suffix-match

Constraint for server domain name. If set, this FQDN is used as a suffix match requirement for dNSName element(s) of the certificate presented by the authentication server. If a matching dNSName is found, this constraint is met. If no dNSName values are present, this constraint is matched against SubjectName CN using same suffix match comparison. Since version 1.24, multiple valid FQDNs can be passed as a ";" delimited list.

Format: string

eap

The allowed EAP method to be used when authenticating to the network with 802.1x. Valid methods are: "leap", "md5", "tls", "peap", "ttls", "pwd", and "fast". Each method requires different configuration using the properties of this setting; refer to wpa_supplicant documentation for the allowed combinations.

Format: array of string

identity

Identity string for EAP authentication methods. Often the user's user or login name.

Format: string

optional

Whether the 802.1X authentication is optional. If TRUE, the activation will continue even after a timeout or an authentication failure. Setting the property to TRUE is currently allowed only for Ethernet connections. If set to FALSE, the activation can continue only after a successful authentication.

Format: boolean

pac-file

UTF-8 encoded file path containing PAC for EAP-FAST.

Format: string

password

UTF-8 encoded password used for EAP authentication methods. If both the "password" property and the "password-raw" property are specified, "password" is preferred.

Format: string

password-flags

Flags indicating how to handle the "password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

password–raw

Password used for EAP authentication methods, given as a byte array to allow passwords in other encodings than UTF-8 to be used. If both the "password" property and the "password–raw" property are specified, "password" is preferred.

Format: byte array

password–raw–flags

Flags indicating how to handle the "password–raw" property. See the section called “Secret flag types:” for flag values.

Format: NMSettingSecretFlags (uint32)

phase1–auth–flags

Specifies authentication flags to use in "phase 1" outer authentication using NMSetting8021xAuthFlags options. The individual TLS versions can be explicitly disabled. If a certain TLS disable flag is not set, it is up to the supplicant to allow or forbid it. The TLS options map to tls_disable_tlv1_x settings. See the wpa_supplicant documentation for more details.

Format: uint32

phase1–fast–provisioning

Enables or disables in-line provisioning of EAP–FAST credentials when FAST is specified as the EAP method in the "eap" property. Recognized values are "0" (disabled), "1" (allow unauthenticated provisioning), "2" (allow authenticated provisioning), and "3" (allow both authenticated and unauthenticated provisioning). See the wpa_supplicant documentation for more details.

Format: string

phase1–peaplabel

Forces use of the new PEAP label during key derivation. Some RADIUS servers may require forcing the new PEAP label to interoperate with PEAPv1. Set to "1" to force use of the new PEAP label. See the wpa_supplicant documentation for more details.

Format: string

phase1–peapver

Forces which PEAP version is used when PEAP is set as the EAP method in the "eap" property. When unset, the version reported by the server will be used. Sometimes when using older RADIUS servers, it is necessary to force the client to use a particular PEAP version. To do so, this property may be set to "0" or "1" to force that specific PEAP version.

Format: string

phase2–altsubject–matches

List of strings to be matched against the altSubjectName of the certificate presented by the authentication server during the inner "phase 2" authentication. If the list is empty, no verification of the server certificate's altSubjectName is performed.

Format: array of string

phase2–auth

Specifies the allowed "phase 2" inner authentication method when an EAP method that uses an inner TLS tunnel is specified in the "eap" property. For TTLS this property selects one of the supported non–EAP inner methods: "pap", "chap", "mschap", "mschapv2" while "phase2–autheap" selects an EAP inner method. For PEAP this selects an inner EAP method, one of: "gtc", "otp", "md5" and "tls". Each "phase 2" inner method requires specific parameters for successful authentication; see the

wpa_supplicant documentation for more details. Both "phase2-auth" and "phase2-autheap" cannot be specified.

Format: string

phase2-autheap

Specifies the allowed "phase 2" inner EAP-based authentication method when TLS is specified in the "eap" property. Recognized EAP-based "phase 2" methods are "md5", "mschapv2", "otp", "gtc", and "tls". Each "phase 2" inner method requires specific parameters for successful authentication; see the wpa_supplicant documentation for more details.

Format: string

phase2-ca-cert

Contains the "phase 2" CA certificate if used by the EAP method specified in the "phase2-auth" or "phase2-autheap" properties. Certificate data is specified using a "scheme"; three are currently supported: blob, path and pkcs#11 URL. When using the blob scheme this property should be set to the certificate's DER encoded data. When using the path scheme, this property should be set to the full UTF-8 encoded path of the certificate, prefixed with the string "file://" and ending with a terminating NUL byte. This property can be unset even if the EAP method supports CA certificates, but this allows man-in-the-middle attacks and is NOT recommended. Note that enabling NMSetting8021x:system-ca-certs will override this setting to use the built-in path, if the built-in path is not a directory.

Format: byte array

phase2-ca-cert-password

The password used to access the "phase2" CA certificate stored in "phase2-ca-cert" property. Only makes sense if the certificate is stored on a PKCS#11 token that requires a login.

Format: string

phase2-ca-cert-password-flags

Flags indicating how to handle the "phase2-ca-cert-password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

phase2-ca-path

UTF-8 encoded path to a directory containing PEM or DER formatted certificates to be added to the verification chain in addition to the certificate specified in the "phase2-ca-cert" property. If NMSetting8021x:system-ca-certs is enabled and the built-in CA path is an existing directory, then this setting is ignored.

Format: string

phase2-client-cert

Contains the "phase 2" client certificate if used by the EAP method specified in the "phase2-auth" or "phase2-autheap" properties. Certificate data is specified using a "scheme"; two are currently supported: blob and path. When using the blob scheme (which is backwards compatible with NM 0.7.x) this property should be set to the certificate's DER encoded data. When using the path scheme, this property should be set to the full UTF-8 encoded path of the certificate, prefixed with the string "file://" and ending with a terminating NUL byte. This property can be unset even if the EAP method supports CA certificates, but this allows man-in-the-middle attacks and is NOT recommended.

Format: byte array

phase2-client-cert-password

The password used to access the "phase2" client certificate stored in "phase2-client-cert" property.

Only makes sense if the certificate is stored on a PKCS#11 token that requires a login.

Format: string

phase2-client-cert-password-flags

Flags indicating how to handle the "phase2-client-cert-password" property. See the section called "Secret flag types." for flag values.

Format: NMSettingSecretFlags (uint32)

phase2-domain-match

Constraint for server domain name. If set, this list of FQDNs is used as a match requirement for dNSName element(s) of the certificate presented by the authentication server during the inner "phase 2" authentication. If a matching dNSName is found, this constraint is met. If no dNSName values are present, this constraint is matched against SubjectName CN using the same comparison. Multiple valid FQDNs can be passed as a ";" delimited list.

Format: string

phase2-domain-suffix-match

Constraint for server domain name. If set, this FQDN is used as a suffix match requirement for dNSName element(s) of the certificate presented by the authentication server during the inner "phase 2" authentication. If a matching dNSName is found, this constraint is met. If no dNSName values are present, this constraint is matched against SubjectName CN using same suffix match comparison. Since version 1.24, multiple valid FQDNs can be passed as a ";" delimited list.

Format: string

phase2-private-key

Contains the "phase 2" inner private key when the "phase2-auth" or "phase2-autheap" property is set to "tls". Key data is specified using a "scheme"; two are currently supported: blob and path. When using the blob scheme and private keys, this property should be set to the key's encrypted PEM encoded data. When using private keys with the path scheme, this property should be set to the full UTF-8 encoded path of the key, prefixed with the string "file://" and ending with a terminating NUL byte. When using PKCS#12 format private keys and the blob scheme, this property should be set to the PKCS#12 data and the "phase2-private-key-password" property must be set to password used to decrypt the PKCS#12 certificate and key. When using PKCS#12 files and the path scheme, this property should be set to the full UTF-8 encoded path of the key, prefixed with the string "file://" and ending with a terminating NUL byte, and as with the blob scheme the "phase2-private-key-password" property must be set to the password used to decode the PKCS#12 private key and certificate.

Format: byte array

phase2-private-key-password

The password used to decrypt the "phase 2" private key specified in the "phase2-private-key" property when the private key either uses the path scheme, or is a PKCS#12 format key.

Format: string

phase2-private-key-password-flags

Flags indicating how to handle the "phase2-private-key-password" property. See the section called "Secret flag types." for flag values.

Format: NMSettingSecretFlags (uint32)

phase2-subject-match

Substring to be matched against the subject of the certificate presented by the authentication server during the inner "phase 2" authentication. When unset, no verification of the authentication server

certificate's subject is performed. This property provides little security, if any, and its use is deprecated in favor of NMSetting8021x:phase2-domain-suffix-match.

Format: string

pin

PIN used for EAP authentication methods.

Format: string

pin-flags

Flags indicating how to handle the "pin" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

private-key

Contains the private key when the "eap" property is set to "tls". Key data is specified using a "scheme"; two are currently supported: blob and path. When using the blob scheme and private keys, this property should be set to the key's encrypted PEM encoded data. When using private keys with the path scheme, this property should be set to the full UTF-8 encoded path of the key, prefixed with the string "file://" and ending with a terminating NUL byte. When using PKCS#12 format private keys and the blob scheme, this property should be set to the PKCS#12 data and the "private-key-password" property must be set to password used to decrypt the PKCS#12 certificate and key. When using PKCS#12 files and the path scheme, this property should be set to the full UTF-8 encoded path of the key, prefixed with the string "file://" and ending with a terminating NUL byte, and as with the blob scheme the "private-key-password" property must be set to the password used to decode the PKCS#12 private key and certificate. WARNING: "private-key" is not a "secret" property, and thus unencrypted private key data using the BLOB scheme may be readable by unprivileged users. Private keys should always be encrypted with a private key password to prevent unauthorized access to unencrypted private key data.

Format: byte array

private-key-password

The password used to decrypt the private key specified in the "private-key" property when the private key either uses the path scheme, or if the private key is a PKCS#12 format key.

Format: string

private-key-password-flags

Flags indicating how to handle the "private-key-password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

subject-match

Substring to be matched against the subject of the certificate presented by the authentication server. When unset, no verification of the authentication server certificate's subject is performed. This property provides little security, if any, and its use is deprecated in favor of NMSetting8021x:domain-suffix-match.

Format: string

system-ca-certs

When TRUE, overrides the "ca-path" and "phase2-ca-path" properties using the system CA directory specified at configure time with the --system-ca-path switch. The certificates in this directory are added to the verification chain in addition to any certificates specified by the "ca-cert" and "phase2-ca-cert" properties. If the path provided with --system-ca-path is rather a file name (bundle

of trusted CA certificates), it overrides "ca-cert" and "phase2-ca-cert" properties instead (sets ca_cert/ca_cert2 options for wpa_supplicant).

Format: boolean

adsl setting

ADSL Settings.

Properties:

encapsulation

Alias: encapsulation

Encapsulation of ADSL connection. Can be "vcmux" or "llc".

Format: string

password

Alias: password

Password used to authenticate with the ADSL service.

Format: string

password-flags

Flags indicating how to handle the "password" property. See the section called “Secret flag types:” for flag values.

Format: NMSettingSecretFlags (uint32)

protocol

Alias: protocol

ADSL connection protocol. Can be "pppoa", "pppoe" or "ipoatm".

Format: string

username

Alias: username

Username used to authenticate with the ADSL service.

Format: string

vci

VCI of ADSL connection

Format: uint32

vpi

VPI of ADSL connection

Format: uint32

bluetooth setting

Bluetooth Settings.

Properties:

bdaddr

Alias: addr

The Bluetooth address of the device.

Format: byte array

type

Alias: bt-type

Either "dun" for Dial-Up Networking connections or "panu" for Personal Area Networking connections to devices supporting the NAP profile.

Format: string

bond setting

Bonding Settings.

Properties:

options

Dictionary of key/value pairs of bonding options. Both keys and values must be strings. Option names must contain only alphanumeric characters (ie, [a-zA-Z0-9]).

Format: dict of string to string

bridge setting

Bridging Settings.

Properties:

ageing-time

Alias: ageing-time

The Ethernet MAC address aging time, in seconds.

Format: uint32

forward-delay

Alias: forward-delay

The Spanning Tree Protocol (STP) forwarding delay, in seconds.

Format: uint32

group-address

If specified, The MAC address of the multicast group this bridge uses for STP. The address must be a link-local address in standard Ethernet MAC address format, ie an address of the form 01:80:C2:00:00:0X, with X in [0, 4..F]. If not specified the default value is 01:80:C2:00:00:00.

Format: byte array

group-forward-mask

Alias: group-forward-mask

A mask of group addresses to forward. Usually, group addresses in the range from 01:80:C2:00:00:00 to 01:80:C2:00:00:0F are not forwarded according to standards. This property is a mask of 16 bits, each corresponding to a group address in that range that must be forwarded. The mask can't have bits 0, 1 or 2 set because they are used for STP, MAC pause frames and LACP.

Format: uint32

hello-time

Alias: hello-time

The Spanning Tree Protocol (STP) hello time, in seconds.

Format: uint32

mac-address

Alias: mac

If specified, the MAC address of bridge. When creating a new bridge, this MAC address will be set. If this field is left unspecified, the "ethernet.cloned-mac-address" is referred instead to generate the initial MAC address. Note that setting "ethernet.cloned-mac-address" anyway overwrites the MAC address of the bridge later while activating the bridge. Hence, this property is deprecated. Deprecated: 1

Format: byte array

max-age

Alias: max-age

The Spanning Tree Protocol (STP) maximum message age, in seconds.

Format: uint32

multicast-hash-max

Set maximum size of multicast hash table (value must be a power of 2).

Format: uint32

multicast-last-member-count

Set the number of queries the bridge will send before stopping forwarding a multicast group after a "leave" message has been received.

Format: uint32

multicast-last-member-interval

Set interval (in deciseconds) between queries to find remaining members of a group, after a "leave" message is received.

Format: uint64

multicast-membership-interval

Set delay (in deciseconds) after which the bridge will leave a group, if no membership reports for this group are received.

Format: uint64

multicast-querier

Enable or disable sending of multicast queries by the bridge. If not specified the option is disabled.

Format: boolean

multicast-querier-interval

If no queries are seen after this delay (in deciseconds) has passed, the bridge will start to send its own queries.

Format: uint64

multicast-query-interval

Interval (in deciseconds) between queries sent by the bridge after the end of the startup phase.

Format: uint64

multicast-query-response-interval

Set the Max Response Time/Max Response Delay (in deciseconds) for IGMP/MLD queries sent by the bridge.

Format: uint64

multicast-query-use-ifaddr

If enabled the bridge's own IP address is used as the source address for IGMP queries otherwise the default of 0.0.0.0 is used.

Format: boolean

multicast-router

Sets bridge's multicast router. Multicast-snooping must be enabled for this option to work. Supported values are: 'auto', 'disabled', 'enabled' to which kernel assigns the numbers 1, 0, and 2, respectively. If not specified the default value is 'auto' (1).

Format: string

multicast-snooping

Alias: multicast-snooping

Controls whether IGMP snooping is enabled for this bridge. Note that if snooping was automatically disabled due to hash collisions, the system may refuse to enable the feature until the collisions are resolved.

Format: boolean

multicast-startup-query-count

Set the number of IGMP queries to send during startup phase.

Format: uint32

multicast-startup-query-interval

Sets the time (in deciseconds) between queries sent out at startup to determine membership information.

Format: uint64

priority

Alias: priority

Sets the Spanning Tree Protocol (STP) priority for this bridge. Lower values are "better"; the lowest priority bridge will be elected the root bridge.

Format: uint32

stp

Alias: stp

Controls whether Spanning Tree Protocol (STP) is enabled for this bridge.

Format: boolean

vlan-default-pvid

The default PVID for the ports of the bridge, that is the VLAN id assigned to incoming untagged frames.

Format: uint32

vlan-filtering

Control whether VLAN filtering is enabled on the bridge.

Format: boolean

vlan-protocol

If specified, the protocol used for VLAN filtering. Supported values are: '802.1Q', '802.1ad'. If not specified the default value is '802.1Q'.

Format: string

vlan-stats-enabled

Controls whether per-VLAN stats accounting is enabled.

Format: boolean

vlans

Array of bridge VLAN objects. In addition to the VLANs specified here, the bridge will also have the default-pvid VLAN configured by the bridge.vlan-default-pvid property. In nmcli the VLAN list can be specified with the following syntax: \$vid [pvid] [untagged] [, \$vid [pvid] [untagged]]... where \$vid is either a single id between 1 and 4094 or a range, represented as a couple of ids separated by a dash.

Format: array of vardict

bridge-port setting

Bridge Port Settings.

Properties:

hairpin-mode

Alias: hairpin

Enables or disables "hairpin mode" for the port, which allows frames to be sent back out through the port the frame was received on.

Format: boolean

path-cost

Alias: path-cost

The Spanning Tree Protocol (STP) port cost for destinations via this port.

Format: uint32

priority

Alias: priority

The Spanning Tree Protocol (STP) priority of this bridge port.

Format: uint32

vlans

Array of bridge VLAN objects. In addition to the VLANs specified here, the port will also have the default-pvid VLAN configured on the bridge by the bridge.vlan-default-pvid property. In nmcli the VLAN list can be specified with the following syntax: \$vid [pvid] [untagged] [, \$vid [pvid] [untagged]]... where \$vid is either a single id between 1 and 4094 or a range, represented as a couple of ids separated by a dash.

Format: array of vardict

cdma setting

CDMA-based Mobile Broadband Settings.

Properties:

mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple frames.

Format: uint32

number

The number to dial to establish the connection to the CDMA-based mobile broadband network, if any. If not specified, the default number (#777) is used when required.

Format: string

password

Alias: password

The password used to authenticate with the network, if required. Many providers do not require a password, or accept any password. But if a password is required, it is specified here.

Format: string

password-flags

Flags indicating how to handle the "password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

username

Alias: user

The username used to authenticate with the network, if required. Many providers do not require a username, or accept any username. But if a username is required, it is specified here.

Format: string

dcb setting

Data Center Bridging Settings.

Properties:

app-fcoe-flags

Specifies the NMSettingDcbFlags for the DCB FCoE application. Flags may be any combination of NM_SETTING_DCB_FLAG_ENABLE (0x1), NM_SETTING_DCB_FLAG_ADVERTISE (0x2), and NM_SETTING_DCB_FLAG_WILLING (0x4).

Format: NMSettingDcbFlags (uint32)

app-fcoe-mode

The FCoE controller mode; either "fabric" or "vn2vn". Since 1.34, NULL is the default and means "fabric". Before 1.34, NULL was rejected as invalid and the default was "fabric".

Format: string

app-fcoe-priority

The highest User Priority (0 – 7) which FCoE frames should use, or -1 for default priority. Only used when the "app-fcoe-flags" property includes the NM_SETTING_DCB_FLAG_ENABLE (0x1) flag.

Format: int32

app-fip-flags

Specifies the NMSettingDcbFlags for the DCB FIP application. Flags may be any combination of NM_SETTING_DCB_FLAG_ENABLE (0x1), NM_SETTING_DCB_FLAG_ADVERTISE (0x2), and NM_SETTING_DCB_FLAG_WILLING (0x4).

Format: NMSettingDcbFlags (uint32)

app-fip-priority

The highest User Priority (0 – 7) which FIP frames should use, or -1 for default priority. Only used when the "app-fip-flags" property includes the NM_SETTING_DCB_FLAG_ENABLE (0x1) flag.

Format: int32

app-iscsi-flags

Specifies the NMSettingDcbFlags for the DCB iSCSI application. Flags may be any combination of NM_SETTING_DCB_FLAG_ENABLE (0x1), NM_SETTING_DCB_FLAG_ADVERTISE (0x2), and NM_SETTING_DCB_FLAG_WILLING (0x4).

Format: NMSettingDcbFlags (uint32)

app-iscsi-priority

The highest User Priority (0 – 7) which iSCSI frames should use, or -1 for default priority. Only used when the "app-iscsi-flags" property includes the NM_SETTING_DCB_FLAG_ENABLE (0x1) flag.

Format: int32

priority-bandwidth

An array of 8 uint values, where the array index corresponds to the User Priority (0 – 7) and the value indicates the percentage of bandwidth of the priority's assigned group that the priority may use. The sum of all percentages for priorities which belong to the same group must total 100 percents.

Format: array of uint32

priority-flow-control

An array of 8 boolean values, where the array index corresponds to the User Priority (0 – 7) and the value indicates whether or not the corresponding priority should transmit priority pause.

Format: array of uint32

priority-flow-control-flags

Specifies the NMSettingDcbFlags for DCB Priority Flow Control (PFC). Flags may be any combination of NM_SETTING_DCB_FLAG_ENABLE (0x1), NM_SETTING_DCB_FLAG_ADVERTISE (0x2), and NM_SETTING_DCB_FLAG_WILLING (0x4).

Format: NMSettingDcbFlags (uint32)

priority-group-bandwidth

An array of 8 uint values, where the array index corresponds to the Priority Group ID (0 – 7) and the value indicates the percentage of link bandwidth allocated to that group. Allowed values are 0 – 100, and the sum of all values must total 100 percents.

Format: array of uint32

priority-group-flags

Specifies the NMSettingDcbFlags for DCB Priority Groups. Flags may be any combination of NM_SETTING_DCB_FLAG_ENABLE (0x1), NM_SETTING_DCB_FLAG_ADVERTISE (0x2), and NM_SETTING_DCB_FLAG_WILLING (0x4).

Format: NMSettingDcbFlags (uint32)

priority-group-id

An array of 8 uint values, where the array index corresponds to the User Priority (0 – 7) and the value indicates the Priority Group ID. Allowed Priority Group ID values are 0 – 7 or 15 for the unrestricted group.

Format: array of uint32

priority-strict-bandwidth

An array of 8 boolean values, where the array index corresponds to the User Priority (0 – 7) and the value indicates whether or not the priority may use all of the bandwidth allocated to its assigned group.

Format: array of uint32

priority-traffic-class

An array of 8 uint values, where the array index corresponds to the User Priority (0 – 7) and the value indicates the traffic class (0 – 7) to which the priority is mapped.

Format: array of uint32

ethtool setting

Ethtool Ethernet Settings.

pause-autoneg

Whether to automatically negotiate on pause frame of flow control mechanism defined by IEEE 802.3x standard.

pause-rx

Whether RX pause should be enabled. Only valid when automatic negotiation is disabled

pause-tx

Whether TX pause should be enabled. Only valid when automatic negotiation is disabled

ring-rx**ring-rx-jumbo****ring-rx-mini****ring-tx****gsm setting**

GSM-based Mobile Broadband Settings.

Properties:

apn

Alias: apn

The GPRS Access Point Name specifying the APN used when establishing a data session with the GSM-based network. The APN often determines how the user will be billed for their network usage and whether the user has access to the Internet or just a provider-specific walled-garden, so it is important to use the correct APN for the user's mobile broadband plan. The APN may only be composed of the characters a-z, 0-9, ., and – per GSM 03.60 Section 14.9.

Format: string

auto-config

When TRUE, the settings such as APN, username, or password will default to values that match the network the modem will register to in the Mobile Broadband Provider database.

Format: boolean

device-id

The device unique identifier (as given by the WWAN management service) which this connection applies to. If given, the connection will only apply to the specified device.

Format: string

home-only

When TRUE, only connections to the home network will be allowed. Connections to roaming networks will not be made.

Format: boolean

mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple frames.

Format: uint32

network-id

The Network ID (GSM LAI format, ie MCC–MNC) to force specific network registration. If the Network ID is specified, NetworkManager will attempt to force the device to register only on the specified network. This can be used to ensure that the device does not roam when direct roaming control of the device is not otherwise possible.

Format: string

number

Legacy setting that used to help establishing PPP data sessions for GSM-based modems. Deprecated:
1

Format: string

password

Alias: password

The password used to authenticate with the network, if required. Many providers do not require a password, or accept any password. But if a password is required, it is specified here.

Format: string

password-flags

Flags indicating how to handle the "password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

pin

If the SIM is locked with a PIN it must be unlocked before any other operations are requested. Specify the PIN here to allow operation of the device.

Format: string

pin-flags

Flags indicating how to handle the "pin" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

sim-id

The SIM card unique identifier (as given by the WWAN management service) which this connection applies to. If given, the connection will apply to any device also allowed by "device-id" which contains a SIM card matching the given identifier.

Format: string

sim-operator-id

A MCC/MNC string like "310260" or "21601" identifying the specific mobile network operator which this connection applies to. If given, the connection will apply to any device also allowed by "device-id" and "sim-id" which contains a SIM card provisioned by the given operator.

Format: string

username

Alias: user

The username used to authenticate with the network, if required. Many providers do not require a username, or accept any username. But if a username is required, it is specified here.

Format: string

infiniband setting

Infiniband Settings.

Properties:

mac-address

Alias: mac

If specified, this connection will only apply to the IPoIB device whose permanent MAC address matches. This property does not change the MAC address of the device (i.e. MAC spoofing).

Format: byte array

mtu

Alias: mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple frames.

Format: uint32

p-key

Alias: p-key

The InfiniBand P_Key to use for this device. A value of -1 means to use the default P_Key (aka "the P_Key at index 0"). Otherwise, it is a 16-bit unsigned integer, whose high bit is set if it is a "full membership" P_Key.

Format: int32

parent

Alias: parent

The interface name of the parent device of this device. Normally NULL, but if the "p_key" property is set, then you must specify the base device by setting either this property or "mac-address".

Format: string

transport-mode

Alias: transport-mode

The IP-over-InfiniBand transport mode. Either "datagram" or "connected".

Format: string

ipv4 setting

IPv4 Settings.

Properties:

addresses

Alias: ip4

A list of IPv4 addresses and their prefix length. Multiple addresses can be separated by comma. For example "192.168.1.5/24, 10.1.0.5/24". The addresses are listed in decreasing priority, meaning the first address will be the primary address.

Format: a comma separated list of addresses

dad-timeout

Timeout in milliseconds used to check for the presence of duplicate IP addresses on the network. If an address conflict is detected, the activation will fail. A zero value means that no duplicate address detection is performed, -1 means the default value (either configuration ipvx.dad-timeout override or zero). A value greater than zero is a timeout in milliseconds. The property is currently implemented only for IPv4.

Format: int32

dhcp-client-id

A string sent to the DHCP server to identify the local machine which the DHCP server may use to customize the DHCP lease and options. When the property is a hex string ('aa:bb:cc') it is interpreted as a binary client ID, in which case the first byte is assumed to be the 'type' field as per RFC 2132 section 9.14 and the remaining bytes may be an hardware address (e.g. '01:xx:xx:xx:xx:xx' where 1 is the Ethernet ARP type and the rest is a MAC address). If the property is not a hex string it is considered as a non-hardware-address client ID and the 'type' field is set to 0. The special values "mac" and "perm-mac" are supported, which use the current or permanent MAC address of the device to generate a client identifier with type ethernet (01). Currently, these options only work for ethernet type of links. The special value "ipv6-duid" uses the DUID from "ipv6.dhcp-duid" property as an RFC4361-compliant client identifier. As IAID it uses "ipv4.dhcp-iaid" and falls back to "ipv6.dhcp-iaid" if unset. The special value "duid" generates a RFC4361-compliant client identifier based on "ipv4.dhcp-iaid" and uses a DUID generated by hashing /etc/machine-id. The special value "stable" is supported to generate a type 0 client identifier based on the stable-id (see connection.stable-id) and a per-host key. If you set the stable-id, you may want to include the "\${DEVICE}" or "\${MAC}" specifier to get a per-device key. If unset, a globally configured default is used. If still unset, the default depends on the DHCP plugin.

Format: string

dhcp-fqdn

If the "dhcp-send-hostname" property is TRUE, then the specified FQDN will be sent to the DHCP server when acquiring a lease. This property and "dhcp-hostname" are mutually exclusive and cannot be set at the same time.

Format: string

dhcp-hostname

If the "dhcp-send-hostname" property is TRUE, then the specified name will be sent to the DHCP server when acquiring a lease. This property and "dhcp-fqdn" are mutually exclusive and cannot be set at the same time.

Format: string

dhcp-hostname-flags

Flags for the DHCP hostname and FQDN. Currently, this property only includes flags to control the FQDN flags set in the DHCP FQDN option. Supported FQDN flags are NM_DHCP_HOSTNAME_FLAG_FQDN_SERV_UPDATE (0x1), NM_DHCP_HOSTNAME_FLAG_FQDN_ENCODED (0x2) and NM_DHCP_HOSTNAME_FLAG_FQDN_NO_UPDATE (0x4). When no FQDN flag is set and NM_DHCP_HOSTNAME_FLAG_FQDN_CLEAR_FLAGS (0x8) is set, the DHCP FQDN option will contain no flag. Otherwise, if no FQDN flag is set and NM_DHCP_HOSTNAME_FLAG_FQDN_CLEAR_FLAGS (0x8) is not set, the standard FQDN flags are set in the request: NM_DHCP_HOSTNAME_FLAG_FQDN_SERV_UPDATE (0x1), NM_DHCP_HOSTNAME_FLAG_FQDN_ENCODED (0x2) for IPv4 and NM_DHCP_HOSTNAME_FLAG_FQDN_SERV_UPDATE (0x1) for IPv6. When this property is set to the default value NM_DHCP_HOSTNAME_FLAG_NONE (0x0), a global default is looked up in NetworkManager configuration. If that value is unset or also NM_DHCP_HOSTNAME_FLAG_NONE (0x0), then the standard FQDN flags described above are sent in the DHCP requests.

Format: uint32

dhcp-iaid

A string containing the "Identity Association Identifier" (IAID) used by the DHCP client. The property is a 32-bit decimal value or a special value among "mac", "perm-mac", "ifname" and "stable". When set to "mac" (or "perm-mac"), the last 4 bytes of the current (or permanent) MAC address are used as IAIID. When set to "ifname", the IAIID is computed by hashing the interface name. The special value "stable" can be used to generate an IAIID based on the stable-id (see connection.stable-id), a per-host key and the interface name. When the property is unset, the value from global configuration is used; if no global default is set then the IAIID is assumed to be "ifname". Note that at the moment this property is ignored for IPv6 by dhclient, which always derives the IAIID from the MAC address.

Format: string

dhcp-reject-servers

Array of servers from which DHCP offers must be rejected. This property is useful to avoid getting a lease from misconfigured or rogue servers. For DHCPv4, each element must be an IPv4 address, optionally followed by a slash and a prefix length (e.g. "192.168.122.0/24"). This property is currently not implemented for DHCPv6.

Format: array of string

dhcp-send-hostname

If TRUE, a hostname is sent to the DHCP server when acquiring a lease. Some DHCP servers use this hostname to update DNS databases, essentially providing a static hostname for the computer. If the "dhcp-hostname" property is NULL and this property is TRUE, the current persistent hostname of the computer is sent.

Format: boolean

dhcp-timeout

A timeout for a DHCP transaction in seconds. If zero (the default), a globally configured default is used. If still unspecified, a device specific timeout is used (usually 45 seconds). Set to 2147483647

(MAXINT32) for infinity.

Format: int32

dhcp-vendor-class-identifier

The Vendor Class Identifier DHCP option (60). Special characters in the data string may be escaped using C-style escapes, nevertheless this property cannot contain nul bytes. If the per-profile value is unspecified (the default), a global connection default gets consulted. If still unspecified, the DHCP option is not sent to the server. Since 1.28

Format: string

dns

Array of IP addresses of DNS servers.

Format: array of uint32

dns-options

Array of DNS options as described in man 5 resolv.conf. NULL means that the options are unset and left at the default. In this case NetworkManager will use default options. This is distinct from an empty list of properties. The currently supported options are "attempts", "debug", "edns0", "inet6", "ip6-bytestring", "ip6-dotint", "ndots", "no-check-names", "no-ip6-dotint", "no-reload", "no-tld-query", "rotate", "single-request", "single-request-reopen", "timeout", "trust-ad", "use-vc". The "trust-ad" setting is only honored if the profile contributes name servers to resolv.conf, and if all contributing profiles have "trust-ad" enabled. When using a caching DNS plugin (dnsmasq or systemd-resolved in NetworkManager.conf) then "edns0" and "trust-ad" are automatically added.

Format: array of string

dns-priority

DNS servers priority. The relative priority for DNS servers specified by this setting. A lower numerical value is better (higher priority). Negative values have the special effect of excluding other configurations with a greater numerical priority value; so in presence of at least one negative priority, only DNS servers from connections with the lowest priority value will be used. To avoid all DNS leaks, set the priority of the profile that should be used to the most negative value of all active connections profiles. Zero selects a globally configured default value. If the latter is missing or zero too, it defaults to 50 for VPNs (including WireGuard) and 100 for other connections. Note that the priority is to order DNS settings for multiple active connections. It does not disambiguate multiple DNS servers within the same connection profile. When multiple devices have configurations with the same priority, VPNs will be considered first, then devices with the best (lowest metric) default route and then all other devices. When using dns=default, servers with higher priority will be on top of resolv.conf. To prioritize a given server over another one within the same connection, just specify them in the desired order. Note that commonly the resolver tries name servers in /etc/resolv.conf in the order listed, proceeding with the next server in the list on failure. See for example the "rotate" option of the dns-options setting. If there are any negative DNS priorities, then only name servers from the devices with that lowest priority will be considered. When using a DNS resolver that supports Conditional Forwarding or Split DNS (with dns=dnsmasq or dns=systemd-resolved settings), each connection is used to query domains in its search list. The search domains determine which name servers to ask, and the DNS priority is used to prioritize name servers based on the domain. Queries for domains not present in any search list are routed through connections having the `.' special wildcard domain, which is added automatically to connections with the default route (or can be added manually). When multiple connections specify the same domain, the one with the best priority (lowest numerical value) wins. If a sub domain is configured on another interface it will be accepted regardless the priority, unless parent domain on the other interface has a negative priority, which causes the sub domain to be shadowed. With Split DNS one can avoid undesired DNS leaks by properly configuring DNS priorities and the search domains, so that only name servers of the desired interface are configured.

Format: int32

dns-search

Array of DNS search domains. Domains starting with a tilde ('~') are considered 'routing' domains and are used only to decide the interface over which a query must be forwarded; they are not used to complete unqualified host names. When using a DNS plugin that supports Conditional Forwarding or Split DNS, then the search domains specify which name servers to query. This makes the behavior different from running with plain /etc/resolv.conf. For more information see also the dns-priority setting.

Format: array of string

gateway

Alias: gw4

The gateway associated with this configuration. This is only meaningful if "addresses" is also set. The gateway's main purpose is to control the next hop of the standard default route on the device. Hence, the gateway property conflicts with "never-default" and will be automatically dropped if the IP configuration is set to never-default. As an alternative to set the gateway, configure a static default route with /0 as prefix length.

Format: string

ignore-auto-dns

When "method" is set to "auto" and this property to TRUE, automatically configured name servers and search domains are ignored and only name servers and search domains specified in the "dns" and "dns-search" properties, if any, are used.

Format: boolean

ignore-auto-routes

When "method" is set to "auto" and this property to TRUE, automatically configured routes are ignored and only routes specified in the "routes" property, if any, are used.

Format: boolean

may-fail

If TRUE, allow overall network configuration to proceed even if the configuration specified by this property times out. Note that at least one IP configuration must succeed or overall network configuration will still fail. For example, in IPv6-only networks, setting this property to TRUE on the NMSettingIP4Config allows the overall network configuration to succeed if IPv4 configuration fails but IPv6 configuration completes successfully.

Format: boolean

method

IP configuration method. NMSettingIP4Config and NMSettingIP6Config both support "disabled", "auto", "manual", and "link-local". See the subclass-specific documentation for other values. In general, for the "auto" method, properties such as "dns" and "routes" specify information that is added on to the information returned from automatic configuration. The "ignore-auto-routes" and "ignore-auto-dns" properties modify this behavior. For methods that imply no upstream network, such as "shared" or "link-local", these properties must be empty. For IPv4 method "shared", the IP subnet can be configured by adding one manual IPv4 address or otherwise 10.42.x.0/24 is chosen. Note that the shared method must be configured on the interface which shares the internet to a subnet, not on the uplink which is shared.

Format: string

never-default

If TRUE, this connection will never be the default connection for this IP type, meaning it will never be assigned the default route by NetworkManager.

Format: boolean

required-timeout

The minimum time interval in milliseconds for which dynamic IP configuration should be tried before the connection succeeds. This property is useful for example if both IPv4 and IPv6 are enabled and are allowed to fail. Normally the connection succeeds as soon as one of the two address families completes; by setting a required timeout for e.g. IPv4, one can ensure that even if IP6 succeeds earlier than IPv4, NetworkManager waits some time for IPv4 before the connection becomes active. Note that if "may-fail" is FALSE for the same address family, this property has no effect as NetworkManager needs to wait for the full DHCP timeout. A zero value means that no required timeout is present, -1 means the default value (either configuration `ipvx.required-timeout` override or zero).

Format: int32

route-metric

The default metric for routes that don't explicitly specify a metric. The default value -1 means that the metric is chosen automatically based on the device type. The metric applies to dynamic routes, manual (static) routes that don't have an explicit metric setting, address prefix routes, and the default route. Note that for IPv6, the kernel accepts zero (0) but coerces it to 1024 (user default). Hence, setting this property to zero effectively mean setting it to 1024. For IPv4, zero is a regular value for the metric.

Format: int64

route-table

Enable policy routing (source routing) and set the routing table used when adding routes. This affects all routes, including device-routes, IPv4LL, DHCP, SLAAC, default-routes and static routes. But note that static routes can individually overwrite the setting by explicitly specifying a non-zero routing table. If the table setting is left at zero, it is eligible to be overwritten via global configuration. If the property is zero even after applying the global configuration value, policy routing is disabled for the address family of this connection. Policy routing disabled means that NetworkManager will add all routes to the main table (except static routes that explicitly configure a different table). Additionally, NetworkManager will not delete any extraneous routes from tables except the main table. This is to preserve backward compatibility for users who manage routing tables outside of NetworkManager.

Format: uint32

routes

A list of IPv4 destination addresses, prefix length, optional IPv4 next hop addresses, optional route metric, optional attribute. The valid syntax is: "ip[/prefix] [next-hop] [metric] [attribute=val]...[,ip[/prefix]...]". For example "192.0.2.0/24 10.1.1.1 77, 198.51.100.0/24".

Various attributes are supported:

- "cwnd" – an unsigned 32 bit integer.
- "initcwnd" – an unsigned 32 bit integer.
- "inirwnd" – an unsigned 32 bit integer.
- "lock-cwnd" – a boolean value.
- "lock-initcwnd" – a boolean value.
- "lock-inirwnd" – a boolean value.
- "lock-mtu" – a boolean value.
- "lock-window" – a boolean value.

- "mtu" – an unsigned 32 bit integer.
- "onlink" – a boolean value.
- "scope" – an unsigned 8 bit integer. IPv4 only.
- "src" – an IPv4 address.
- "table" – an unsigned 32 bit integer. The default depends on ipv4.route-table.
- "tos" – an unsigned 8 bit integer. IPv4 only.
- "type" – one of unicast, local, blackhole, unavailable, prohibit. The default is unicast.
- "window" – an unsigned 32 bit integer.

For details see also ‘man ip–route‘.

Format: a comma separated list of routes

routing–rules

A comma separated list of routing rules for policy routing. The format is based on **ip rule add** syntax and mostly compatible. One difference is that routing rules in NetworkManager always need a fixed priority.

Example: priority 5 from 192.167.4.0/24 table 45

Format: a comma separated list of routing rules

ipv6 setting

IPv6 Settings.

Properties:

addr–gen–mode

Configure method for creating the address for use with RFC4862 IPv6 Stateless Address

Autoconfiguration. The permitted values are:

NM_SETTING_IP6_CONFIG_ADDR_GEN_MODE_EUI64 (0) or

NM_SETTING_IP6_CONFIG_ADDR_GEN_MODE_STABLE_PRIVACY (1). If the property is set to EUI64, the addresses will be generated using the interface tokens derived from hardware address.

This makes the host part of the address to stay constant, making it possible to track host's presence when it changes networks. The address changes when the interface hardware is replaced. The value of stable–privacy enables use of cryptographically secure hash of a secret host–specific key along with the connection's stable–id and the network address as specified by RFC7217. This makes it impossible to use the address track host's presence, and makes the address stable when the network interface hardware is replaced. On D-Bus, the absence of an addr–gen–mode setting equals enabling stable–privacy. For keyfile plugin, the absence of the setting on disk means EUI64 so that the property doesn't change on upgrade from older versions. Note that this setting is distinct from the Privacy Extensions as configured by "ip6–privacy" property and it does not affect the temporary addresses configured with this option.

Format: int32

addresses

Alias: ip6

A list of IPv6 addresses and their prefix length. Multiple addresses can be separated by comma. For example "2001:db8:85a3::8a2e:370:7334/64, 2001:db8:85a3::5/64". The addresses are listed in increasing priority, meaning the last address will be the primary address.

Format: a comma separated list of addresses

dhcp-duid

A string containing the DHCPv6 Unique Identifier (DUID) used by the dhcp client to identify itself to DHCPv6 servers (RFC 3315). The DUID is carried in the Client Identifier option. If the property is a hex string ('aa:bb:cc') it is interpreted as a binary DUID and filled as an opaque value in the Client Identifier option. The special value "lease" will retrieve the DUID previously used from the lease file belonging to the connection. If no DUID is found and "dhclient" is the configured dhcp client, the DUID is searched in the system-wide dhclient lease file. If still no DUID is found, or another dhcp client is used, a global and permanent DUID–UUID (RFC 6355) will be generated based on the machine–id. The special values "llt" and "ll" will generate a DUID of type LLT or LL (see RFC 3315) based on the current MAC address of the device. In order to try providing a stable DUID–LLT, the time field will contain a constant timestamp that is used globally (for all profiles) and persisted to disk. The special values "stable–llt", "stable–ll" and "stable–uuid" will generate a DUID of the corresponding type, derived from the connection's stable–id and a per–host unique key. You may want to include the "\${DEVICE}" or "\${MAC}" specifier in the stable–id, in case this profile gets activated on multiple devices. So, the link–layer address of "stable–ll" and "stable–llt" will be a generated address derived from the stable id. The DUID–LLT time value in the "stable–llt" option will be picked among a static timespan of three years (the upper bound of the interval is the same constant timestamp used in "llt"). When the property is unset, the global value provided for "ipv6.dhcp–duid" is used. If no global value is provided, the default "lease" value is assumed.

Format: string

dhcp–hostname

If the "dhcp–send–hostname" property is TRUE, then the specified name will be sent to the DHCP server when acquiring a lease. This property and "dhcp–fqdn" are mutually exclusive and cannot be set at the same time.

Format: string

dhcp–hostname–flags

Flags for the DHCP hostname and FQDN. Currently, this property only includes flags to control the FQDN flags set in the DHCP FQDN option. Supported FQDN flags are NM_DHCP_HOSTNAME_FLAG_FQDN_SERV_UPDATE (0x1), NM_DHCP_HOSTNAME_FLAG_FQDN_ENCODED (0x2) and NM_DHCP_HOSTNAME_FLAG_FQDN_NO_UPDATE (0x4). When no FQDN flag is set and NM_DHCP_HOSTNAME_FLAG_FQDN_CLEAR_FLAGS (0x8) is set, the DHCP FQDN option will contain no flag. Otherwise, if no FQDN flag is set and NM_DHCP_HOSTNAME_FLAG_FQDN_CLEAR_FLAGS (0x8) is not set, the standard FQDN flags are set in the request: NM_DHCP_HOSTNAME_FLAG_FQDN_SERV_UPDATE (0x1), NM_DHCP_HOSTNAME_FLAG_FQDN_ENCODED (0x2) for IPv4 and NM_DHCP_HOSTNAME_FLAG_FQDN_SERV_UPDATE (0x1) for IPv6. When this property is set to the default value NM_DHCP_HOSTNAME_FLAG_NONE (0x0), a global default is looked up in NetworkManager configuration. If that value is unset or also NM_DHCP_HOSTNAME_FLAG_NONE (0x0), then the standard FQDN flags described above are sent in the DHCP requests.

Format: uint32

dhcp–iaid

A string containing the "Identity Association Identifier" (IAID) used by the DHCP client. The property is a 32-bit decimal value or a special value among "mac", "perm–mac", "ifname" and "stable". When set to "mac" (or "perm–mac"), the last 4 bytes of the current (or permanent) MAC address are used as IAIID. When set to "ifname", the IAIID is computed by hashing the interface name. The special value "stable" can be used to generate an IAIID based on the stable–id (see connection.stable–id), a per–host key and the interface name. When the property is unset, the value from global configuration is used; if no global default is set then the IAIID is assumed to be "ifname". Note that at the moment this property

is ignored for IPv6 by dhclient, which always derives the IAID from the MAC address.

Format: string

dhcp-send-hostname

If TRUE, a hostname is sent to the DHCP server when acquiring a lease. Some DHCP servers use this hostname to update DNS databases, essentially providing a static hostname for the computer. If the "dhcp-hostname" property is NULL and this property is TRUE, the current persistent hostname of the computer is sent.

Format: boolean

dhcp-timeout

A timeout for a DHCP transaction in seconds. If zero (the default), a globally configured default is used. If still unspecified, a device specific timeout is used (usually 45 seconds). Set to 2147483647 (MAXINT32) for infinity.

Format: int32

dns

Array of IP addresses of DNS servers.

Format: array of byte array

dns-options

Array of DNS options as described in man 5 resolv.conf. NULL means that the options are unset and left at the default. In this case NetworkManager will use default options. This is distinct from an empty list of properties. The currently supported options are "attempts", "debug", "edns0", "inet6", "ip6-bytes", "ip6-dotint", "ndots", "no-check-names", "no-ip6-dotint", "no-reload", "no-tld-query", "rotate", "single-request", "single-request-reopen", "timeout", "trust-ad", "use-vc". The "trust-ad" setting is only honored if the profile contributes name servers to resolv.conf, and if all contributing profiles have "trust-ad" enabled. When using a caching DNS plugin (dnsmasq or systemd-resolved in NetworkManager.conf) then "edns0" and "trust-ad" are automatically added.

Format: array of string

dns-priority

DNS servers priority. The relative priority for DNS servers specified by this setting. A lower numerical value is better (higher priority). Negative values have the special effect of excluding other configurations with a greater numerical priority value; so in presence of at least one negative priority, only DNS servers from connections with the lowest priority value will be used. To avoid all DNS leaks, set the priority of the profile that should be used to the most negative value of all active connections profiles. Zero selects a globally configured default value. If the latter is missing or zero too, it defaults to 50 for VPNs (including WireGuard) and 100 for other connections. Note that the priority is to order DNS settings for multiple active connections. It does not disambiguate multiple DNS servers within the same connection profile. When multiple devices have configurations with the same priority, VPNs will be considered first, then devices with the best (lowest metric) default route and then all other devices. When using dns=default, servers with higher priority will be on top of resolv.conf. To prioritize a given server over another one within the same connection, just specify them in the desired order. Note that commonly the resolver tries name servers in /etc/resolv.conf in the order listed, proceeding with the next server in the list on failure. See for example the "rotate" option of the dns-options setting. If there are any negative DNS priorities, then only name servers from the devices with that lowest priority will be considered. When using a DNS resolver that supports Conditional Forwarding or Split DNS (with dns=dnsmasq or dns=systemd-resolved settings), each connection is used to query domains in its search list. The search domains determine which name servers to ask, and the DNS priority is used to prioritize name servers based on the domain. Queries for domains not present in any search list are routed through connections having the '^' special

wildcard domain, which is added automatically to connections with the default route (or can be added manually). When multiple connections specify the same domain, the one with the best priority (lowest numerical value) wins. If a sub domain is configured on another interface it will be accepted regardless the priority, unless parent domain on the other interface has a negative priority, which causes the sub domain to be shadowed. With Split DNS one can avoid undesired DNS leaks by properly configuring DNS priorities and the search domains, so that only name servers of the desired interface are configured.

Format: int32

dns-search

Array of DNS search domains. Domains starting with a tilde ('~') are considered 'routing' domains and are used only to decide the interface over which a query must be forwarded; they are not used to complete unqualified host names. When using a DNS plugin that supports Conditional Forwarding or Split DNS, then the search domains specify which name servers to query. This makes the behavior different from running with plain /etc/resolv.conf. For more information see also the dns-priority setting.

Format: array of string

gateway

Alias: gw6

The gateway associated with this configuration. This is only meaningful if "addresses" is also set. The gateway's main purpose is to control the next hop of the standard default route on the device. Hence, the gateway property conflicts with "never-default" and will be automatically dropped if the IP configuration is set to never-default. As an alternative to set the gateway, configure a static default route with /0 as prefix length.

Format: string

ignore-auto-dns

When "method" is set to "auto" and this property to TRUE, automatically configured name servers and search domains are ignored and only name servers and search domains specified in the "dns" and "dns-search" properties, if any, are used.

Format: boolean

ignore-auto-routes

When "method" is set to "auto" and this property to TRUE, automatically configured routes are ignored and only routes specified in the "routes" property, if any, are used.

Format: boolean

ip6-privacy

Configure IPv6 Privacy Extensions for SLAAC, described in RFC4941. If enabled, it makes the kernel generate a temporary IPv6 address in addition to the public one generated from MAC address via modified EUI-64. This enhances privacy, but could cause problems in some applications, on the other hand. The permitted values are: -1: unknown, 0: disabled, 1: enabled (prefer public address), 2: enabled (prefer temporary addresses). Having a per-connection setting set to "-1" (unknown) means fallback to global configuration "ipv6.ip6-privacy". If also global configuration is unspecified or set to "-1", fallback to read "/proc/sys/net/ipv6/conf/default/use_tempaddr". Note that this setting is distinct from the Stable Privacy addresses that can be enabled with the "addr-gen-mode" property's "stable-privacy" setting as another way of avoiding host tracking with IPv6 addresses.

Format: NMSettingIP6ConfigPrivacy (int32)

may-fail

If TRUE, allow overall network configuration to proceed even if the configuration specified by this property times out. Note that at least one IP configuration must succeed or overall network configuration will still fail. For example, in IPv6-only networks, setting this property to TRUE on the NMSettingIP4Config allows the overall network configuration to succeed if IPv4 configuration fails but IPv6 configuration completes successfully.

Format: boolean

method

IP configuration method. NMSettingIP4Config and NMSettingIP6Config both support "disabled", "auto", "manual", and "link-local". See the subclass-specific documentation for other values. In general, for the "auto" method, properties such as "dns" and "routes" specify information that is added on to the information returned from automatic configuration. The "ignore-auto-routes" and "ignore-auto-dns" properties modify this behavior. For methods that imply no upstream network, such as "shared" or "link-local", these properties must be empty. For IPv4 method "shared", the IP subnet can be configured by adding one manual IPv4 address or otherwise 10.42.x.0/24 is chosen. Note that the shared method must be configured on the interface which shares the internet to a subnet, not on the uplink which is shared.

Format: string

never-default

If TRUE, this connection will never be the default connection for this IP type, meaning it will never be assigned the default route by NetworkManager.

Format: boolean

ra-timeout

A timeout for waiting Router Advertisements in seconds. If zero (the default), a globally configured default is used. If still unspecified, the timeout depends on the sysctl settings of the device. Set to 2147483647 (MAXINT32) for infinity.

Format: int32

required-timeout

The minimum time interval in milliseconds for which dynamic IP configuration should be tried before the connection succeeds. This property is useful for example if both IPv4 and IPv6 are enabled and are allowed to fail. Normally the connection succeeds as soon as one of the two address families completes; by setting a required timeout for e.g. IPv4, one can ensure that even if IP6 succeeds earlier than IPv4, NetworkManager waits some time for IPv4 before the connection becomes active. Note that if "may-fail" is FALSE for the same address family, this property has no effect as NetworkManager needs to wait for the full DHCP timeout. A zero value means that no required timeout is present, -1 means the default value (either configuration ipvx.required-timeout override or zero).

Format: int32

route-metric

The default metric for routes that don't explicitly specify a metric. The default value -1 means that the metric is chosen automatically based on the device type. The metric applies to dynamic routes, manual (static) routes that don't have an explicit metric setting, address prefix routes, and the default route. Note that for IPv6, the kernel accepts zero (0) but coerces it to 1024 (user default). Hence, setting this property to zero effectively mean setting it to 1024. For IPv4, zero is a regular value for the metric.

Format: int64

route-table

Enable policy routing (source routing) and set the routing table used when adding routes. This affects all routes, including device-routes, IPv4LL, DHCP, SLAAC, default-routes and static routes. But note

that static routes can individually overwrite the setting by explicitly specifying a non-zero routing table. If the table setting is left at zero, it is eligible to be overwritten via global configuration. If the property is zero even after applying the global configuration value, policy routing is disabled for the address family of this connection. Policy routing disabled means that NetworkManager will add all routes to the main table (except static routes that explicitly configure a different table). Additionally, NetworkManager will not delete any extraneous routes from tables except the main table. This is to preserve backward compatibility for users who manage routing tables outside of NetworkManager.

Format: uint32

routes

A list of IPv6 destination addresses, prefix length, optional IPv6 next hop addresses, optional route metric, optional attribute. The valid syntax is: "ip[/prefix] [next-hop] [metric] [attribute=val]...[,ip[/prefix]...]".

Various attributes are supported:

- "cwnd" – an unsigned 32 bit integer.
- "from" – an IPv6 address with optional prefix. IPv6 only.
- "initcwnd" – an unsigned 32 bit integer.
- "initrwnd" – an unsigned 32 bit integer.
- "lock-cwnd" – a boolean value.
- "lock-initcwnd" – a boolean value.
- "lock-initrwnd" – a boolean value.
- "lock-mtu" – a boolean value.
- "lock-window" – a boolean value.
- "mtu" – an unsigned 32 bit integer.
- "onlink" – a boolean value.
- "src" – an IPv6 address.
- "table" – an unsigned 32 bit integer. The default depends on ipv6.route-table.
- "type" – one of unicast, local, blackhole, unavailable, prohibit. The default is unicast.
- "window" – an unsigned 32 bit integer.

For details see also ‘man ip-route’.

Format: a comma separated list of routes

routing-rules

A comma separated list of routing rules for policy routing. The format is based on **ip rule add** syntax and mostly compatible. One difference is that routing rules in NetworkManager always need a fixed priority.

Example: priority 5 from 1:2:3::5/128 table 45

Format: a comma separated list of routing rules

token

Configure the token for draft-chown-6man-tokenised-ipv6-identifiers-02 IPv6 tokenized interface identifiers. Useful with eui64 addr-gen-mode.

Format: string

ip-tunnel setting

IP Tunneling Settings.

Properties:

encapsulation-limit

How many additional levels of encapsulation are permitted to be prepended to packets. This property applies only to IPv6 tunnels.

Format: uint32

flags

Tunnel flags. Currently, the following values are supported:

NM_IP_TUNNEL_FLAG_IP6_IGN_ENCAP_LIMIT (0x1),

NM_IP_TUNNEL_FLAG_IP6_USE_ORIG_TCLASS (0x2),

NM_IP_TUNNEL_FLAG_IP6_USE_ORIG_FLOWLABEL (0x4),

NM_IP_TUNNEL_FLAG_IP6_MIP6_DEV (0x8),

NM_IP_TUNNEL_FLAG_IP6_RCV_DSCP_COPY (0x10),

NM_IP_TUNNEL_FLAG_IP6_USE_ORIG_FWMARK (0x20). They are valid only for IPv6 tunnels.

Format: uint32

flow-label

The flow label to assign to tunnel packets. This property applies only to IPv6 tunnels.

Format: uint32

input-key

The key used for tunnel input packets; the property is valid only for certain tunnel modes (GRE, IP6GRE). If empty, no key is used.

Format: string

local

Alias: local

The local endpoint of the tunnel; the value can be empty, otherwise it must contain an IPv4 or IPv6 address.

Format: string

mode

Alias: mode

The tunneling mode, for example NM_IP_TUNNEL_MODE_IPIP (1) or NM_IP_TUNNEL_MODE_GRE (2).

Format: uint32

mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple fragments.

Format: uint32

output-key

The key used for tunnel output packets; the property is valid only for certain tunnel modes (GRE, IP6GRE). If empty, no key is used.

Format: string

parent

Alias: dev

If given, specifies the parent interface name or parent connection UUID the new device will be bound to so that tunneled packets will only be routed via that interface.

Format: string

path-mtu-discovery

Whether to enable Path MTU Discovery on this tunnel.

Format: boolean

remote

Alias: remote

The remote endpoint of the tunnel; the value must contain an IPv4 or IPv6 address.

Format: string

tos

The type of service (IPv4) or traffic class (IPv6) field to be set on tunneled packets.

Format: uint32

ttl

The TTL to assign to tunneled packets. 0 is a special value meaning that packets inherit the TTL value.

Format: uint32

macsec setting

MACSec Settings.

Properties:

encrypt

Alias: encrypt

Whether the transmitted traffic must be encrypted.

Format: boolean

mka-cak

Alias: cak

The pre-shared CAK (Connectivity Association Key) for MACsec Key Agreement.

Format: string

mka-cak-flags

Flags indicating how to handle the "mka-cak" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

mka-ckn

Alias: ckn

The pre-shared CKN (Connectivity-association Key Name) for MACsec Key Agreement.

Format: string

mode

Alias: mode

Specifies how the CAK (Connectivity Association Key) for MKA (MACsec Key Agreement) is obtained.

Format: int32

parent

Alias: dev

If given, specifies the parent interface name or parent connection UUID from which this MACSEC interface should be created. If this property is not specified, the connection must contain an "802-3-ethernet" setting with a "mac-address" property.

Format: string

port

Alias: port

The port component of the SCI (Secure Channel Identifier), between 1 and 65534.

Format: int32

send-sci

Specifies whether the SCI (Secure Channel Identifier) is included in every packet.

Format: boolean

validation

Specifies the validation mode for incoming frames.

Format: int32

macvlan setting

MAC VLAN Settings.

Properties:

mode

Alias: mode

The macvlan mode, which specifies the communication mechanism between multiple macvlans on the same lower device.

Format: uint32

parent

Alias: dev

If given, specifies the parent interface name or parent connection UUID from which this MAC-VLAN interface should be created. If this property is not specified, the connection must contain an "802-3-ethernet" setting with a "mac-address" property.

Format: string

promiscuous

Whether the interface should be put in promiscuous mode.

Format: boolean

tap

Alias: tap

Whether the interface should be a MACVTAP.

Format: boolean

match setting

Match settings.

Properties:

driver

A list of driver names to match. Each element is a shell wildcard pattern. See NMSettingMatch:interface-name for how special characters '|', '&', '!' and '\' are used for optional and mandatory matches and inverting the pattern.

Format: array of string

interface-name

A list of interface names to match. Each element is a shell wildcard pattern. An element can be prefixed with a pipe symbol (|) or an ampersand (&). The former means that the element is optional and the latter means that it is mandatory. If there are any optional elements, than the match evaluates to true if at least one of the optional element matches (logical OR). If there are any mandatory elements, then they all must match (logical AND). By default, an element is optional. This means that an element "foo" behaves the same as "|foo". An element can also be inverted with exclamation mark (!) between the pipe symbol (or the ampersand) and before the pattern. Note that "!foo" is a shortcut for the mandatory match "&!foo". Finally, a backslash can be used at the beginning of the element (after the optional special characters) to escape the start of the pattern. For example, "&\!a" is an mandatory match for literally "\a".

Format: array of string

kernel-command-line

A list of kernel command line arguments to match. This may be used to check whether a specific kernel command line option is set (or unset, if prefixed with the exclamation mark). The argument must either be a single word, or an assignment (i.e. two words, joined by "="). In the former case the kernel command line is searched for the word appearing as is, or as left hand side of an assignment. In the latter case, the exact assignment is looked for with right and left hand side matching. Wildcard patterns are not supported. See NMSettingMatch:interface-name for how special characters '|', '&', '!' and '\' are used for optional and mandatory matches and inverting the match.

Format: array of string

path

A list of paths to match against the ID_PATH udev property of devices. ID_PATH represents the topological persistent path of a device. It typically contains a subsystem string (pci, usb, platform, etc.) and a subsystem-specific identifier. For PCI devices the path has the form "pci-\$domain:\$bus:\$device.\$function", where each variable is an hexadecimal value; for example "pci-0000:0a:00.0". The path of a device can be obtained with "udevadm info /sys/class/net/\$dev | grep ID_PATH=" or by looking at the "path" property exported by NetworkManager ("nmcli -f general.path device show \$dev"). Each element of the list is a shell wildcard pattern. See NMSettingMatch:interface-name for how special characters '|', '&', '!' and '\' are used for optional and mandatory matches and inverting the pattern.

Format: array of string

802-11-olpc-mesh setting

Alias: olpc-mesh

OLPC Wireless Mesh Settings.

Properties:

channel

Alias: channel

Channel on which the mesh network to join is located.

Format: uint32

dhcp-anycast-address

Alias: dhcp-anycast

Anycast DHCP MAC address used when requesting an IP address via DHCP. The specific anycast address used determines which DHCP server class answers the request. This is currently only implemented by dhclient DHCP plugin.

Format: byte array

ssid

Alias: ssid

SSID of the mesh network to join.

Format: byte array

ovs-bridge setting

OvsBridge Link Settings.

Properties:

datapath-type

The data path type. One of "system", "netdev" or empty.

Format: string

fail-mode

The bridge failure mode. One of "secure", "standalone" or empty.

Format: string

mcast-snooping-enable

Enable or disable multicast snooping.

Format: boolean

rstp-enable

Enable or disable RSTP.

Format: boolean

stp-enable

Enable or disable STP.

Format: boolean

ovs-dpdk setting

OvsDpdk Link Settings.

Properties:

devargs

Open vSwitch DPDK device arguments.

Format: string

n-rxq

Open vSwitch DPDK number of rx queues. Defaults to zero which means to leave the parameter in OVS unspecified and effectively configures one queue.

Format: uint32

ovs-interface setting

Open vSwitch Interface Settings.

Properties:

type

The interface type. Either "internal", "system", "patch", "dpdk", or empty.

Format: string

ovs-patch setting

OvsPatch Link Settings.

Properties:

peer

Specifies the name of the interface for the other side of the patch. The patch on the other side must also set this interface as peer.

Format: string

ovs-port setting

OvsPort Link Settings.

Properties:

bond-downdelay

The time port must be inactive in order to be considered down.

Format: uint32

bond-mode

Bonding mode. One of "active-backup", "balance-slb", or "balance-tcp".

Format: string

bond-updelay

The time port must be active before it starts forwarding traffic.

Format: uint32

lacp

LACP mode. One of "active", "off", or "passive".

Format: string

tag

The VLAN tag in the range 0–4095.

Format: uint32

vlan-mode

The VLAN mode. One of "access", "native-tagged", "native-untagged", "trunk" or unset.

Format: string

ppp setting

Point-to-Point Protocol Settings.

Properties:

baud

If non-zero, instruct pppd to set the serial port to the specified baudrate. This value should normally be left as 0 to automatically choose the speed.

Format: uint32

crtsets

If TRUE, specify that pppd should set the serial port to use hardware flow control with RTS and CTS signals. This value should normally be set to FALSE.

Format: boolean

lcp-echo-failure

If non-zero, instruct pppd to presume the connection to the peer has failed if the specified number of LCP echo-requests go unanswered by the peer. The "lcp-echo-interval" property must also be set to a non-zero value if this property is used.

Format: uint32

lcp-echo-interval

If non-zero, instruct pppd to send an LCP echo-request frame to the peer every n seconds (where n is the specified value). Note that some PPP peers will respond to echo requests and some will not, and it is not possible to autodetect this.

Format: uint32

mppe-stateful

If TRUE, stateful MPPE is used. See pppd documentation for more information on stateful MPPE.

Format: boolean

mru

If non-zero, instruct pppd to request that the peer send packets no larger than the specified size. If non-zero, the MRU should be between 128 and 16384.

Format: uint32

mtu

If non-zero, instruct pppd to send packets no larger than the specified size.

Format: uint32

no-vj-comp

If TRUE, Van Jacobson TCP header compression will not be requested.

Format: boolean

noauth

If TRUE, do not require the other side (usually the PPP server) to authenticate itself to the client. If FALSE, require authentication from the remote side. In almost all cases, this should be TRUE.

Format: boolean

nobsdcomp

If TRUE, BSD compression will not be requested.

Format: boolean

nodeflate

If TRUE, "deflate" compression will not be requested.

Format: boolean

refuse-chap

If TRUE, the CHAP authentication method will not be used.

Format: boolean

refuse-eap

If TRUE, the EAP authentication method will not be used.

Format: boolean

refuse-mschap

If TRUE, the MSCHAP authentication method will not be used.

Format: boolean

refuse-mschapv2

If TRUE, the MSCHAPv2 authentication method will not be used.

Format: boolean

refuse-pap

If TRUE, the PAP authentication method will not be used.

Format: boolean

require-mppe

If TRUE, MPPE (Microsoft Point-to-Point Encryption) will be required for the PPP session. If either 64-bit or 128-bit MPPE is not available the session will fail. Note that MPPE is not used on mobile broadband connections.

Format: boolean

require-mppe-128

If TRUE, 128-bit MPPE (Microsoft Point-to-Point Encryption) will be required for the PPP session, and the "require-mppe" property must also be set to TRUE. If 128-bit MPPE is not available the session will fail.

Format: boolean

pppoe setting

PPP-over-Ethernet Settings.

Properties:

parent

Alias: parent

If given, specifies the parent interface name on which this PPPoE connection should be created. If this property is not specified, the connection is activated on the interface specified in "interface-name" of NMSettingConnection.

Format: string

password

Alias: password

Password used to authenticate with the PPPoE service.

Format: string

password-flags

Flags indicating how to handle the "password" property. See the section called "Secret flag types:" for flag values.

Format: NMSettingSecretFlags (uint32)

service

Alias: service

If specified, instruct PPPoE to only initiate sessions with access concentrators that provide the specified service. For most providers, this should be left blank. It is only required if there are multiple access concentrators or a specific service is known to be required.

Format: string

username

Alias: username

Username used to authenticate with the PPPoE service.

Format: string

proxy setting

WWW Proxy Settings.

Properties:

browser-only

Alias: browser-only

Whether the proxy configuration is for browser only.

Format: boolean

method

Alias: method

Method for proxy configuration, Default is NM_SETTING_PROXY_METHOD_NONE (0)

Format: int32

pac-script

Alias: pac-script

PAC script for the connection.

Format: string

pac-url

Alias: pac-url

PAC URL for obtaining PAC file.

Format: string

serial setting

Serial Link Settings.

Properties:

baud

Speed to use for communication over the serial port. Note that this value usually has no effect for mobile broadband modems as they generally ignore speed settings and use the highest available speed.

Format: uint32

bits

Byte-width of the serial communication. The 8 in "8n1" for example.

Format: uint32

parity

Parity setting of the serial port.

Format: NMSettingSerialParity (byte)

send-delay

Time to delay between each byte sent to the modem, in microseconds.

Format: uint64

stopbits

Number of stop bits for communication on the serial port. Either 1 or 2. The 1 in "8n1" for example.

Format: uint32

sriov setting

SR-IOV settings.

Properties:

autoprobe-drivers

Whether to autoprobe virtual functions by a compatible driver. If set to NM_TERNARY_TRUE (1), the kernel will try to bind VFs to a compatible driver and if this succeeds a new network interface will be instantiated for each VF. If set to NM_TERNARY_FALSE (0), VFs will not be claimed and no network interfaces will be created for them. When set to NM_TERNARY_DEFAULT (-1), the global default is used; in case the global default is unspecified it is assumed to be NM_TERNARY_TRUE (1).

Format: NMternary (int32)

total-vfs

The total number of virtual functions to create. Note that when the sriov setting is present NetworkManager enforces the number of virtual functions on the interface (also when it is zero) during activation and resets it upon deactivation. To prevent any changes to SR-IOV parameters don't add a sriov setting to the connection.

Format: uint32

vfs

Array of virtual function descriptors. Each VF descriptor is a dictionary mapping attribute names to GVariant values. The 'index' entry is mandatory for each VF. When represented as string a VF is in the form: "INDEX [ATTR=VALUE[ATTR=VALUE]...]". for example: "2 mac=00:11:22:33:44:55

`spoof-check=true".` Multiple VFs can be specified using a comma as separator. Currently, the following attributes are supported: mac, spoof-check, trust, min-tx-rate, max-tx-rate, vlans. The "vlans" attribute is represented as a semicolon-separated list of VLAN descriptors, where each descriptor has the form "ID[.PRIORITY[.PROTO]]". PROTO can be either 'q' for 802.1Q (the default) or 'ad' for 802.1ad.

Format: array of vardict

tc setting

Linux Traffic Control Settings.

Properties:

qdiscs

Array of TC queueing disciplines. qdisc is a basic block in the Linux traffic control subsystem

Each qdisc can be specified by the following attributes:

handle HANDLE

specifies the qdisc handle. A qdisc, which potentially can have children, gets assigned a major number, called a 'handle', leaving the minor number namespace available for classes. The handle is expressed as '10:'. It is customary to explicitly assign a handle to qdiscs expected to have children.

parent HANDLE

specifies the handle of the parent qdisc the current qdisc must be attached to.

root

specifies that the qdisc is attached to the root of device.

KIND

this is the qdisc kind. NetworkManager currently supports the following kinds: fq_codel, sfq, tbf. Each qdisc kind has a different set of parameters, described below. There are also some kinds like pfifo, pfifo_fast, prio supported by NetworkManager but their parameters are not supported by NetworkManager.

Parameters for 'fq_codel':

limit U32

the hard limit on the real queue size. When this limit is reached, incoming packets are dropped. Default is 10240 packets.

memory_limit U32

sets a limit on the total number of bytes that can be queued in this FQ-CoDel instance. The lower of the packet limit of the limit parameter and the memory limit will be enforced. Default is 32 MB.

flows U32

the number of flows into which the incoming packets are classified. Due to the stochastic nature of hashing, multiple flows may end up being hashed into the same slot. Newer flows have priority over older ones. This parameter can be set only at load time since memory has to be allocated for the hash table. Default value is 1024.

target U32

the acceptable minimum standing/persistent queue delay. This minimum delay is identified by tracking the local minimum queue delay that packets experience. The unit of measurement is microsecond(us). Default value is 5ms.

interval U32

used to ensure that the measured minimum delay does not become too stale. The minimum delay must be experienced in the last epoch of length .B interval. It should be set on the order of the worst-case RTT through the bottleneck to give endpoints sufficient time to react. Default value is

100ms.

quantum U32

the number of bytes used as 'deficit' in the fair queuing algorithm. Default is set to 1514 bytes which corresponds to the Ethernet MTU plus the hardware header length of 14 bytes.

ecn BOOL

can be used to mark packets instead of dropping them. *ecn* is turned on by default.

ce_threshold U32

sets a threshold above which all packets are marked with ECN Congestion Experienced. This is useful for DCTCP-style congestion control algorithms that require marking at very shallow queueing thresholds.

Parameters for 'sfq':

divisor U32

can be used to set a different hash table size, available from kernel 2.6.39 onwards. The specified divisor must be a power of two and cannot be larger than 65536. Default value: 1024.

limit U32

Upper limit of the SFQ. Can be used to reduce the default length of 127 packets.

depth U32

Limit of packets per flow. Default to 127 and can be lowered.

perturb_period U32

Interval in seconds for queue algorithm perturbation. Defaults to 0, which means that no perturbation occurs. Do not set too low for each perturbation may cause some packet reordering or losses. Advised value: 60 This value has no effect when external flow classification is used. Its better to increase divisor value to lower risk of hash collisions.

quantum U32

Amount of bytes a flow is allowed to dequeue during a round of the round robin process. Defaults to the MTU of the interface which is also the advised value and the minimum value.

flows U32

Default value is 127.

Parameters for 'tbf':

rate U64

Bandwidth or rate. These parameters accept a floating point number, possibly followed by either a unit (both SI and IEC units supported), or a float followed by a percent character to specify the rate as a percentage of the device's speed.

burst U32

Also known as buffer or maxburst. Size of the bucket, in bytes. This is the maximum amount of bytes that tokens can be available for instantaneously. In general, larger shaping rates require a larger buffer. For 10mbit/s on Intel, you need at least 10kbyte buffer if you want to reach your configured rate!

If your buffer is too small, packets may be dropped because more tokens arrive per timer tick than fit in your bucket. The minimum buffer size can be calculated by dividing the rate by HZ.

Token usage calculations are performed using a table which by default has a resolution of 8 packets. This resolution can be changed by specifying the cell size with the burst. For example, to specify a 6000 byte buffer with a 16 byte cell size, set a burst of 6000/16. You will probably never have to set this. Must be an integral power of 2.

limit U32

Limit is the number of bytes that can be queued waiting for tokens to become available.

latency U32

specifies the maximum amount of time a packet can sit in the TBF. The latency calculation takes into account the size of the bucket, the rate and possibly the peakrate (if set). The latency and limit are mutually exclusive.

Format: GPtrArray(NMTCQdisc)

tfilters

Array of TC traffic filters. Traffic control can manage the packet content during classification by using filters.

Each tfilters can be specified by the following attributes:

handle HANDLE

specifies the tfilters handle. A filter is used by a classful qdisc to determine in which class a packet will be enqueued. It is important to notice that filters reside within qdiscs. Therefore, see qdiscs handle for detailed information.

parent HANDLE

specifies the handle of the parent qdisc the current qdisc must be attached to.

root

specifies that the qdisc is attached to the root of device.

KIND

this is the tfilters kind. NetworkManager currently supports following kinds: mirred, simple. Each filter kind has a different set of actions, described below. There are also some other kinds like matchall, basic, u32 supported by NetworkManager.

Actions for 'mirred':

egress bool

Define whether the packet should exit from the interface.

ingress bool

Define whether the packet should come into the interface.

mirror bool

Define whether the packet should be copied to the destination space.

redirect bool

Define whether the packet should be moved to the destination space.

Action for 'simple':

sdata char[32]

The actual string to print.

Format: GPtrArray(NMTCTfilter)

team setting

Teaming Settings.

Properties:

config

Alias: config

The JSON configuration for the team network interface. The property should contain raw JSON configuration data suitable for teamd, because the value is passed directly to teamd. If not specified, the default configuration is used. See man teamd.conf for the format details.

Format: string

link-watchers

Link watchers configuration for the connection: each link watcher is defined by a dictionary, whose keys depend upon the selected link watcher. Available link watchers are 'ethtool', 'nsna_ping' and 'arp_ping' and it is specified in the dictionary with the key 'name'. Available keys are: ethtool: 'delay-up', 'delay-down', 'init-wait'; nsna_ping: 'init-wait', 'interval', 'missed-max', 'target-host'; arp_ping: all the ones in nsna_ping and 'source-host', 'validate-active', 'validate-inactive', 'send-always'. See teamd.conf man for more details.

Format: array of vardict

mcast-rejoin-count

Corresponds to the teamd mcast_rejoin.count.

Format: int32

mcast-rejoin-interval

Corresponds to the teamd mcast_rejoin.interval.

Format: int32

notify-peers-count

Corresponds to the teamd notify_peers.count.

Format: int32

notify-peers-interval

Corresponds to the teamd notify_peers.interval.

Format: int32

runner

Corresponds to the teamd runner.name. Permitted values are: "roundrobin", "broadcast", "activebackup", "loadbalance", "lacp", "random".

Format: string

runner-active

Corresponds to the teamd runner.active.

Format: boolean

runner-agg-select-policy

Corresponds to the teamd runner.agg_select_policy.

Format: string

runner-fast-rate

Corresponds to the teamd runner.fast_rate.

Format: boolean

runner-hwaddr-policy

Corresponds to the teamd runner.hwaddr_policy.

Format: string

runner-min-ports

Corresponds to the teamd runner.min_ports.

Format: int32

runner-sys-prio

Corresponds to the teamd runner.sys_prio.

Format: int32

runner-tx-balancer

Corresponds to the teamd runner.tx_balancer.name.

Format: string

runner-tx-balancer-interval

Corresponds to the teamd runner.tx_balancer.interval.

Format: int32

runner-tx-hash

Corresponds to the teamd runner.tx_hash.

Format: array of string

team-port setting

Team Port Settings.

Properties:

config

Alias: config

The JSON configuration for the team port. The property should contain raw JSON configuration data suitable for teamd, because the value is passed directly to teamd. If not specified, the default configuration is used. See man teamd.conf for the format details.

Format: string

lacp-key

Corresponds to the teamd ports.PORTIFNAME.lacp_key.

Format: int32

lacp-prio

Corresponds to the teamd ports.PORTIFNAME.lacp_prio.

Format: int32

link-watchers

Link watchers configuration for the connection: each link watcher is defined by a dictionary, whose keys depend upon the selected link watcher. Available link watchers are 'ethtool', 'nsna_ping' and 'arp_ping' and it is specified in the dictionary with the key 'name'. Available keys are: ethtool: 'delay-up', 'delay-down', 'init-wait'; nsna_ping: 'init-wait', 'interval', 'missed-max', 'target-host'; arp_ping: all the ones in nsna_ping and 'source-host', 'validate-active', 'validate-inactive', 'send-always'. See teamd.conf man for more details.

Format: array of vardict

prio

Corresponds to the teamd ports.PORTIFNAME.prio.

Format: int32

queue-id

Corresponds to the teamd ports.PORTIFNAME.queue_id. When set to -1 means the parameter is skipped from the json config.

Format: int32

sticky

Corresponds to the teamd ports.PORTIFNAME.sticky.

Format: boolean

tun setting

Tunnel Settings.

Properties:

group

Alias: group

The group ID which will own the device. If set to NULL everyone will be able to use the device.

Format: string

mode

Alias: mode

The operating mode of the virtual device. Allowed values are NM_SETTING_TUN_MODE_TUN (1) to create a layer 3 device and NM_SETTING_TUN_MODE_TAP (2) to create an Ethernet-like layer 2 one.

Format: uint32

multi-queue

Alias: multi-queue

If the property is set to TRUE, the interface will support multiple file descriptors (queues) to parallelize packet sending or receiving. Otherwise, the interface will only support a single queue.

Format: boolean

owner

Alias: owner

The user ID which will own the device. If set to NULL everyone will be able to use the device.

Format: string

pi

Alias: pi

If TRUE the interface will prepend a 4 byte header describing the physical interface to the packets.

Format: boolean

vnet-hdr

Alias: vnet-hdr

If TRUE the IFF_VNET_HDR the tunnel packets will include a virtio network header.

Format: boolean

vlan setting

VLAN Settings.

Properties:

egress-priority-map

Alias: egress

For outgoing packets, a list of mappings from Linux SKB priorities to 802.1p priorities. The mapping is given in the format "from:to" where both "from" and "to" are unsigned integers, ie "7:3".

Format: array of string

flags

Alias: flags

One or more flags which control the behavior and features of the VLAN interface. Flags include NM_VLAN_FLAG_REORDER_HEADERS (0x1) (reordering of output packet headers), NM_VLAN_FLAG_GVRP (0x2) (use of the GVRP protocol), and NM_VLAN_FLAG_LOOSE_BINDING (0x4) (loose binding of the interface to its master device's operating state). NM_VLAN_FLAG_MVRP (0x8) (use of the MVRP protocol). The default value of this property is NM_VLAN_FLAG_REORDER_HEADERS, but it used to be 0. To preserve backward compatibility, the default-value in the D-Bus API continues to be 0 and a missing property on D-Bus is still considered as 0.

Format: NMVlanFlags (uint32)

id

Alias: id

The VLAN identifier that the interface created by this connection should be assigned. The valid range is from 0 to 4094, without the reserved id 4095.

Format: uint32

ingress-priority-map

Alias: ingress

For incoming packets, a list of mappings from 802.1p priorities to Linux SKB priorities. The mapping is given in the format "from:to" where both "from" and "to" are unsigned integers, ie "7:3".

Format: array of string

parent

Alias: dev

If given, specifies the parent interface name or parent connection UUID from which this VLAN interface should be created. If this property is not specified, the connection must contain an "802-3-ethernet" setting with a "mac-address" property.

Format: string

vpn setting

VPN Settings.

Properties:

data

Dictionary of key/value pairs of VPN plugin specific data. Both keys and values must be strings.

Format: dict of string to string

persistent

If the VPN service supports persistence, and this property is TRUE, the VPN will attempt to stay connected across link changes and outages, until explicitly disconnected.

Format: boolean

secrets

Dictionary of key/value pairs of VPN plugin specific secrets like passwords or private keys. Both keys and values must be strings.

Format: dict of string to string

service-type

Alias: vpn-type

D-Bus service name of the VPN plugin that this setting uses to connect to its network. i.e. org.freedesktop.NetworkManager.vpnc for the vpnc plugin.

Format: string

timeout

Timeout for the VPN service to establish the connection. Some services may take quite a long time to connect. Value of 0 means a default timeout, which is 60 seconds (unless overridden by vpn.timeout in configuration file). Values greater than zero mean timeout in seconds.

Format: uint32

user-name

Alias: user

If the VPN connection requires a user name for authentication, that name should be provided here. If the connection is available to more than one user, and the VPN requires each user to supply a different name, then leave this property empty. If this property is empty, NetworkManager will automatically supply the username of the user which requested the VPN connection.

Format: string

vrf setting

VRF settings.

Properties:

table

Alias: table

The routing table for this VRF.

Format: uint32

vxlan setting

VXLAN Settings.

Properties:

ageing

Specifies the lifetime in seconds of FDB entries learnt by the kernel.

Format: uint32

destination-port

Alias: destination-port

Specifies the UDP destination port to communicate to the remote VXLAN tunnel endpoint.

Format: uint32

id

Alias: id

Specifies the VXLAN Network Identifier (or VXLAN Segment Identifier) to use.

Format: uint32

l2-miss

Specifies whether netlink LL ADDR miss notifications are generated.

Format: boolean

l3-miss

Specifies whether netlink IP ADDR miss notifications are generated.

Format: boolean

learning

Specifies whether unknown source link layer addresses and IP addresses are entered into the VXLAN device forwarding database.

Format: boolean

limit

Specifies the maximum number of FDB entries. A value of zero means that the kernel will store unlimited entries.

Format: uint32

local

Alias: local

If given, specifies the source IP address to use in outgoing packets.

Format: string

parent

Alias: dev

If given, specifies the parent interface name or parent connection UUID.

Format: string

proxy

Specifies whether ARP proxy is turned on.

Format: boolean

remote

Alias: remote

Specifies the unicast destination IP address to use in outgoing packets when the destination link layer address is not known in the VXLAN device forwarding database, or the multicast IP address to join.

Format: string

rsc

Specifies whether route short circuit is turned on.

Format: boolean

source-port-max

Alias: source-port-max

Specifies the maximum UDP source port to communicate to the remote VXLAN tunnel endpoint.

Format: uint32

source-port-min

Alias: source-port-min

Specifies the minimum UDP source port to communicate to the remote VXLAN tunnel endpoint.

Format: uint32

tos

Specifies the TOS value to use in outgoing packets.

Format: uint32

ttl

Specifies the time-to-live value to use in outgoing packets.

Format: uint32

wifi-p2p setting

Wi-Fi P2P Settings.

Properties:

peer

Alias: peer

The P2P device that should be connected to. Currently, this is the only way to create or join a group.

Format: string

wfd-ies

The Wi-Fi Display (WFD) Information Elements (IEs) to set. Wi-Fi Display requires a protocol specific information element to be set in certain Wi-Fi frames. These can be specified here for the purpose of establishing a connection. This setting is only useful when implementing a Wi-Fi Display client.

Format: byte array

wps-method

Flags indicating which mode of WPS is to be used. There's little point in changing the default setting as NetworkManager will automatically determine the best method to use.

Format: uint32

wimax setting

WiMax Settings.

Properties:

mac-address

Alias: mac

If specified, this connection will only apply to the WiMAX device whose MAC address matches. This property does not change the MAC address of the device (known as MAC spoofing). Deprecated: 1

Format: byte array

network-name

Alias: nsp

Network Service Provider (NSP) name of the WiMAX network this connection should use.

Deprecated: 1

Format: string

802-3-ethernet setting

Alias: ethernet

Wired Ethernet Settings.

Properties:

accept-all-mac-addresses

When TRUE, setup the interface to accept packets for all MAC addresses. This is enabling the kernel interface flag IFF_PROMISC. When FALSE, the interface will only accept the packets with the interface destination mac address or broadcast.

Format: NMternary (int32)

auto-negotiate

When TRUE, enforce auto-negotiation of speed and duplex mode. If "speed" and "duplex" properties are both specified, only that single mode will be advertised and accepted during the link auto-negotiation process: this works only for BASE-T 802.3 specifications and is useful for enforcing gigabits modes, as in these cases link negotiation is mandatory. When FALSE, "speed" and "duplex" properties should be both set or link configuration will be skipped.

Format: boolean

cloned-mac-address

Alias: cloned-mac

If specified, request that the device use this MAC address instead. This is known as MAC cloning or spoofing. Beside explicitly specifying a MAC address, the special values "preserve", "permanent", "random" and "stable" are supported. "preserve" means not to touch the MAC address on activation. "permanent" means to use the permanent hardware address if the device has one (otherwise this is treated as "preserve"). "random" creates a random MAC address on each connect. "stable" creates a hashed MAC address based on connection.stable-id and a machine dependent key. If unspecified, the value can be overwritten via global defaults, see manual of NetworkManager.conf. If still unspecified, it defaults to "preserve" (older versions of NetworkManager may use a different default value). On D-Bus, this field is expressed as "assigned-mac-address" or the deprecated "cloned-mac-address".

Format: byte array

duplex

When a value is set, either "half" or "full", configures the device to use the specified duplex mode. If "auto-negotiate" is "yes" the specified duplex mode will be the only one advertised during link negotiation: this works only for BASE-T 802.3 specifications and is useful for enforcing gigabits modes, as in these cases link negotiation is mandatory. If the value is unset (the default), the link

configuration will be either skipped (if "auto-negotiate" is "no", the default) or will be auto-negotiated (if "auto-negotiate" is "yes") and the local device will advertise all the supported duplex modes. Must be set together with the "speed" property if specified. Before specifying a duplex mode be sure your device supports it.

Format: string

generate-mac-address-mask

With "cloned-mac-address" setting "random" or "stable", by default all bits of the MAC address are scrambled and a locally-administered, unicast MAC address is created. This property allows to specify that certain bits are fixed. Note that the least significant bit of the first MAC address will always be unset to create a unicast MAC address. If the property is NULL, it is eligible to be overwritten by a default connection setting. If the value is still NULL or an empty string, the default is to create a locally-administered, unicast MAC address. If the value contains one MAC address, this address is used as mask. The set bits of the mask are to be filled with the current MAC address of the device, while the unset bits are subject to randomization. Setting "FE:FF:FF:00:00:00" means to preserve the OUI of the current MAC address and only randomize the lower 3 bytes using the "random" or "stable" algorithm. If the value contains one additional MAC address after the mask, this address is used instead of the current MAC address to fill the bits that shall not be randomized. For example, a value of "FE:FF:FF:00:00:00 68:F7:28:00:00:00" will set the OUI of the MAC address to 68:F7:28, while the lower bits are randomized. A value of "02:00:00:00:00 00:00:00:00:00:00" will create a fully scrambled globally-administered, burned-in MAC address. If the value contains more than one additional MAC addresses, one of them is chosen randomly. For example, "02:00:00:00:00:00 00:00:00:00:00:00 02:00:00:00:00:00" will create a fully scrambled MAC address, randomly locally or globally administered.

Format: string

mac-address

Alias: mac

If specified, this connection will only apply to the Ethernet device whose permanent MAC address matches. This property does not change the MAC address of the device (i.e. MAC spoofing).

Format: byte array

mac-address-blacklist

If specified, this connection will never apply to the Ethernet device whose permanent MAC address matches an address in the list. Each MAC address is in the standard hex-digits-and-colons notation (00:11:22:33:44:55).

Format: array of string

mtu

Alias: mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple Ethernet frames.

Format: uint32

port

Specific port type to use if the device supports multiple attachment methods. One of "tp" (Twisted Pair), "aui" (Attachment Unit Interface), "bnc" (Thin Ethernet) or "mii" (Media Independent Interface). If the device supports only one port type, this setting is ignored.

Format: string

s390-nettype

s390 network device type; one of "qeth", "lcs", or "ctc", representing the different types of virtual network devices available on s390 systems.

Format: string

s390-options

Dictionary of key/value pairs of s390-specific device options. Both keys and values must be strings. Allowed keys include "portno", "layer2", "portname", "protocol", among others. Key names must contain only alphanumeric characters (ie, [a-zA-Z0-9]). Currently, NetworkManager itself does nothing with this information. However, s390utils ships a udev rule which parses this information and applies it to the interface.

Format: dict of string to string

s390-subchannels

Identifies specific subchannels that this network device uses for communication with z/VM or s390 host. Like the "mac-address" property for non-z/VM devices, this property can be used to ensure this connection only applies to the network device that uses these subchannels. The list should contain exactly 3 strings, and each string may only be composed of hexadecimal characters and the period (.) character.

Format: array of string

speed

When a value greater than 0 is set, configures the device to use the specified speed. If "auto-negotiate" is "yes" the specified speed will be the only one advertised during link negotiation: this works only for BASE-T 802.3 specifications and is useful for enforcing gigabit speeds, as in this case link negotiation is mandatory. If the value is unset (0, the default), the link configuration will be either skipped (if "auto-negotiate" is "no", the default) or will be auto-negotiated (if "auto-negotiate" is "yes") and the local device will advertise all the supported speeds. In Mbit/s, ie 100 == 100Mbit/s. Must be set together with the "duplex" property when non-zero. Before specifying a speed value be sure your device supports it.

Format: uint32

wake-on-lan

The NMSettingWiredWakeOnLan options to enable. Not all devices support all options. May be any combination of NM_SETTING_WIRED_WAKE_ON_LAN_PHY (0x2), NM_SETTING_WIRED_WAKE_ON_LAN_UNICAST (0x4), NM_SETTING_WIRED_WAKE_ON_LAN_MULTICAST (0x8), NM_SETTING_WIRED_WAKE_ON_LAN_BROADCAST (0x10), NM_SETTING_WIRED_WAKE_ON_LAN_ARP (0x20), NM_SETTING_WIRED_WAKE_ON_LAN_MAGIC (0x40) or the special values NM_SETTING_WIRED_WAKE_ON_LAN_DEFAULT (0x1) (to use global settings) and NM_SETTING_WIRED_WAKE_ON_LAN_IGNORE (0x8000) (to disable management of Wake-on-LAN in NetworkManager).

Format: uint32

wake-on-lan-password

If specified, the password used with magic-packet-based Wake-on-LAN, represented as an Ethernet MAC address. If NULL, no password will be required.

Format: string

wireguard setting

WireGuard Settings.

Properties:

fwmark

The use of fwmark is optional and is by default off. Setting it to 0 disables it. Otherwise, it is a 32-bit fwmark for outgoing packets. Note that "ip4-auto-default-route" or "ip6-auto-default-route" enabled, implies to automatically choose a fwmark.

Format: uint32

ip4-auto-default-route

Whether to enable special handling of the IPv4 default route. If enabled, the IPv4 default route from wireguard.peer-routes will be placed to a dedicated routing-table and two policy routing rules will be added. The fwmark number is also used as routing-table for the default-route, and if fwmark is zero, an unused fwmark/table is chosen automatically. This corresponds to what wg-quick does with Table=auto and what WireGuard calls "Improved Rule-based Routing". Note that for this automatism to work, you usually don't want to set ipv4.gateway, because that will result in a conflicting default route. Leaving this at the default will enable this option automatically if ipv4.never-default is not set and there are any peers that use a default-route as allowed-ips.

Format: NMternary (int32)

ip6-auto-default-route

Like ip4-auto-default-route, but for the IPv6 default route.

Format: NMternary (int32)

listen-port

The listen-port. If listen-port is not specified, the port will be chosen randomly when the interface comes up.

Format: uint32

mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple fragments. If zero a default MTU is used. Note that contrary to wg-quick's MTU setting, this does not take into account the current routes at the time of activation.

Format: uint32

peer-routes

Whether to automatically add routes for the AllowedIPs ranges of the peers. If TRUE (the default), NetworkManager will automatically add routes in the routing tables according to ipv4.route-table and ipv6.route-table. Usually you want this automatism enabled. If FALSE, no such routes are added automatically. In this case, the user may want to configure static routes in ipv4.routes and ipv6.routes, respectively. Note that if the peer's AllowedIPs is "0.0.0.0/0" or "::/0" and the profile's ipv4.never-default or ipv6.never-default setting is enabled, the peer route for this peer won't be added automatically.

Format: boolean

private-key

The 256 bit private-key in base64 encoding.

Format: string

private-key-flags

Flags indicating how to handle the "private-key" property. See the section called "Secret flag types:"

for flag values.

Format: NMSettingSecretFlags (uint32)

802-11-wireless setting

Alias: wifi

Wi-Fi Settings.

Properties:

ap-isolation

Configures AP isolation, which prevents communication between wireless devices connected to this AP. This property can be set to a value different from NM_TERNARY_DEFAULT (-1) only when the interface is configured in AP mode. If set to NM_TERNARY_TRUE (1), devices are not able to communicate with each other. This increases security because it protects devices against attacks from other clients in the network. At the same time, it prevents devices to access resources on the same wireless networks as file shares, printers, etc. If set to NM_TERNARY_FALSE (0), devices can talk to each other. When set to NM_TERNARY_DEFAULT (-1), the global default is used; in case the global default is unspecified it is assumed to be NM_TERNARY_FALSE (0).

Format: NMternary (int32)

band

802.11 frequency band of the network. One of "a" for 5GHz 802.11a or "bg" for 2.4GHz 802.11. This will lock associations to the Wi-Fi network to the specific band, i.e. if "a" is specified, the device will not associate with the same network in the 2.4GHz band even if the network's settings are compatible. This setting depends on specific driver capability and may not work with all drivers.

Format: string

bssid

If specified, directs the device to only associate with the given access point. This capability is highly driver dependent and not supported by all devices. Note: this property does not control the BSSID used when creating an Ad-Hoc network and is unlikely to in the future.

Format: byte array

channel

Wireless channel to use for the Wi-Fi connection. The device will only join (or create for Ad-Hoc networks) a Wi-Fi network on the specified channel. Because channel numbers overlap between bands, this property also requires the "band" property to be set.

Format: uint32

cloned-mac-address

Alias: cloned-mac

If specified, request that the device use this MAC address instead. This is known as MAC cloning or spoofing. Beside explicitly specifying a MAC address, the special values "preserve", "permanent", "random" and "stable" are supported. "preserve" means not to touch the MAC address on activation. "permanent" means to use the permanent hardware address of the device. "random" creates a random MAC address on each connect. "stable" creates a hashed MAC address based on connection.stable-id and a machine dependent key. If unspecified, the value can be overwritten via global defaults, see manual of NetworkManager.conf. If still unspecified, it defaults to "preserve" (older versions of NetworkManager may use a different default value). On D-Bus, this field is expressed as "assigned-mac-address" or the deprecated "cloned-mac-address".

Format: byte array

generate-mac-address-mask

With "cloned-mac-address" setting "random" or "stable", by default all bits of the MAC address are scrambled and a locally-administered, unicast MAC address is created. This property allows to specify that certain bits are fixed. Note that the least significant bit of the first MAC address will always be unset to create a unicast MAC address. If the property is NULL, it is eligible to be overwritten by a default connection setting. If the value is still NULL or an empty string, the default is to create a locally-administered, unicast MAC address. If the value contains one MAC address, this address is used as mask. The set bits of the mask are to be filled with the current MAC address of the device, while the unset bits are subject to randomization. Setting "FE:FF:FF:00:00:00" means to preserve the OUI of the current MAC address and only randomize the lower 3 bytes using the "random" or "stable" algorithm. If the value contains one additional MAC address after the mask, this address is used instead of the current MAC address to fill the bits that shall not be randomized. For example, a value of "FE:FF:FF:00:00:00 68:F7:28:00:00:00" will set the OUI of the MAC address to 68:F7:28, while the lower bits are randomized. A value of "02:00:00:00:00:00 00:00:00:00:00:00" will create a fully scrambled globally-administered, burned-in MAC address. If the value contains more than one additional MAC addresses, one of them is chosen randomly. For example, "02:00:00:00:00:00 00:00:00:00:00:00 02:00:00:00:00:00" will create a fully scrambled MAC address, randomly locally or globally administered.

Format: string

hidden

If TRUE, indicates that the network is a non-broadcasting network that hides its SSID. This works both in infrastructure and AP mode. In infrastructure mode, various workarounds are used for a more reliable discovery of hidden networks, such as probe-scanning the SSID. However, these workarounds expose inherent insecurities with hidden SSID networks, and thus hidden SSID networks should be used with caution. In AP mode, the created network does not broadcast its SSID. Note that marking the network as hidden may be a privacy issue for you (in infrastructure mode) or client stations (in AP mode), as the explicit probe-scans are distinctly recognizable on the air.

Format: boolean

mac-address

Alias: mac

If specified, this connection will only apply to the Wi-Fi device whose permanent MAC address matches. This property does not change the MAC address of the device (i.e. MAC spoofing).

Format: byte array

mac-address-blacklist

A list of permanent MAC addresses of Wi-Fi devices to which this connection should never apply. Each MAC address should be given in the standard hex-digits-and-colons notation (eg "00:11:22:33:44:55").

Format: array of string

mac-address-randomization

One of NM_SETTING_MAC_RANDOMIZATION_DEFAULT (0) (never randomize unless the user has set a global default to randomize and the supplicant supports randomization), NM_SETTING_MAC_RANDOMIZATION_NEVER (1) (never randomize the MAC address), or NM_SETTING_MAC_RANDOMIZATION_ALWAYS (2) (always randomize the MAC address). This property is deprecated for 'cloned-mac-address'. Deprecated: 1

Format: uint32

mode

Alias: mode

Wi-Fi network mode; one of "infrastructure", "mesh", "adhoc" or "ap". If blank, infrastructure is assumed.

Format: string

mtu

Alias: mtu

If non-zero, only transmit packets of the specified size or smaller, breaking larger packets up into multiple Ethernet frames.

Format: uint32

powersave

One of NM_SETTING_WIRELESS_POWERSAVE_DISABLE (2) (disable Wi-Fi power saving), NM_SETTING_WIRELESS_POWERSAVE_ENABLE (3) (enable Wi-Fi power saving), NM_SETTING_WIRELESS_POWERSAVE_IGNORE (1) (don't touch currently configured setting) or NM_SETTING_WIRELESS_POWERSAVE_DEFAULT (0) (use the globally configured value). All other values are reserved.

Format: uint32

rate

If non-zero, directs the device to only use the specified bitrate for communication with the access point. Units are in Kb/s, ie 5500 = 5.5 Mbit/s. This property is highly driver dependent and not all devices support setting a static bitrate.

Format: uint32

seen-bssids

A list of BSSIDs (each BSSID formatted as a MAC address like "00:11:22:33:44:55") that have been detected as part of the Wi-Fi network. NetworkManager internally tracks previously seen BSSIDs. The property is only meant for reading and reflects the BSSID list of NetworkManager. The changes you make to this property will not be preserved.

Format: array of string

ssid

Alias: ssid

SSID of the Wi-Fi network. Must be specified.

Format: byte array

tx-power

If non-zero, directs the device to use the specified transmit power. Units are dBm. This property is highly driver dependent and not all devices support setting a static transmit power.

Format: uint32

wake-on-wlan

The NMSettingWirelessWakeOnWlan options to enable. Not all devices support all options. May be any combination of NM_SETTING_WIRELESS_WAKE_ON_WLAN_ANY (0x2), NM_SETTING_WIRELESS_WAKE_ON_WLAN_DISCONNECT (0x4), NM_SETTING_WIRELESS_WAKE_ON_WLAN_MAGIC (0x8), NM_SETTING_WIRELESS_WAKE_ON_WLAN_GTK_REKEY_FAILURE (0x10), NM_SETTING_WIRELESS_WAKE_ON_WLAN_EAP_IDENTITY_REQUEST (0x20),

NM_SETTING_WIRELESS_WAKE_ON_WLAN_4WAY_HANDSHAKE (0x40),
 NM_SETTING_WIRELESS_WAKE_ON_WLAN_RFKILL_RELEASE (0x80),
 NM_SETTING_WIRELESS_WAKE_ON_WLAN_TCP (0x100) or the special values
 NM_SETTING_WIRELESS_WAKE_ON_WLAN_DEFAULT (0x1) (to use global settings) and
 NM_SETTING_WIRELESS_WAKE_ON_WLAN_IGNORE (0x8000) (to disable management of
 Wake-on-LAN in NetworkManager).

Format: uint32

802-11-wireless-security setting

Alias: wifi-sec

Wi-Fi Security Settings.

Properties:

auth-alg

When WEP is used (ie, key-mgmt = "none" or "ieee8021x") indicate the 802.11 authentication algorithm required by the AP here. One of "open" for Open System, "shared" for Shared Key, or "leap" for Cisco LEAP. When using Cisco LEAP (ie, key-mgmt = "ieee8021x" and auth-alg = "leap") the "leap-username" and "leap-password" properties must be specified.

Format: string

fils

Indicates whether Fast Initial Link Setup (802.11ai) must be enabled for the connection. One of NM_SETTING_WIRELESS_SECURITY_FILS_DEFAULT (0) (use global default value), NM_SETTING_WIRELESS_SECURITY_FILS_DISABLE (1) (disable FILS), NM_SETTING_WIRELESS_SECURITY_FILS_OPTIONAL (2) (enable FILS if the supplicant and the access point support it) or NM_SETTING_WIRELESS_SECURITY_FILS_REQUIRED (3) (enable FILS and fail if not supported). When set to NM_SETTING_WIRELESS_SECURITY_FILS_DEFAULT (0) and no global default is set, FILS will be optionally enabled.

Format: int32

group

A list of group/broadcast encryption algorithms which prevents connections to Wi-Fi networks that do not utilize one of the algorithms in the list. For maximum compatibility leave this property empty. Each list element may be one of "wep40", "wep104", "tkip", or "ccmp".

Format: array of string

key-mgmt

Key management used for the connection. One of "none" (WEP or no password protection), "ieee8021x" (Dynamic WEP), "owe" (Opportunistic Wireless Encryption), "wpa-psk" (WPA2 + WPA3 personal), "sae" (WPA3 personal only), "wpa-eap" (WPA2 + WPA3 enterprise) or "wpa-eap-suite-b-192" (WPA3 enterprise only). This property must be set for any Wi-Fi connection that uses security.

Format: string

leap-password

The login password for legacy LEAP connections (ie, key-mgmt = "ieee8021x" and auth-alg = "leap").

Format: string

leap-password-flags

Flags indicating how to handle the "leap-password" property. See the section called "Secret flag

types:” for flag values.

Format: NMSettingSecretFlags (uint32)

leap-username

The login username for legacy LEAP connections (ie, key-mgmt = "ieee8021x" and auth-alg = "leap").

Format: string

pairwise

A list of pairwise encryption algorithms which prevents connections to Wi-Fi networks that do not utilize one of the algorithms in the list. For maximum compatibility leave this property empty. Each list element may be one of "tkip" or "ccmp".

Format: array of string

pmf

Indicates whether Protected Management Frames (802.11w) must be enabled for the connection. One of NM_SETTING_WIRELESS_SECURITY_PMF_DEFAULT (0) (use global default value), NM_SETTING_WIRELESS_SECURITY_PMF_DISABLE (1) (disable PMF), NM_SETTING_WIRELESS_SECURITY_PMF_OPTIONAL (2) (enable PMF if the supplicant and the access point support it) or NM_SETTING_WIRELESS_SECURITY_PMF_REQUIRED (3) (enable PMF and fail if not supported). When set to NM_SETTING_WIRELESS_SECURITY_PMF_DEFAULT (0) and no global default is set, PMF will be optionally enabled.

Format: int32

proto

List of strings specifying the allowed WPA protocol versions to use. Each element may be one "wpa" (allow WPA) or "rsn" (allow WPA2/RSN). If not specified, both WPA and RSN connections are allowed.

Format: array of string

psk

Pre-Shared-Key for WPA networks. For WPA-PSK, it's either an ASCII passphrase of 8 to 63 characters that is (as specified in the 802.11i standard) hashed to derive the actual key, or the key in form of 64 hexadecimal character. The WPA3-Personal networks use a passphrase of any length for SAE authentication.

Format: string

psk-flags

Flags indicating how to handle the "psk" property. See the section called “Secret flag types:” for flag values.

Format: NMSettingSecretFlags (uint32)

wep-key-flags

Flags indicating how to handle the "wep-key0", "wep-key1", "wep-key2", and "wep-key3" properties. See the section called “Secret flag types:” for flag values.

Format: NMSettingSecretFlags (uint32)

wep-key-type

Controls the interpretation of WEP keys. Allowed values are NM_WEP_KEY_TYPE_KEY (1), in which case the key is either a 10- or 26-character hexadecimal string, or a 5- or 13-character ASCII

password; or NM_WEP_KEY_TYPE_PASSPHRASE (2), in which case the passphrase is provided as a string and will be hashed using the de-facto MD5 method to derive the actual WEP key.

Format: NMWepKeyType (uint32)

wep-key0

Index 0 WEP key. This is the WEP key used in most networks. See the "wep-key-type" property for a description of how this key is interpreted.

Format: string

wep-key1

Index 1 WEP key. This WEP index is not used by most networks. See the "wep-key-type" property for a description of how this key is interpreted.

Format: string

wep-key2

Index 2 WEP key. This WEP index is not used by most networks. See the "wep-key-type" property for a description of how this key is interpreted.

Format: string

wep-key3

Index 3 WEP key. This WEP index is not used by most networks. See the "wep-key-type" property for a description of how this key is interpreted.

Format: string

wep-tx-keyidx

When static WEP is used (ie, key-mgmt = "none") and a non-default WEP key index is used by the AP, put that WEP key index here. Valid values are 0 (default key) through 3. Note that some consumer access points (like the Linksys WRT54G) number the keys 1 – 4.

Format: uint32

wps-method

Flags indicating which mode of WPS is to be used if any. There's little point in changing the default setting as NetworkManager will automatically determine whether it's feasible to start WPS enrollment from the Access Point capabilities. WPS can be disabled by setting this property to a value of 1.

Format: uint32

wpan setting

IEEE 802.15.4 (WPAN) MAC Settings.

Properties:

channel

Alias: channel

IEEE 802.15.4 channel. A positive integer or -1, meaning "do not set, use whatever the device is already set to".

Format: int32

mac-address

Alias: mac

If specified, this connection will only apply to the IEEE 802.15.4 (WPAN) MAC layer device whose

permanent MAC address matches.

Format: string

page

Alias: page

IEEE 802.15.4 channel page. A positive integer or -1, meaning "do not set, use whatever the device is already set to".

Format: int32

pan-id

Alias: pan-id

IEEE 802.15.4 Personal Area Network (PAN) identifier.

Format: uint32

short-address

Alias: short-addr

Short IEEE 802.15.4 address to be used within a restricted environment.

Format: uint32

bond-port setting

Bond Port Settings.

Properties:

queue-id

Alias: queue-id

The queue ID of this bond port. The maximum value of queue ID is the number of TX queues currently active in device.

Format: uint32

hostname setting

Hostname settings.

Properties:

from-dhcp

Whether the system hostname can be determined from DHCP on this connection. When set to NM_TERNARY_DEFAULT (-1), the value from global configuration is used. If the property doesn't have a value in the global configuration, NetworkManager assumes the value to be NM_TERNARY_TRUE (1).

Format: NMternary (int32)

from-dns-lookup

Whether the system hostname can be determined from reverse DNS lookup of addresses on this device. When set to NM_TERNARY_DEFAULT (-1), the value from global configuration is used. If the property doesn't have a value in the global configuration, NetworkManager assumes the value to be NM_TERNARY_TRUE (1).

Format: NMternary (int32)

only-from-default

If set to NM_TERNARY_TRUE (1), NetworkManager attempts to get the hostname via DHCPv4/DHCPv6 or reverse DNS lookup on this device only when the device has the default route for the given address family (IPv4/IPv6). If set to NM_TERNARY_FALSE (0), the hostname can be set from this device even if it doesn't have the default route. When set to NM_TERNARY_DEFAULT (-1), the value from global configuration is used. If the property doesn't have a value in the global configuration, NetworkManager assumes the value to be NM_TERNARY_FALSE (0).

Format: NMternary (int32)

priority

The relative priority of this connection to determine the system hostname. A lower numerical value is better (higher priority). A connection with higher priority is considered before connections with lower priority. If the value is zero, it can be overridden by a global value from NetworkManager configuration. If the property doesn't have a value in the global configuration, the value is assumed to be 100. Negative values have the special effect of excluding other connections with a greater numerical priority value; so in presence of at least one negative priority, only connections with the lowest priority value will be used to determine the hostname.

Format: int32

veth setting

Veth Settings.

Properties:

peer

Alias: peer

This property specifies the peer interface name of the veth. This property is mandatory.

Format: string

Secret flag types:

Each password or secret property in a setting has an associated *flags* property that describes how to handle that secret. The *flags* property is a bitfield that contains zero or more of the following values logically OR-ed together.

- 0x0 (none) – the system is responsible for providing and storing this secret. This may be required so that secrets are already available before the user logs in. It also commonly means that the secret will be stored in plain text on disk, accessible to root only. For example via the keyfile settings plugin as described in the "PLUGINS" section in **NetworkManager.conf(5)**.
- 0x1 (agent-owned) – a user-session secret agent is responsible for providing and storing this secret; when it is required, agents will be asked to provide it.
- 0x2 (not-saved) – this secret should not be saved but should be requested from the user each time it is required. This flag should be used for One-Time-Pad secrets, PIN codes from hardware tokens, or if the user simply does not want to save the secret.
- 0x4 (not-required) – in some situations it cannot be automatically determined that a secret is required or not. This flag hints that the secret is not required and should not be requested from the user.

NAME

nmcli-examples – usage examples of nmcli

SYNOPSIS

nmcli [OPTIONS...]

DESCRIPTION

nmcli is a command-line client for NetworkManager. It allows controlling NetworkManager and reporting its status. For more information please refer to **nmcli(1)** manual page.

The purpose of this manual page is to provide you with various examples and usage scenarios of *nmcli*.

EXAMPLES**Example 1. Listing available Wi-Fi APs**

```
$ nmcli device wifi list
* SSID      MODE  CHAN RATE   SIGNAL BARS SECURITY
  netdatacomm_local Infra 6 54 Mbit/s 37   __ WEP
* F1        Infra 11 54 Mbit/s 98   WPA1
  LoremCorp     Infra 1 54 Mbit/s 62   _ WPA2 802.1X
  Internet     Infra 6 54 Mbit/s 29   __ WPA1
  HPB110a.F2672A Ad-Hoc 6 54 Mbit/s 22   __ --
  Jozinet     Infra 1 54 Mbit/s 19   __ WEP
  VOIP        Infra 1 54 Mbit/s 20   __ WEP
  MARTINA     Infra 4 54 Mbit/s 32   __ WPA2
  N24PU1      Infra 7 11 Mbit/s 22   __ --
  alfa        Infra 1 54 Mbit/s 67   _ WPA2
  bertnet     Infra 5 54 Mbit/s 20   __ WPA1 WPA2
```

This command shows how to list available Wi-Fi networks (APs). You can also use *--fields* option for displaying different columns. **nmcli -f all dev wifi list** will show all of them.

Example 2. Connect to a password-protected wifi network

```
$ nmcli device wifi connect "$SSID" password "$PASSWORD"
```

```
$ nmcli --ask device wifi connect "$SSID"
```

Example 3. Showing general information and properties for a Wi-Fi interface

```
$ nmcli -p -f general,wifi-properties device show wlan0
```

```
=====
Device details (wlan0)
=====

GENERAL.DEVICE:      wlan0
GENERAL.TYPE:        wifi
GENERAL.VENDOR:      Intel Corporation
GENERAL.PRODUCT:     PRO/Wireless 5100 AGN [Shiloh] Network Connection
GENERAL.DRIVER:       iwlwifi
GENERAL.DRIVER-VERSION: 3.8.13-100.fc17.x86_64
GENERAL.FIRMWARE-VERSION: 8.83.5.1 build 33692
GENERAL.HWADDR:      00:1E:65:37:A1:D3
GENERAL.MTU:         1500
GENERAL.STATE:       100 (connected)
GENERAL.REASON:      0 (No reason given)
GENERAL.UDI:         /sys/devices/pci0000:00/0000:00:1c.1/net/wlan0
GENERAL.IP-IFACE:    wlan0
GENERAL.IS-SOFTWARE: no
GENERAL.NM-MANAGED:  yes
```

```

GENERAL.AUTOCONNECT: yes
GENERAL.FIRMWARE-MISSING: no
GENERAL.CONNECTION: My Alfa WiFi
GENERAL.CON-UUID: 85194f4c-d496-4eec-bae0-d880b4cbcf26

10

WIFI-PROPERTIES.WEP: yes
WIFI-PROPERTIES.WPA: yes
WIFI-PROPERTIES.WPA2: yes
WIFI-PROPERTIES.TKIP: yes
WIFI-PROPERTIES.CCMP: yes
WIFI-PROPERTIES.AP: no
WIFI-PROPERTIES.ADHOC: yes

```

This command shows information about a Wi-Fi device.

Example 4. Listing NetworkManager polkit permissions

\$ nmcli general permissions

PERMISSION	VALUE
org.freedesktop.NetworkManager.enable-disable-network	yes
org.freedesktop.NetworkManager.enable-disable-wifi	yes
org.freedesktop.NetworkManager.enable-disable-wwan	yes
org.freedesktop.NetworkManager.enable-disable-wimax	yes
org.freedesktop.NetworkManager.sleep-wake	no
org.freedesktop.NetworkManager.network-control	yes
org.freedesktop.NetworkManager.wifi.share.protected	yes
org.freedesktop.NetworkManager.wifi.share.open	yes
org.freedesktop.NetworkManager.settings.modify.system	yes
org.freedesktop.NetworkManager.settings.modify.own	yes
org.freedesktop.NetworkManager.settings.modify.hostname	auth
org.freedesktop.NetworkManager.settings.modify.global-dns	auth
org.freedesktop.NetworkManager.reload	auth

This command shows configured polkit permissions for various NetworkManager operations. These permissions or actions (using polkit language) are configured by a system administrator and are not meant to be changed by users. The usual place for the polkit configuration is `/usr/share/polkit-1/actions/org.freedesktop.NetworkManager.policy`. `pkaction` command can display description for polkit actions.

pkaction --action-id org.freedesktop.NetworkManager.network-control --verbose

More information about polkit can be found at <http://www.freedesktop.org/wiki/Software/polkit>.

Example 5. Listing NetworkManager log level and domains

\$ nmcli general logging

LEVEL DOMAINS

INFO PLATFORM,RFKILL,ETHER,WIFI,BT,MB,DHCP4,DHCP6,PPP,WIFI_SCAN,IP4,IP6,A
UTOIP4,DNS,VPN,SHARING,SUPPLICANT,AGENTS,SETTINGS,SUSPEND,CORE,DEVICE,OLPC,
WIMAX,INFINIBAND,FIREWALL,ADSL,BOND,VLAN,BRIDGE,DBUS_PROPS,TEAM,CONCHECK,DC
B,DISPATCH

This command shows current NetworkManager logging status.

Example 6. Changing NetworkManager logging

```
$ nmcli g log level DEBUG domains CORE,ETHER,IP
$ nmcli g log level INFO domains DEFAULT
```

The first command makes NetworkManager log in DEBUG level, and only for CORE, ETHER and IP domains. The second command restores the default logging state. Please refer to the **NetworkManager.conf(5)** manual page for available logging levels and domains.

Example 7. Activating a VPN connection profile requiring interactive password input

```
$ nmcli --ask con up my-vpn-con
```

This command activates a VPN connection profile enabling nmcli to interact with the user ('--ask'): this will allow nmcli to prompt for the VPN password on the command line when the *password-flags* are set to '0x02' ('always ask', see **nm-settings(5)**). This is particularly useful for OTP based VPNs, as the user needs to be prompted for the password each time the connection is activated.

Example 8. Adding a bonding master and two slave connection profiles

```
$ nmcli con add type bond ifname mybond0 mode active-backup
$ nmcli con add type ethernet ifname eth1 master mybond0
$ nmcli con add type ethernet ifname eth2 master mybond0
```

This example demonstrates adding a bond master connection and two slaves. The first command adds a master bond connection, naming the bonding interface *mybond0* and using *active-backup* mode. The next two commands add slaves connections, both enslaved to *mybond0*. The first slave will be bound to *eth1* interface, the second to *eth2*.

Example 9. Adding a team master and two slave connection profiles

```
$ nmcli con add type team con-name Team1 ifname Team1 config team1-master-json.conf
$ nmcli con add type ethernet con-name Team1-slave1 ifname em1 master Team1
$ nmcli con add type ethernet con-name Team1-slave2 ifname em2 master Team1
```

This example demonstrates adding a team master connection profile and two slaves. It is very similar to the bonding example. The first command adds a master team profile, naming the team interface and the profile *Team1*. The team configuration for the master is read from *team1-master-json.conf* file. Later, you can change the configuration with *modify* command (**nmcli con modify Team1 team.config team1-master-another-json.conf**). The last two commands add slaves profiles, both enslaved to *Team1*. The first slave will be bound to the *em1* interface, the second to *em2*. The slaves don't specify *config* and thus *teamd* will use its default configuration. You will activate the whole setup by activating both slaves:

```
$ nmcli con up Team1-slave1
$ nmcli con up Team1-slave2
```

By default, the created profiles are marked for auto-activation. But if another connection has been activated on the device, the new profile won't activate automatically and you need to activate it manually.

Example 10. Adding a bridge and two slave profiles

```
$ nmcli con add type bridge con-name TowerBridge ifname TowerBridge
$ nmcli con add type ethernet con-name br-slave-1 ifname ens3 master TowerBridge
$ nmcli con add type ethernet con-name br-slave-2 ifname ens4 master TowerBridge
$ nmcli con modify TowerBridge bridge.stp no
```

This example demonstrates adding a bridge master connection and two slaves. The first command adds a master bridge connection, naming the bridge interface and the profile as *TowerBridge*. The next two commands add slaves profiles, both will be enslaved to *TowerBridge*. The first slave will be tied to *ens3* interface, the second to *ens4*. The last command will disable 802.1D STP for the *TowerBridge* profile.

Example 11. Adding an ethernet connection profile with manual IP configuration

```
$ nmcli con add con-name my-con-em1 ifname em1 type ethernet \
  ip4 192.168.100.100/24 gw4 192.168.100.1 ip4 1.2.3.4 ip6 abbe::cafe
$ nmcli con mod my-con-em1 ipv4.dns "8.8.8.8 8.8.4.4"
$ nmcli con mod my-con-em1 +ipv4.dns 1.2.3.4
$ nmcli con mod my-con-em1 ipv6.dns "2001:4860:4860::8888 2001:4860:4860::8844"
$ nmcli -p con show my-con-em1
```

The first command adds an Ethernet connection profile named *my-con-em1* that is bound to interface name *em1*. The profile is configured with static IP addresses. Three addresses are added, two IPv4 addresses and one IPv6. The first IP 192.168.100.100 has a prefix of 24 (netmask equivalent of 255.255.255.0). Gateway entry will become the default route if this profile is activated on em1 interface (and there is no connection with higher priority). The next two addresses do not specify a prefix, so a default prefix will be used, i.e. 32 for IPv4 and 128 for IPv6. The second, third and fourth commands modify DNS parameters of the new connection profile. The last *con show* command displays the profile so that all parameters can be reviewed.

Example 12. Convenient field values retrieval for scripting

```
$ nmcli -g ip4.address connection show my-con-eth0  
192.168.1.12/24  
  
$ nmcli -g ip4.address,ip4.dns connection show my-con-eth0  
192.168.1.12/24  
192.168.1.1  
  
$ nmcli -g ip4 connection show my-con-eth0  
IP4[192.168.1.12/24,192.168.1.1,192.168.1.1]
```

This example shows retrieval of ip4 connection field values via the `--get-values` option. Multiple comma separated fields can be provided: they will be printed one per line. If a whole section is provided instead of a single field, the name of the section will be printed followed by all the related field values on the same line. See also `--terse`, `--mode`, `--fields` and `--escape` options in **nmcli(1)** manual page for more customized output.

Example 13. Adding an Ethernet connection and configuring SR-IOV VFs

```
$ nmcli con add type ethernet con-name EthernetPF ifname em1
$ nmcli con modify EthernetPF sriov.total-vfs 3 sriov.autoprobe-drivers false
$ nmcli con modify EthernetPF sriov.vfs '0 mac=00:11:22:33:44:55 vlans=10, 1 trust=true spoof-check=false'
$ nmcli con modify EthernetPF +sriov.vfs '2 max-tx-rate=20'
```

This example demonstrates adding an Ethernet connection for physical function (PF) `ens4` and configuring 3 SR-IOV virtual functions (VFs) on it. The first VF is configured with MAC address 00:11:22:33:44:55 and VLAN 10, the second one has the *trust* and *spoof-check* features respectively enabled and disabled. VF number 2 has a maximum transmission rate of 20Mbps. The kernel is instructed to not automatically instantiate a network interface for the VFs.

Example 14. Escaping colon characters in tabular mode

```
$ nmcli -t -f general -e yes -m tab dev show eth0
GENERAL:eth0:ethernet:Intel Corporation:82567LM Gigabit Network Connection:
e1000e:2.1.4-k:1.8-3:00\;22\;68\;15\;29\;21:1500:100 (connected):0 (No reas
on given):\sys\devices\pci0000\00\0000\00\19.0\net\eth0:eth0:yes:yes:no:
ethernet-13:89cbcfc6-dc85-456c-9c8b-bd828fee3917:/org/freedesktop/NetworkMa
nager/ActiveConnection/9
```

This example shows escaping colon characters in tabular mode. It may be useful for script processing,

because ':' is used as a field separator.

Example 15. nmcli usage in a NetworkManager dispatcher script to make Ethernet and Wi-Fi mutually exclusive

```
#!/bin/bash
export LC_ALL=C

enable_disable_wifi () {
    result=$(nmcli dev | grep "ethernet" | grep -w "connected")
    if [ -n "$result" ]; then
        nmcli radio wifi off
    else
        nmcli radio wifi on
    fi
}

if [ "$2" = "up" ]; then
    enable_disable_wifi
fi

if [ "$2" = "down" ]; then
    enable_disable_wifi
fi
```

This dispatcher script makes Wi-Fi mutually exclusive with wired networking. When a wired interface is connected, Wi-Fi will be set to airplane mode (rfkill). When the wired interface is disconnected, Wi-Fi will be turned back on. Name this script e.g. 70-wifi-wired-exclusive.sh and put it into /etc/NetworkManager/dispatcher.d/ directory. See **NetworkManager(8)** manual page for more information about NetworkManager dispatcher scripts.

Example sessions of interactive connection editor

Example 16. Adding an ethernet connection profile in interactive editor (a)

```
$ nmcli connection edit type ethernet
```

```
====| nmcli interactive connection editor |====
```

Adding a new '802-3-ethernet' connection

Type 'help' or '?' for available commands.

Type 'describe [<setting>.<prop>]' for detailed property description.

You may edit the following settings: connection, 802-3-ethernet (ethernet), 802-1x, ipv4, ipv6, dcb

nmcli> **print**

```
=====

```

Example session in the nmcli interactive connection editor. The scenario creates an Ethernet connection profile with static addressing (IPs and DNS).

Example 17. Bluetooth connection profiles

NetworkManger supports both connecting to NAP and DUN devices as a client. It also supports sharing the network via a NAP server.

For NAP client connections, NetworkManager automatically creates a suitable in-memory profile for paired devices if none is available. You may use that generated profile directly, but you may also modify and persist it, which will prevent it from automatically re-creating it. You may also create a profile from scratch.

For example, the following uses DHCP and IPv6 autoconf for address configuration:

```
$ nmcli connection add type bluetooth con-name "Profile for My Bluetooth Device (NAP)" autoconnect no bluetoo
```

For DUN connections, the user needs to configure modem settings and hence no profile gets created automatically. The modem settings depend on your device and you either need a "gsm" or a "csma" section. For example,

```
$ nmcli connection add type bluetooth con-name "Profile for My Bluetooth Device (DUN)" autoconnect no bluetoo
```

Finally, you can create a bluetooth hotspot. BlueZ implements those as a bridge device, so such profiles also have a bridge section. Also, you probably want to set IP methods as "shared", so that clients get automatic IP addressing. Note that the "shared" IPv4 method requires dnsmasq to be available.

```
$ nmcli connection add type bluetooth con-name "My Bluetooth Hotspot" autoconnect no ifname btnap0 bluetooth
```

NAME

nmcli – command-line tool for controlling NetworkManager

SYNOPSIS

```
nmcli [OPTIONS...] {help | general | networking | radio | connection | device | agent | monitor}  
[COMMAND] [ARGUMENTS...]
```

DESCRIPTION

nmcli is a command-line tool for controlling NetworkManager and reporting network status. It can be utilized as a replacement for **nm-applet** or other graphical clients. **nmcli** is used to create, display, edit, delete, activate, and deactivate network connections, as well as control and display network device status. See **nmcli-examples(7)** for ready to run nmcli examples.

Typical uses include:

- Scripts: Utilize NetworkManager via **nmcli** instead of managing network connections manually. **nmcli** supports a terse output format which is better suited for script processing. Note that NetworkManager can also execute scripts, called "dispatcher scripts", in response to network events. See **NetworkManager(8)** for details about these dispatcher scripts.
- Servers, headless machines, and terminals: **nmcli** can be used to control NetworkManager without a GUI, including creating, editing, starting and stopping network connections and viewing network status.

OPTIONS

-a | **--ask**

When using this option **nmcli** will stop and ask for any missing required arguments, so do not use this option for non-interactive purposes like scripts. This option controls, for example, whether you will be prompted for a password if it is required for connecting to a network.

-c | **--colors** {yes | no | auto}

This option controls color output (using terminal escape sequences). yes enables colors, no disables them, auto only produces colors when standard output is directed to a terminal. The default value is auto.

The actual colors used are configured as described in **terminal-colors.d(5)**. Please refer to the COLORS section for a list of color names supported by **nmcli**.

If the environment variable NO_COLOR is set (to any value), then coloring is disabled with mode "auto". Explicitly enabling coloring overrides the environment variable.

--complete-args

Instead of conducting the desired action, **nmcli** will list possible completions for the last argument. This is useful to implement argument completion in shell.

The exit status will indicate success or return a code 65 to indicate the last argument is a file name.

NetworkManager ships with command completion support for GNU Bash.

-e | **--escape** {yes | no}

Whether to escape : and \ characters in terse tabular mode. The escape character is \.

If omitted, default is yes.

-f | **--fields** {field1,field2... | all | common}

This option is used to specify what fields (column names) should be printed. Valid field names differ for specific commands. List available fields by providing an invalid value to the **--fields** option. all is used to print all valid field values of the command. common is used to print common field values of the command.

If omitted, default is common.

-g | --get-values {field1,field2... | all | common}

This option is used to print values from specific fields. It is basically a shortcut for --mode tabular --terse --fields and is a convenient way to retrieve values for particular fields. The values are printed one per line without headers.

If a section is specified instead of a field, the section name will be printed followed by colon separated values of the fields belonging to that section, all on the same line.

-h | --help

Print help information.

-m | --mode {tabular | multiline}

Switch between tabular and multiline output:

tabular

Output is a table where each line describes a single entry. Columns define particular properties of the entry.

multiline

Each entry comprises multiple lines, each property on its own line. The values are prefixed with the property name.

If omitted, default is tabular for most commands. For the commands producing more structured information, that cannot be displayed on a single line, default is multiline. Currently, they are:

- nmcli connection show *ID*
- nmcli device show

-p | --pretty

Output is pretty. This causes **nmcli** to produce easily readable outputs for humans, i.e. values are aligned, headers are printed, etc.

-s | --show-secrets

When using this option **nmcli** will display passwords and secrets that might be present in an output of an operation. This option also influences echoing passwords typed by user as an input.

-t | --terse

Output is terse. This mode is designed and suitable for computer (script) processing.

-v | --version

Show **nmcli** version.

-w | --wait seconds

This option sets a timeout period for which **nmcli** will wait for NetworkManager to finish operations. It is especially useful for commands that may take a longer time to complete, e.g. connection activation.

Specifying a value of 0 instructs **nmcli** not to wait but to exit immediately with a status of success. The default value depends on the executed command.

GENERAL COMMANDS

nmcli general {status | hostname | permissions | logging | reload} [ARGUMENTS...]

Use this command to show NetworkManager status and permissions. You can also get and change system hostname, as well as NetworkManager logging level and domains.

status

Show overall status of NetworkManager. This is the default action, when no additional command is provided for **nmcli general**.

hostname [hostname]

Get and change system hostname. With no arguments, this prints currently configured hostname. When you pass a hostname, it will be handed over to NetworkManager to be set as a new system hostname.

Note that the term "system" hostname may also be referred to as "persistent" or "static" by other programs or tools. The hostname is stored in /etc/hostname file in most distributions. For example, systemd-hostnamed service uses the term "static" hostname and it only reads the /etc/hostname file when it starts.

permissions

Show the permissions a caller has for various authenticated operations that NetworkManager provides, like enable and disable networking, changing Wi-Fi and WWAN state, modifying connections, etc.

logging [level level] [domains domains...]

Get and change NetworkManager logging level and domains. Without any argument current logging level and domains are shown. In order to change logging state, provide **level** and, or, **domain** parameters. See **NetworkManager.conf(5)** for available level and domain values.

reload [flags...]

Reload NetworkManager's configuration and perform certain updates, like flushing caches or rewriting external state to disk. This is similar to sending SIGHUP to NetworkManager but it allows for more fine-grained control over what to reload through the flags argument. It also allows non-root access via PolicyKit and contrary to signals it is synchronous. Available flags are:

conf

Reload the NetworkManager.conf configuration from disk. Note that this does not include connections, which can be reloaded through **nmcli connection reload** instead.

dns-rc

Update DNS configuration, which usually involves writing /etc/resolv.conf anew. This is equivalent to sending the SIGUSR1 signal to the NetworkManager process.

dns-full

Restart the DNS plugin. This is for example useful when using dnsmasq plugin, which uses additional configuration in /etc/NetworkManager/dnsmasq.d. If you edit those files, you can restart the DNS plugin. This action shortly interrupts name resolution.

With no flags, everything that is supported is reloaded, which is identical to sending a SIGHUP. See **NetworkManager(8)** for more details about signals.

NETWORKING CONTROL COMMANDS

nmcli networking {on | off | connectivity} [ARGUMENTS...]

Query NetworkManager networking status, enable and disable networking.

on, off

Enable or disable networking control by NetworkManager. All interfaces managed by NetworkManager are deactivated when networking is disabled.

connectivity [check]

Get network connectivity state. The optional **check** argument tells NetworkManager to re-check the connectivity, else the most recent known connectivity state is displayed without re-checking.

Possible states are:

none

the host is not connected to any network.

portal

the host is behind a captive portal and cannot reach the full Internet.

limited

the host is connected to a network, but it has no access to the Internet.

full

the host is connected to a network and has full access to the Internet.

unknown

the connectivity status cannot be found out.

RADIO TRANSMISSION CONTROL COMMANDS

nmcli radio {all | wifi | wwan} [ARGUMENTS...]

Show radio switches status, or enable and disable the switches.

wifi [on | off]

Show or set status of Wi-Fi in NetworkManager. If no arguments are supplied, Wi-Fi status is printed; **on** enables Wi-Fi; **off** disables Wi-Fi.

wwan [on | off]

Show or set status of WWAN (mobile broadband) in NetworkManager. If no arguments are supplied, mobile broadband status is printed; **on** enables mobile broadband, **off** disables it.

all [on | off]

Show or set all previously mentioned radio switches at the same time.

ACTIVITY MONITOR

nmcli monitor

Observe NetworkManager activity. Watches for changes in connectivity state, devices or connection profiles.

See also **nmcli connection monitor** and **nmcli device monitor** to watch for changes in certain devices or connections.

CONNECTION MANAGEMENT COMMANDS

nmcli connection {show | up | down | modify | add | edit | clone | delete | monitor | reload | load | import | export} [ARGUMENTS...]

NetworkManager stores all network configuration as "connections", which are collections of data (Layer2 details, IP addressing, etc.) that describe how to create or connect to a network. A connection is "active" when a device uses that connection's configuration to create or connect to a network. There may be multiple connections that apply to a device, but only one of them can be active on that device at any given time. The additional connections can be used to allow quick switching between different networks and configurations.

Consider a machine which is usually connected to a DHCP-enabled network, but sometimes connected to a testing network which uses static IP addressing. Instead of manually reconfiguring eth0 each time the network is changed, the settings can be saved as two connections which both apply to eth0, one for DHCP (called default) and one with the static addressing details (called testing). When connected to the DHCP-enabled network the user would run **nmcli con up default**, and when connected to the static network the user would run **nmcli con up testing**.

show [--active] [--order [+--]category:...]

List in-memory and on-disk connection profiles, some of which may also be active if a device is using that connection profile. Without a parameter, all profiles are listed. When **--active** option is specified, only the active profiles are shown.

The **--order** option can be used to get custom ordering of connections. The connections can be ordered by active status (active), name (name), type (type) or D-Bus path (path). If connections are equal according to a sort order category, an additional category can be specified. The default sorting order is equivalent to **--order active:name:path**. + or no prefix means sorting in ascending order (alphabetically or in numbers), - means reverse (descending) order. The category names can be abbreviated (e.g. **--order -a:na**).

show [--active] [id | uuid | path | apath] ID...

Show details for specified connections. By default, both static configuration and active connection data are displayed. When **--active** option is specified, only the active profiles are taken into account. Use global **--show-secrets** option to display secrets associated with the profile.

id, **uuid**, **path** and **apath** keywords can be used if *ID* is ambiguous. Optional *ID*-specifying keywords are:

id

the *ID* denotes a connection name.

uuid

the *ID* denotes a connection UUID.

path

the *ID* denotes a D-Bus static connection path in the format of
`/org/freedesktop/NetworkManager/Settings/num` or just *num*.

apath

the *ID* denotes a D-Bus active connection path in the format of
`/org/freedesktop/NetworkManager/ActiveConnection/num` or just *num*.

It is possible to filter the output using the global **--fields** option. Use the following values:

profile

only shows static profile configuration.

active

only shows active connection data (when the profile is active).

You can also specify particular fields. For static configuration, use setting and property names as described in **nm-settings-nmcli(5)** manual page. For active data use GENERAL, IP4, DHCP4, IP6, DHCP6, VPN.

When no command is given to the **nmcli connection**, the default action is **nmcli connection show**.

up [id | uuid | path] ID [ifname ifname] [ap BSSID] [passwd-file file]

Activate a connection. The connection is identified by its name, UUID or D-Bus path. If *ID* is ambiguous, a keyword **id**, **uuid** or **path** can be used. When requiring a particular device to activate the connection on, the **ifname** option with interface name should be given. If the *ID* is not given an **ifname** is required, and NetworkManager will activate the best available connection for the given **ifname**. In case of a VPN connection, the **ifname** option specifies the device of the base connection. The **ap** option specify what particular AP should be used in case of a Wi-Fi connection.

If **--wait** option is not specified, the default timeout will be 90 seconds.

See **connection show** above for the description of the *ID*-specifying keywords.

Available options are:

ifname

interface that will be used for activation.

ap

BSSID of the AP which the command should connect to (for Wi-Fi connections).

passwd-file

some networks may require credentials during activation. You can give these credentials using this option. Each line of the file should contain one password in the form:

`setting_name.property_name:the password`

For example, for WPA Wi-Fi with PSK, the line would be

```
802-11-wireless-security.psk:secret12345
```

For 802.1X password, the line would be

```
802-1x.password:my 1X password
```

nmcli also accepts wifi-sec and wifi strings instead of 802-11-wireless-security. When NetworkManager requires a password and it is not given, **nmcli** will ask for it when run with --ask. If --ask was not passed, NetworkManager can ask another secret agent that may be running (typically a GUI secret agent, such as nm-applet or gnome-shell).

down [id | uuid | path | apath] ID...

Deactivate a connection from a device without preventing the device from further auto-activation. Multiple connections can be passed to the command.

Be aware that this command deactivates the specified active connection, but the device on which the connection was active, is still ready to connect and will perform auto-activation by looking for a suitable connection that has the 'autoconnect' flag set. Note that the deactivating connection profile is internally blocked from autoconnecting again. Hence it will not autoconnect until reboot or until the user performs an action that unblocks autoconnect, like modifying the profile or explicitly activating it.

In most cases you may want to use **device down** command instead.

The connection is identified by its name, UUID or D-Bus path. If *ID* is ambiguous, a keyword **id**, **uuid**, **path** or **apath** can be used.

See **connection show** above for the description of the *ID*-specifying keywords.

If --wait option is not specified, the default timeout will be 10 seconds.

modify [--temporary] [id | uuid | path] ID {option value | [+|-]setting.property value}...

Add, modify or remove properties in the connection profile.

To set the property just specify the property name followed by the value. An empty value ("") resets the property value to the default.

See **nm-settings-nmcli(5)** for complete reference of setting and property names, their descriptions and default values. The *setting* and *property* can be abbreviated provided they are unique.

If you want to append an item or a flag to the existing value, use + prefix for the property name or alias. If you want to remove items from a container-type or flag property, use - prefix. For certain properties you can also remove elements by specifying the zero-based index(es). The + and - modifiers only have a real effect for properties that support them. These are for example multi-value (container) properties or flags like ipv4.dns, ip4, ipv4.addresses, bond.options, 802-1x.phase1-auth-flags etc.

The connection is identified by its name, UUID or D-Bus path. If *ID* is ambiguous, a keyword **id**, **uuid** or **path** can be used.

modify [--temporary] [id | uuid | path] ID remove setting

Removes a setting from the connection profile.

add [save {yes | no}] {option value | [+|-]setting.property value}...

Create a new connection using specified properties.

You need to describe the newly created connections with the property and value pairs. See **nm-settings-nmcli(5)** for the complete reference. The syntax is the same as of the **nmcli connection modify** command.

To construct a meaningful connection you at the very least need to set the **connection.type** property (or use the **type** alias) to one of known NetworkManager connection types:

- 6lowpan
- 802-11-olpc-mesh (alias olpc-mesh)
- 802-11-wireless (alias wifi)
- 802-3-ethernet (alias ethernet)
- adsl
- bluetooth
- bond
- bond-slave (deprecated for ethernet with master)
- bridge
- bridge-slave (deprecated for ethernet with master)
- cdma
- dummy
- generic
- gsm
- infiniband
- ip-tunnel
- macsec
- macvlan
- olpc-mesh
- ovs-bridge
- ovs-dpdk
- ovs-interface
- ovs-patch
- ovs-port
- pppoe
- team
- team-slave (deprecated for ethernet with master)
- tun
- veth
- vlan
- vpn
- vrf
- vxlan
- wifi-p2p

- wimax
- wireguard
- wpan

The most typical uses are described in the EXAMPLES section.

Aside from the properties and values two special options are accepted:

save

Controls whether the connection should be persistent, i.e. NetworkManager should store it on disk (default: yes).

If a single -- argument is encountered it is ignored. This is for compatibility with older versions on **nmcli**.

edit {[id | uuid | path] ID | [type type] [con-name name]}

Edit an existing connection or add a new one, using an interactive editor.

The existing connection is identified by its name, UUID or D-Bus path. If *ID* is ambiguous, a keyword **id**, **uuid**, or **path** can be used. See **connection show** above for the description of the *ID*-specifying keywords. Not providing an *ID* means that a new connection will be added.

The interactive editor will guide you through the connection editing and allow you to change connection parameters according to your needs by means of a simple menu-driven interface. The editor indicates what settings and properties can be modified and provides in-line help.

Available options:

type

type of the new connection; valid types are the same as for **connection add** command.

con-name

name for the new connection. It can be changed later in the editor.

See also **nm-settings-nmcli(5)** for all NetworkManager settings and property names, and their descriptions; and **nmcli-examples(7)** for sample editor sessions.

clone [--temporary] [id | uuid | path] ID new_name

Clone a connection. The connection to be cloned is identified by its name, UUID or D-Bus path. If *ID* is ambiguous, a keyword **id**, **uuid** or **path** can be used. See **connection show** above for the description of the *ID*-specifying keywords. *new_name* is the name of the new cloned connection. The new connection will be the exact copy except the connection.id (*new_name*) and connection.uuid (generated) properties.

The new connection profile will be saved as persistent unless **--temporary** option is specified, in which case the new profile won't exist after NetworkManager restart.

delete [id | uuid | path] ID...

Delete a configured connection. The connection to be deleted is identified by its name, UUID or D-Bus path. If *ID* is ambiguous, a keyword **id**, **uuid** or **path** can be used. See **connection show** above for the description of the *ID*-specifying keywords.

If **--wait** option is not specified, the default timeout will be 10 seconds.

monitor [id | uuid | path] ID...

Monitor connection profile activity. This command prints a line whenever the specified connection changes. The connection to be monitored is identified by its name, UUID or D-Bus path. If *ID* is

ambiguous, a keyword **id**, **uuid** or **path** can be used. See **connection show** above for the description of the *ID*-specifying keywords.

Monitors all connection profiles in case none is specified. The command terminates when all monitored connections disappear. If you want to monitor connection creation consider using the global monitor with **nmcli monitor** command.

reload

Reload all connection files from disk. NetworkManager does not monitor changes to connection. So you need to use this command in order to tell NetworkManager to re-read the connection profiles from disk when a change was made to them.

load *filename...*

Load/reload one or more connection files from disk. Use this after manually editing a connection file to ensure that NetworkManager is aware of its latest state.

import [**--temporary**] **type** *type* **file** *file*

Import an external/foreign configuration as a NetworkManager connection profile. The type of the input file is specified by **type** option.

Only VPN configurations are supported at the moment. The configuration is imported by NetworkManager VPN plugins. **type** values are the same as for **vpn-type** option in **nmcli connection add**. VPN configurations are imported by VPN plugins. Therefore the proper VPN plugin has to be installed so that **nmcli** could import the data.

The imported connection profile will be saved as persistent unless **--temporary** option is specified, in which case the new profile won't exist after NetworkManager restart.

export [**id** | **uuid** | **path**] *ID* [*file*]

Export a connection.

Only VPN connections are supported at the moment. A proper VPN plugin has to be installed so that **nmcli** could export a connection. If no *file* is provided, the VPN configuration data will be printed to standard output.

DEVICE MANAGEMENT COMMANDS

```
nmcli device {status | show | set | up | connect | reapply | modify | down | disconnect | delete | monitor |
              wifi | llidp} {ARGUMENTS...}
```

Show and manage network interfaces.

status

Print status of devices.

This is the default action if no command is specified to **nmcli device**.

show [*ifname*]

Show detailed information about devices. Without an argument, all devices are examined. To get information for a specific device, the interface name has to be provided.

set [*ifname*] *ifname* [**autoconnect** {yes | no}] [**managed** {yes | no}]

Set device properties.

up *ifname*

Connect the device. NetworkManager will try to find a suitable connection that will be activated. It will also consider connections that are not set to auto connect.

If no compatible connection exists, a new profile with default settings will be created and activated. This differentiates **nmcli connection up ifname "\$DEVICE"** from **nmcli device up "\$DEVICE"**

If **--wait** option is not specified, the default timeout will be 90 seconds.

connect *ifname*

Alias for command **up**. Before version 1.34.0 **up** was not supported.

reapply *ifname*

Attempt to update device with changes to the currently active connection made since it was last applied.

modify *ifname* {*option value* | [+|-]*setting.property value*}...

Modify the settings currently active on the device.

This command lets you do temporary changes to a configuration active on a particular device. The changes are not preserved in the connection profile.

See **nm-settings-nmcli(5)** for the list of available properties. Please note that some properties can't be changed on an already connected device.

down *ifname*...

Disconnect a device and prevent the device from automatically activating further connections without user/manual intervention. Note that disconnecting software devices may mean that the devices will disappear.

If **--wait** option is not specified, the default timeout will be 10 seconds.

disconnect *ifname*...

Alias for command **down**. Before version 1.34.0 **down** was not supported.

delete *ifname*...

Delete a device. The command removes the interface from the system. Note that this only works for software devices like bonds, bridges, teams, etc. Hardware devices (like Ethernet) cannot be deleted by the command.

If **--wait** option is not specified, the default timeout will be 10 seconds.

monitor [*ifname*...]

Monitor device activity. This command prints a line whenever the specified devices change state.

Monitors all devices in case no interface is specified. The monitor terminates when all specified devices disappear. If you want to monitor device addition consider using the global monitor with **nmcli monitor** command.

wifi [list [--rescan | auto | no | yes] [*ifname ifname*] [**bssid** *BSSID*]]

List available Wi-Fi access points. The **ifname** and **bssid** options can be used to list APs for a particular interface or with a specific BSSID, respectively.

By default, **nmcli** ensures that the access point list is no older than 30 seconds and triggers a network scan if necessary. The **--rescan** can be used to either force or disable the scan regardless of how fresh the access point list is.

wifi connect(B)*SSID* [**passw ord** *password*] [**wep–key–type** {key | phrase}] [*ifname ifname*] [**bssid** *BSSID*] [**name** *name*] [**private** {yes | no}] [**hidden** {yes | no}])

Connect to a Wi-Fi network specified by SSID or BSSID. The command finds a matching connection or creates one and then activates it on a device. This is a command-line counterpart of clicking an SSID in a GUI client. If a connection for the network already exists, it is possible to bring up (activate) the existing profile as follows: **nmcli con up id** *name*. Note that only open, WEP and WPA-PSK networks are supported if no previous connection exists. It is also assumed that IP configuration is obtained via DHCP.

If **--wait** option is not specified, the default timeout will be 90 seconds.

Available options are:

password

password for secured networks (WEP or WPA).

wep-key-type

type of WEP secret, either **key** for ASCII/HEX key or **phrase** for passphrase.

ifname

interface that will be used for activation.

bssid

if specified, the created connection will be restricted just for the BSSID.

name

if specified, the connection will use the name (else NM creates a name itself).

private

if set to yes, the connection will only be visible to the user who created it. Otherwise, the connection is system-wide, which is the default.

hidden

set to yes when connecting for the first time to an AP not broadcasting its SSID. Otherwise, the SSID would not be found and the connection attempt would fail.

wifi hotspot[ifname ifname] [con-name name] [ssid SSID] [band {a | bg}] [channel c channel] [password password]

Create a Wi-Fi hotspot. The command creates a hotspot connection profile according to Wi-Fi device capabilities and activates it on the device. The hotspot is secured with WPA if device/driver supports that, otherwise WEP is used. Use **connection down** or **device down** to stop the hotspot.

Parameters of the hotspot can be influenced by the optional parameters:

ifname

what Wi-Fi device is used.

con-name

name of the created hotspot connection profile.

ssid

SSID of the hotspot.

band

Wi-Fi band to use.

channel

Wi-Fi channel to use.

password

password to use for the created hotspot. If not provided, **nmcli** will generate a password. The password is either WPA pre-shared key or WEP key.

Note that **--show-secrets** global option can be used to print the hotspot password. It is useful especially when the password was generated.

wifi rescan [ifname ifname] [ssid SSID...]

Request that NetworkManager immediately re-scan for available access points. NetworkManager scans Wi-Fi networks periodically, but in some cases it can be useful to start scanning manually (e.g. after resuming the computer). By using **ssid**, it is possible to scan for a specific SSID, which is useful for APs with hidden SSIDs. You can provide multiple **ssid** parameters in order to scan more SSIDs.

This command does not show the APs, use **nmcli device wifi list** for that.

wifi show-password [ifname ifname]

Show the details of the active Wi-Fi networks, including the secrets.

lldp [list [ifname ifname]]

Display information about neighboring devices learned through the Link Layer Discovery Protocol (LLDP). The **ifname** option can be used to list neighbors only for a given interface. The protocol must be enabled in the connection settings.

SECRET AGENT

nmcli agent {secret | polkit | all}

Run **nmcli** as a NetworkManager secret agent, or polkit agent.

secret

Register **nmcli** as a NetworkManager secret agent and listen for secret requests. You usually do not need this command, because **nmcli** can handle secrets when connecting to networks. However, you may find the command useful when you use another tool for activating connections and you do not have a secret agent available (like nm-applet).

polkit

Register **nmcli** as a polkit agent for the user session and listen for authorization requests. You do not usually need this command, because **nmcli** can handle polkit actions related to NetworkManager operations (when run with **--ask**). However, you may find the command useful when you want to run a simple text based polkit agent and you do not have an agent of a desktop environment. Note that running this command makes **nmcli** handle all polkit requests, not only NetworkManager related ones, because only one polkit agent can run for the session.

all

Runs **nmcli** as both NetworkManager secret and a polkit agent.

COLORS

Implicit coloring can be disabled by an empty file /etc/terminal-colors.d/nmcli.disable.

See **terminal-colors.d(5)** for more details about colorization configuration. The logical color names supported by **nmcli** are:

connection-activated

A connection that is active.

connection-activating

Connection that is being activated.

connection-disconnecting

Connection that is being disconnected.

connection-external

Connection representing configuration created externally to NetworkManager.

connection-invisible

Connection whose details is the user not permitted to see.

connectivity-full

Connectivity state when Internet is reachable.

connectivity-limited

Connectivity state when only a local network reachable.

connectivity-none

Connectivity state when the network is disconnected.

connectivity-portal

Connectivity state when a captive portal hijacked the connection.

connectivity-unknown

Connectivity state when a connectivity check didn't run.

device-activated

Device that is connected.

device-activating

Device that is being configured.

device-disconnected

Device that is not connected.

device-external

Device configured externally to NetworkManager.

device-firmware-missing

Warning of a missing device firmware.

device-plugin-missing

Warning of a missing device plugin.

device-unavailable

Device that is not available for activation.

device-disabled

Device is disabled by software or hardware kill switch.

manager-running

Notice that the NetworkManager daemon is available.

manager-starting

Notice that the NetworkManager daemon is being initially connected.

manager-stopped

Notice that the NetworkManager daemon is not available.

permission-auth

An action that requires user authentication to get permission.

permission-no

An action that is not permitted.

permission-yes

An action that is permitted.

prompt

Prompt in interactive mode.

state-asleep

Indication that NetworkManager in suspended state.

state-connected-global

Indication that NetworkManager in connected to Internet.

state-connected-local

Indication that NetworkManager in local network.

state-connected-site

Indication that NetworkManager in connected to networks other than Internet.

state-connecting

Indication that NetworkManager is establishing a network connection.

state-disconnected

Indication that NetworkManager is disconnected from a network.

state-disconnecting

Indication that NetworkManager is being disconnected from a network.

wifi-signal-excellent

Wi-Fi network with an excellent signal level.

wifi-signal-fair

Wi-Fi network with a fair signal level.

wifi-signal-good

Wi-Fi network with a good signal level.

wifi-signal-poor

Wi-Fi network with a poor signal level.

wifi-signal-unknown

Wi-Fi network that hasn't been actually seen (a hidden AP).

disabled

A property that is turned off.

enabled

A property that is turned on.

ENVIRONMENT VARIABLES

nmcli's behavior is affected by the following environment variables.

LC_ALL

If set to a non-empty string value, it overrides the values of all the other internationalization variables.

LC_MESSAGES

Determines the locale to be used for internationalized messages.

LANG

Provides a default value for the internationalization variables that are unset or null.

INTERNATIONALIZATION NOTES

Be aware that **nmcli** is localized and that is why the output depends on your environment. This is important to realize especially when you parse the output.

Call **nmcli** as **LC_ALL=C nmcli** to be sure the locale is set to C while executing in a script.

LC_ALL, **LC_MESSAGES**, **LANG** variables specify the **LC_MESSAGES** locale category (in that order), which determines the language that **nmcli** uses for messages. The C locale is used if none of these variables are set, and this locale uses English messages.

EXIT STATUS

nmcli exits with status 0 if it succeeds, a value greater than 0 is returned if an error occurs.

0

Success – indicates the operation succeeded.

1

Unknown or unspecified error.

2

Invalid user input, wrong **nmcli** invocation.

3

Timeout expired (see **--wait** option).

4

Connection activation failed.

5

Connection deactivation failed.

6

Disconnecting device failed.

7

Connection deletion failed.

8

NetworkManager is not running.

10

Connection, device, or access point does not exist.

65

When used with **--complete-args** option, a file name is expected to follow.

EXAMPLES

This section presents various examples of **nmcli** usage. If you want even more, please refer to **nmcli-examples(7)** manual page.

nmcli -t -f RUNNING general

tells you whether NetworkManager is running or not.

nmcli -t -f STATE general

shows the overall status of NetworkManager.

nmcli radio wifi off

switches Wi-Fi off.

nmcli connection show

lists all connections NetworkManager has.

nmcli -p -m multiline -f all con show

shows all configured connections in multi-line mode.

nmcli connection show --active

lists all currently active connections.

nmcli -f name,autoconnect c s

shows all connection profile names and their auto-connect property.

nmcli -p connection show "My default em1"

shows details for "My default em1" connection profile.

nmcli --show-secrets connection show "My Home Wi-Fi"

shows details for "My Home Wi-Fi" connection profile with all passwords. Without **--show-secrets** option, secrets would not be displayed.

nmcli -f active connection show "My default em1"

shows details for "My default em1" active connection, like IP, DHCP information, etc.

nmcli -f profile con s "My wired connection"

shows static configuration details of the connection profile with "My wired connection" name.

nmcli -p con up "My wired connection" ifname eth0

activates the connection profile with name "My wired connection" on interface eth0. The **-p** option makes **nmcli** show progress of the activation.

nmcli con up 6b028a27-6dc9-4411-9886-e9ad1dd43761 ap 00:3A:98:7C:42:D3

connects the Wi-Fi connection with UUID 6b028a27-6dc9-4411-9886-e9ad1dd43761 to the AP with BSSID 00:3A:98:7C:42:D3.

nmcli device status

shows the status for all devices.

nmcli dev down em2

disconnects a connection on interface em2 and marks the device as unavailable for auto-connecting.

As a result, no connection will automatically be activated on the device until the device's 'autoconnect' is set to TRUE or the user manually activates a connection.

nmcli -f GENERAL,WIFI-PROPERTIES dev show wlan0

shows details for wlan0 interface; only GENERAL and WIFI-PROPERTIES sections will be shown.

nmcli -f CONNECTIONS device show wlp3s0

shows all available connection profiles for your Wi-Fi interface wlp3s0.

nmcli dev wifi

lists available Wi-Fi access points known to NetworkManager.

nmcli dev wifi con "Cafe Hotspot 1" password caffeine name "My cafe"

creates a new connection named "My cafe" and then connects it to "Cafe Hotspot 1" SSID using password "caffeine". This is mainly useful when connecting to "Cafe Hotspot 1" for the first time.

Next time, it is better to use **nmcli con up id "My cafe"** so that the existing connection profile can be used and no additional is created.

nmcli -s dev wifi hotspot con-name QuickHotspot

creates a hotspot profile and connects it. Prints the hotspot password the user should use to connect to the hotspot from other devices.

nmcli dev modify em1 ipv4.method shared

starts IPv4 connection sharing using em1 device. The sharing will be active until the device is disconnected.

nmcli dev modify em1 ipv6.address 2001:db8::a:bad:c0de

temporarily adds an IP address to a device. The address will be removed when the same connection is activated again.

nmcli connection add type ethernet autoconnect no ifname eth0

non-interactively adds an Ethernet connection tied to eth0 interface with automatic IP configuration (DHCP), and disables the connection's autoconnect flag.

nmcli c a ifname Maxipes-fik type vlan dev eth0 id 55

non-interactively adds a VLAN connection with ID 55. The connection will use eth0 and the VLAN interface will be named Maxipes-fik.

nmcli c a ifname eth0 type ethernet ipv4.method disabled ipv6.method link-local

non-interactively adds a connection that will use eth0 Ethernet interface and only have an IPv6 link-local address configured.

nmcli connection edit ethernet-em1-2

edits existing "ethernet-em1-2" connection in the interactive editor.

nmcli connection edit type ethernet con-name "yet another Ethernet connection"

adds a new Ethernet connection in the interactive editor.

nmcli con mod ethernet-2 connection.autoconnect no

modifies 'autoconnect' property in the 'connection' setting of 'ethernet-2' connection.

nmcli con mod "Home Wi-Fi" wifi.mtu 1350

modifies 'mtu' property in the 'wifi' setting of 'Home Wi-Fi' connection.

nmcli con mod em1-1 ipv4.method manual ipv4.addr "192.168.1.23/24 192.168.1.1, 10.10.1.5/8, 10.0.0.11"

sets manual addressing and the addresses in em1-1 profile.

nmcli con modify ABC +ipv4.dns 8.8.8.8

appends a Google public DNS server to DNS servers in ABC profile.

nmcli con modify ABC -ipv4.addresses "192.168.100.25/24 192.168.1.1"

removes the specified IP address from (static) profile ABC.

nmcli con import type openvpn file ~/Downloads/frootvpn.ovpn

imports an OpenVPN configuration to NetworkManager.

nmcli con export corp-vpnc /home/joe/corpvpnc.conf

exports NetworkManager VPN profile corp-vpnc as standard Cisco (vpnc) configuration.

NOTES

nmcli accepts abbreviations, as long as they are a unique prefix in the set of possible options. As new options get added, these abbreviations are not guaranteed to stay unique. For scripting and long term compatibility it is therefore strongly advised to spell out the full option names.

BUGS

There are probably some bugs. If you find a bug, please report it to your distribution or upstream at <https://gitlab.freedesktop.org/NetworkManager/NetworkManager>.

NAME

nohup – run a command immune to hangups, with output to a non-tty

SYNOPSIS

nohup *COMMAND* [*ARG*]...
nohup *OPTION*

DESCRIPTION

Run *COMMAND*, ignoring hangup signals.

--help display this help and exit

--version

output version information and exit

If standard input is a terminal, redirect it from an unreadable file. If standard output is a terminal, append output to 'nohup.out' if possible, '\$HOME/nohup.out' otherwise. If standard error is a terminal, redirect it to standard output. To save output to FILE, use 'nohup *COMMAND* > FILE'.

NOTE: your shell may have its own version of nohup, which usually supersedes the version described here. Please refer to your shell's documentation for details about the options it supports.

NAME

nslookup – query Internet name servers interactively

SYNOPSIS

nslookup [–option] [name | –] [server]

DESCRIPTION

nslookup is a program to query Internet domain name servers. **nslookup** has two modes: interactive and non-interactive. Interactive mode allows the user to query name servers for information about various hosts and domains or to print a list of hosts in a domain. Non-interactive mode prints just the name and requested information for a host or domain.

ARGUMENTS

Interactive mode is entered in the following cases:

- when no arguments are given (the default name server is used);
- when the first argument is a hyphen (–) and the second argument is the host name or Internet address of a name server.

Non-interactive mode is used when the name or Internet address of the host to be looked up is given as the first argument. The optional second argument specifies the host name or address of a name server.

Options can also be specified on the command line if they precede the arguments and are prefixed with a hyphen. For example, to change the default query type to host information, with an initial timeout of 10 seconds, type:

```
nslookup -query=hinfo -timeout=10
```

The **–version** option causes **nslookup** to print the version number and immediately exit.

INTERACTIVE COMMANDS**host [server]**

This command looks up information for **host** using the current default server or using **server**, if specified. If **host** is an Internet address and the query type is A or PTR, the name of the host is returned. If **host** is a name and does not have a trailing period (.), the search list is used to qualify the name.

To look up a host not in the current domain, append a period to the name.

server domain | lserver domain

These commands change the default server to **domain**; **lserver** uses the initial server to look up information about **domain**, while **server** uses the current default server. If an authoritative answer cannot be found, the names of servers that might have the answer are returned.

- | | |
|---------------|----------------------------------|
| root | This command is not implemented. |
| finger | This command is not implemented. |
| ls | This command is not implemented. |
| view | This command is not implemented. |
| help | This command is not implemented. |
| ? | This command is not implemented. |
| exit | This command exits the program. |

set keyword[=value]

This command is used to change state information that affects the lookups. Valid keywords are:

- | | |
|------------|--|
| all | This keyword prints the current values of the frequently used options to set . Information about the current default server and host is also printed. |
|------------|--|

class=value

This keyword changes the query class to one of:

- IN** the Internet class
- CH** the Chaos class
- HS** the Hesiod class
- ANY** wildcard

The class specifies the protocol group of the information. The default is **IN**; the abbreviation for this keyword is **cl**.

nodebug

This keyword turns on or off the display of the full response packet, and any intermediate response packets, when searching. The default for this keyword is **nodebug**; the abbreviation for this keyword is **[no]deb**.

- nod2** This keyword turns debugging mode on or off. This displays more about what nslookup is doing. The default is **nod2**.

domain=name

This keyword sets the search list to **name**.

nosearch

If the lookup request contains at least one period, but does not end with a trailing period, this keyword appends the domain names in the domain search list to the request until an answer is received. The default is **search**.

port=value

This keyword changes the default TCP/UDP name server port to **value** from its default, port 53. The abbreviation for this keyword is **po**.

querytype=value | type=value

This keyword changes the type of the information query to **value**. The defaults are **A** and then **AAAA**; the abbreviations for these keywords are **q** and **ty**.

Please note that it is only possible to specify one query type. Only the default behavior looks up both when an alternative is not specified.

norecurse

This keyword tells the name server to query other servers if it does not have the information. The default is **recurse**; the abbreviation for this keyword is **[no]rec**.

ndots=number

This keyword sets the number of dots (label separators) in a domain that disables searching. Absolute names always stop searching.

retry=number

This keyword sets the number of retries to **number**.

timeout=number

This keyword changes the initial timeout interval to wait for a reply to **number**, in seconds.

- novc** This keyword indicates that a virtual circuit should always be used when sending requests to the server. **novc** is the default.
- nofail** This keyword tries the next nameserver if a nameserver responds with SERVFAIL or a referral (nofail), or terminates the query (fail) on such a response. The default is **nofail**.

RETURN VALUES

nslookup returns with an exit status of 1 if any query failed, and 0 otherwise.

IDN SUPPORT

If **nslookup** has been built with IDN (internationalized domain name) support, it can accept and display non-ASCII domain names. **nslookup** appropriately converts character encoding of a domain name before sending a request to a DNS server or displaying a reply from the server. To turn off IDN support, define the **IDN_DISABLE** environment variable. IDN support is disabled if the variable is set when **nslookup** runs, or when the standard output is not a tty.

NAME

pam - portable arbitrary map file format

DESCRIPTION

The PAM image format is a lowest common denominator 2 dimensional map format.

It is designed to be used for any of myriad kinds of graphics, but can theoretically be used for any kind of data that is arranged as a two dimensional rectangular array. Actually, from another perspective it can be seen as a format for data arranged as a three dimensional array.

This format does not define the meaning of the data at any particular point in the array. It could be red, green, and blue light intensities such that the array represents a visual image, or it could be the same red, green, and blue components plus a transparency component, or it could contain annual rainfalls for places on the surface of the Earth. Any process that uses the PAM format must further define the format to specify the meanings of the data.

A PAM image describes a two dimensional grid of tuples. The tuples are arranged in rows and columns. The width of the image is the number of columns. The height of the image is the number of rows. All rows are the same width and all columns are the same height. The tuples may have any degree, but all tuples have the same degree. The degree of the tuples is called the depth of the image. Each member of a tuple is called a sample. A sample is an unsigned integer which represents a locus along a scale which starts at zero and ends at a certain maximum value greater than zero called the maxval. The maxval is the same for every sample in the image. The two dimensional array of all the Nth samples of each tuple is called the Nth plane or Nth channel of the image.

Though the format does not assign any meaning to the tuple values, it does include an optional string that describes that meaning. The contents of this string, called the tuple type, are arbitrary from the point of view of the PAM format, but users of the format may assign meaning to it by convention so they can identify their particular implementations of the PAM format.

The Layout

A PAM file consists of a sequence of one or more PAM images. There are no data, delimiters, or padding before, after, or between images.

Each PAM image consists of a header followed immediately by a raster.

Here is an example header:

```
P7
WIDTH 227
HEIGHT 149
DEPTH 3
MAXVAL 255
TUPLTYPE RGB
ENDHDR
```

The header begins with the ASCII characters "P7" followed by newline. This is the magic number.

The header continues with an arbitrary number of lines of ASCII text. Each line ends with and is delimited by a newline character.

Each header line consists of zero or more whitespace-delimited tokens or begins with "#". If it begins with "#" it is a comment and the rest of this specification does not apply to it.

A header line which has zero tokens is valid but has no meaning.

The type of header line is identified by its first token, which is 8 characters or less:

ENDHDR

This is the last line in the header. The header must contain exactly one of these header lines.

HEIGHT

The second token is a decimal number representing the height of the image (number of rows). The header must contain exactly one of these header lines.

WIDTH

The second token is a decimal number representing the width of the image (number of columns). The header must contain exactly one of these header lines.

DEPTH

The second token is a decimal number representing the depth of the image (number of planes or channels). The header must contain exactly one of these header lines.

MAXVAL

The second token is a decimal number representing the maxval of the image. The header must contain exactly one of these header lines.

TUPLTYPE

The header may contain any number of these header lines, including zero. The rest of the line is part of the tuple type. The rest of the line is not tokenized, but the tuple type does not include any white space immediately following **TUPLTYPE** or at the very end of the line. It does not include a newline. If there are multiple **TUPL TYPE** header lines, the tuple type is the concatenation of the values from each of them, separated by a single blank, in the order in which they appear in the header. If there are no **TUPL TYPE** header lines the tuple type is the null string.

The raster consists of each row of the image, in order from top to bottom, consecutive with no delimiter of any kind between, before, or after, rows.

Each row consists of every tuple in the row, in order from left to right, consecutive with no delimiter of any kind between, before, or after, tuples.

Each tuple consists of every sample in the tuple, in order, consecutive with no delimiter of any kind between, before, or after, samples.

Each sample consists of an unsigned integer in pure binary format, with the most significant byte first. The number of bytes is the minimum number of bytes required to represent the maxval of the image.

PAM Used For PNM (PBM, PGM, or PPM) Images

A common use of PAM images is to represent the older and more concrete PBM, PGM, and PPM images.

A PBM image is conventionally represented as a PAM image of depth 1 with maxval 1 where the one sample in each tuple is 0 to represent a black pixel and 1 to represent a white one. The height, width, and raster bear the obvious relationship to those of the PBM image. The tuple type for PBM images represented as

PAM images is conventionally "BLACKANDWHITE".

A PGM image is conventionally represented as a PAM image of depth 1. The maxval, height, width, and raster bear the obvious relationship to those of the PGM image. The tuple type for PGM images represented as PAM images is conventionally "GRAYSCALE".

A PPM image is conventionally represented as a PAM image of depth 3. The maxval, height, width, and raster bear the obvious relationship to those of the PPM image. The first plane represents red, the second green, and the third blue. The tuple type for PPM images represented as PAM images is conventionally "RGB".

The Confusing Universe of Netpbm Formats

It is easy to get confused about the relationship between the PAM format and PBM, PGM, PPM, and PNM. Here is a little enlightenment:

"PNM" is not really a format. It is a shorthand for the PBM, PGM, and PPM formats collectively. It is also the name of a group of library functions that can each handle all three of those formats.

"PAM" is in fact a fourth format. But it is so general that you can represent the same information in a PAM image as you can in a PBM, PGM, or PPM image. And in fact a program that is designed to read PBM, PGM, or PPM and does so with a recent version of the Netpbm library, will read an equivalent PAM image just fine and the program will never know the difference.

To confuse things more, there is a collection of library routines called the "pam" functions that read and write the PAM format, but also read and write the PBM, PGM, and PPM formats. They do this because the latter formats are much older and more popular, so this makes it convenient to write programs that use the newer PAM format.

NAME

PAM, pam – Pluggable Authentication Modules for Linux

DESCRIPTION

This manual is intended to offer a quick introduction to **Linux–PAM**. For more information the reader is directed to the **Linux–PAM system administrators' guide**.

Linux–PAM is a system of libraries that handle the authentication tasks of applications (services) on the system. The library provides a stable general interface (Application Programming Interface – API) that privilege granting programs (such as **login(1)** and **su(1)**) defer to to perform standard authentication tasks.

The principal feature of the PAM approach is that the nature of the authentication is dynamically configurable. In other words, the system administrator is free to choose how individual service—providing applications will authenticate users. This dynamic configuration is set by the contents of the single **Linux–PAM** configuration file `/etc/pam.conf`. Alternatively, the configuration can be set by individual configuration files located in the `/etc/pam.d/` directory. The presence of this directory will cause **Linux–PAM** to *ignore* `/etc/pam.conf`.

Vendor-supplied PAM configuration files might be installed in the system directory `/usr/lib/pam.d/` or a configurable vendor specific directory instead of the machine configuration directory `/etc/pam.d/`. If no machine configuration file is found, the vendor-supplied file is used. All files in `/etc/pam.d/` override files with the same name in other directories.

From the point of view of the system administrator, for whom this manual is provided, it is not of primary importance to understand the internal behavior of the **Linux–PAM** library. The important point to recognize is that the configuration file(s) *define* the connection between applications (**services**) and the pluggable authentication modules (**PAMs**) that perform the actual authentication tasks.

Linux–PAM separates the tasks of *authentication* into four independent management groups: **account** management; **authentication** management; **password** management; and **session** management. (We highlight the abbreviations used for these groups in the configuration file.)

Simply put, these groups take care of different aspects of a typical user's request for a restricted service:

account – provide account verification types of service: has the user's password expired?; is this user permitted access to the requested service?

authentication – authenticate a user and set up user credentials. Typically this is via some challenge-response request that the user must satisfy: if you are who you claim to be please enter your password. Not all authentications are of this type, there exist hardware based authentication schemes (such as the use of smart-cards and biometric devices), with suitable modules, these may be substituted seamlessly for more standard approaches to authentication – such is the flexibility of **Linux–PAM**.

password – this group's responsibility is the task of updating authentication mechanisms. Typically, such services are strongly coupled to those of the **auth** group. Some authentication mechanisms lend themselves well to being updated with such a function. Standard UN*X password-based access is the obvious example: please enter a replacement password.

session – this group of tasks cover things that should be done prior to a service being given and after it is withdrawn. Such tasks include the maintenance of audit trails and the mounting of the user's home directory. The **session** management group is important as it provides both an opening and closing hook for modules to affect the services available to a user.

FILES

`/etc/pam.conf`

the configuration file

`/etc/pam.d`

the **Linux–PAM** configuration directory. Generally, if this directory is present, the `/etc/pam.conf` file is ignored.

`/usr/lib/pam.d`

the **Linux–PAM** vendor configuration directory. Files in `/etc/pam.d` override files with the same name

in this directory.

<vendordir>/pam.d

the **Linux–PAM** vendor configuration directory. Files in /etc/pam.d and /usr/lib/pam.d override files with the same name in this directory. Only available if Linux–PAM was compiled with vendordir enabled.

ERRORS

Typically errors generated by the **Linux–PAM** system of libraries, will be written to **syslog(3)**.

CONFORMING TO

DCE–RFC 86.0, October 1995. Contains additional features, but remains backwardly compatible with this RFC.

NAME

pam.conf, pam.d – PAM configuration files

DESCRIPTION

When a *PAM* aware privilege granting application is started, it activates its attachment to the PAM–API. This activation performs a number of tasks, the most important being the reading of the configuration file(s): /etc/pam.conf. Alternatively, this may be the contents of the /etc/pam.d/ directory. The presence of this directory will cause Linux–PAM to ignore /etc/pam.conf.

These files list the *PAMs* that will do the authentication tasks required by this service, and the appropriate behavior of the PAM–API in the event that individual *PAMs* fail.

The syntax of the /etc/pam.conf configuration file is as follows. The file is made up of a list of rules, each rule is typically placed on a single line, but may be extended with an escaped end of line: ‘\<LF>’. Comments are preceded with ‘#’ marks and extend to the next end of line.

The format of each rule is a space separated collection of tokens, the first three being case–insensitive:

service type control module–path module–arguments

The syntax of files contained in the /etc/pam.d/ directory, are identical except for the absence of any *service* field. In this case, the *service* is the name of the file in the /etc/pam.d/ directory. This filename must be in lower case.

An important feature of *PAM*, is that a number of rules may be *stacked* to combine the services of a number of *PAMs* for a given authentication task.

The *service* is typically the familiar name of the corresponding application: *login* and *su* are good examples. The *service*–name, *other*, is reserved for giving *default* rules. Only lines that mention the current service (or in the absence of such, the *other* entries) will be associated with the given service–application.

The *type* is the management group that the rule corresponds to. It is used to specify which of the management groups the subsequent module is to be associated with. Valid entries are:

account

this module type performs non–authentication based account management. It is typically used to restrict/permit access to a service based on the time of day, currently available system resources (maximum number of users) or perhaps the location of the applicant user — ‘root’ login only on the console.

auth

this module type provides two aspects of authenticating the user. Firstly, it establishes that the user is who they claim to be, by instructing the application to prompt the user for a password or other means of identification. Secondly, the module can grant group membership or other privileges through its credential granting properties.

password

this module type is required for updating the authentication token associated with the user. Typically, there is one module for each ‘challenge/response’ based authentication (auth) type.

session

this module type is associated with doing things that need to be done for the user before/after they can be given service. Such things include the logging of information concerning the opening/closing of some data exchange with a user, mounting directories, etc.

If the *type* value from the list above is prepended with a – character the PAM library will not log to the system log if it is not possible to load the module because it is missing in the system. This can be useful especially for modules which are not always installed on the system and are not required for correct authentication and authorization of the login session.

The third field, *control*, indicates the behavior of the PAM–API should the module fail to succeed in its authentication task. There are two types of syntax for this control field: the simple one has a single simple keyword; the more complicated one involves a square–bracketed selection of *value*=*action* pairs.

For the simple (historical) syntax valid *control* values are:

required

failure of such a PAM will ultimately lead to the PAM-API returning failure but only after the remaining *stacked* modules (for this *service* and *type*) have been invoked.

requisite

like *required*, however, in the case that such a module returns a failure, control is directly returned to the application or to the superior PAM stack. The return value is that associated with the first required or requisite module to fail. Note, this flag can be used to protect against the possibility of a user getting the opportunity to enter a password over an unsafe medium. It is conceivable that such behavior might inform an attacker of valid accounts on a system. This possibility should be weighed against the not insignificant concerns of exposing a sensitive password in a hostile environment.

sufficient

if such a module succeeds and no prior *required* module has failed the PAM framework returns success to the application or to the superior PAM stack immediately without calling any further modules in the stack. A failure of a *sufficient* module is ignored and processing of the PAM module stack continues unaffected.

optional

the success or failure of this module is only important if it is the only module in the stack associated with this *service+type*.

include

include all lines of given type from the configuration file specified as an argument to this control.

substack

include all lines of given type from the configuration file specified as an argument to this control. This differs from *include* in that evaluation of the *done* and *die* actions in a substack does not cause skipping the rest of the complete module stack, but only of the substack. Jumps in a substack also can not make evaluation jump out of it, and the whole substack is counted as one module when the jump is done in a parent stack. The *reset* action will reset the state of a module stack to the state it was in as of beginning of the substack evaluation.

For the more complicated syntax valid *control* values have the following form:

[value1=action1 value2=action2 ...]

Where *valueN* corresponds to the return code from the function invoked in the module for which the line is defined. It is selected from one of these: *success*, *open_err*, *symbol_err*, *service_err*, *system_err*, *buf_err*, *perm_denied*, *auth_err*, *cred_insufficient*, *authinfo_unavail*, *user_unknown*, *maxtries*, *new_authtok_reqd*, *acct_expired*, *session_err*, *cred_unavail*, *cred_expired*, *cred_err*, *no_module_data*, *conv_err*, *authtok_err*, *authtok_recover_err*, *authtok_lock_busy*, *authtok_disable_aging*, *try_again*, *ignore*, *abort*, *authtok_expired*, *module_unknown*, *bad_item*, *conv_again*, *incomplete*, and *default*.

The last of these, *default*, implies 'all *valueN*'s not mentioned explicitly. Note, the full list of PAM errors is available in /usr/include/security/_pam_types.h. The *actionN* can take one of the following forms:

ignore

when used with a stack of modules, the module's return status will not contribute to the return code the application obtains.

bad

this action indicates that the return code should be thought of as indicative of the module failing. If this module is the first in the stack to fail, its status value will be used for that of the whole stack.

die

equivalent to bad with the side effect of terminating the module stack and PAM immediately returning to the application.

ok

this tells PAM that the administrator thinks this return code should contribute directly to the return code of the full stack of modules. In other words, if the former state of the stack would lead to a return of *PAM_SUCCESS*, the module's return code will override this value. Note, if the former state of the stack holds some value that is indicative of a module's failure, this 'ok' value will not be used to override that value.

done

equivalent to ok with the side effect of terminating the module stack and PAM immediately returning to the application.

N (an unsigned integer)

jump over the next N modules in the stack. Note that N equal to 0 is not allowed, it would be treated as *ignore* in such case. The side effect depends on the PAM function call: for *pam_authenticate*, *pam_acct_mgmt*, *pam_chauthtok*, and *pam_open_session* it is *ignore*; for *pam_setcred* and *pam_close_session* it is one of *ignore*, *ok*, or *bad* depending on the module's return value.

reset

clear all memory of the state of the module stack and start again with the next stacked module.

Each of the four keywords: required; requisite; sufficient; and optional, have an equivalent expression in terms of the [...] syntax. They are as follows:

required

[success=ok new_authok_reqd=ok ignore=ignore default=bad]

requisite

[success=ok new_authok_reqd=ok ignore=ignore default=die]

sufficient

[success=done new_authok_reqd=done default=ignore]

optional

[success=ok new_authok_reqd=ok default=ignore]

module-path is either the full filename of the PAM to be used by the application (it begins with a '/'), or a relative pathname from the default module location: /lib/security/ or /lib64/security/, depending on the architecture.

module-arguments are a space separated list of tokens that can be used to modify the specific behavior of the given PAM. Such arguments will be documented for each individual module. Note, if you wish to include spaces in an argument, you should surround that argument with square brackets.

```
squid auth required pam_mysql.so user=passwd_query passwd=mada \
    db=eminence [query=select user_name from internet_service \
    where user_name='%u' and password=PASSWORD('%p') and \
    service='web_proxy']
```

When using this convention, you can include '[' characters inside the string, and if you wish to include a ']' character inside the string that will survive the argument parsing, you should use '\]'. In other words:

[..[.]..] --> ..[.]..

Any line in (one of) the configuration file(s), that is not formatted correctly, will generally tend (erring on the side of caution) to make the authentication process fail. A corresponding error is written to the system log files with a call to **syslog(3)**.

More flexible than the single configuration file is it to configure libpam via the contents of the /etc/pam.d/ directory. In this case the directory is filled with files each of which has a filename equal to a service-name (in lower-case): it is the personal configuration file for the named service.

The syntax of each file in /etc/pam.d/ is similar to that of the /etc/pam.conf file and is made up of lines of the following form:

```
type control module-path module-arguments
```

The only difference being that the service-name is not present. The service-name is of course the name of the given configuration file. For example, /etc/pam.d/login contains the configuration for the **login** service.

NAME

pam.conf, pam.d – PAM configuration files

DESCRIPTION

When a *PAM* aware privilege granting application is started, it activates its attachment to the PAM–API. This activation performs a number of tasks, the most important being the reading of the configuration file(s): /etc/pam.conf. Alternatively, this may be the contents of the /etc/pam.d/ directory. The presence of this directory will cause Linux–PAM to ignore /etc/pam.conf.

These files list the *PAMs* that will do the authentication tasks required by this service, and the appropriate behavior of the PAM–API in the event that individual *PAMs* fail.

The syntax of the /etc/pam.conf configuration file is as follows. The file is made up of a list of rules, each rule is typically placed on a single line, but may be extended with an escaped end of line: ‘\<LF>’. Comments are preceded with '#' marks and extend to the next end of line.

The format of each rule is a space separated collection of tokens, the first three being case–insensitive:

service type control module–path module–arguments

The syntax of files contained in the /etc/pam.d/ directory, are identical except for the absence of any *service* field. In this case, the *service* is the name of the file in the /etc/pam.d/ directory. This filename must be in lower case.

An important feature of *PAM*, is that a number of rules may be *stacked* to combine the services of a number of *PAMs* for a given authentication task.

The *service* is typically the familiar name of the corresponding application: *login* and *su* are good examples. The *service*–name, *other*, is reserved for giving *default* rules. Only lines that mention the current service (or in the absence of such, the *other* entries) will be associated with the given service–application.

The *type* is the management group that the rule corresponds to. It is used to specify which of the management groups the subsequent module is to be associated with. Valid entries are:

account

this module type performs non–authentication based account management. It is typically used to restrict/permit access to a service based on the time of day, currently available system resources (maximum number of users) or perhaps the location of the applicant user — 'root' login only on the console.

auth

this module type provides two aspects of authenticating the user. Firstly, it establishes that the user is who they claim to be, by instructing the application to prompt the user for a password or other means of identification. Secondly, the module can grant group membership or other privileges through its credential granting properties.

password

this module type is required for updating the authentication token associated with the user. Typically, there is one module for each 'challenge/response' based authentication (auth) type.

session

this module type is associated with doing things that need to be done for the user before/after they can be given service. Such things include the logging of information concerning the opening/closing of some data exchange with a user, mounting directories, etc.

If the *type* value from the list above is prepended with a – character the PAM library will not log to the system log if it is not possible to load the module because it is missing in the system. This can be useful especially for modules which are not always installed on the system and are not required for correct authentication and authorization of the login session.

The third field, *control*, indicates the behavior of the PAM–API should the module fail to succeed in its authentication task. There are two types of syntax for this control field: the simple one has a single simple keyword; the more complicated one involves a square–bracketed selection of *value*=*action* pairs.

For the simple (historical) syntax valid *control* values are:

required

failure of such a PAM will ultimately lead to the PAM-API returning failure but only after the remaining *stacked* modules (for this *service* and *type*) have been invoked.

requisite

like *required*, however, in the case that such a module returns a failure, control is directly returned to the application or to the superior PAM stack. The return value is that associated with the first required or requisite module to fail. Note, this flag can be used to protect against the possibility of a user getting the opportunity to enter a password over an unsafe medium. It is conceivable that such behavior might inform an attacker of valid accounts on a system. This possibility should be weighed against the not insignificant concerns of exposing a sensitive password in a hostile environment.

sufficient

if such a module succeeds and no prior *required* module has failed the PAM framework returns success to the application or to the superior PAM stack immediately without calling any further modules in the stack. A failure of a *sufficient* module is ignored and processing of the PAM module stack continues unaffected.

optional

the success or failure of this module is only important if it is the only module in the stack associated with this *service+type*.

include

include all lines of given type from the configuration file specified as an argument to this control.

substack

include all lines of given type from the configuration file specified as an argument to this control. This differs from *include* in that evaluation of the *done* and *die* actions in a substack does not cause skipping the rest of the complete module stack, but only of the substack. Jumps in a substack also can not make evaluation jump out of it, and the whole substack is counted as one module when the jump is done in a parent stack. The *reset* action will reset the state of a module stack to the state it was in as of beginning of the substack evaluation.

For the more complicated syntax valid *control* values have the following form:

[value1=action1 value2=action2 ...]

Where *valueN* corresponds to the return code from the function invoked in the module for which the line is defined. It is selected from one of these: *success*, *open_err*, *symbol_err*, *service_err*, *system_err*, *buf_err*, *perm_denied*, *auth_err*, *cred_insufficient*, *authinfo_unavail*, *user_unknown*, *maxtries*, *new_authtok_reqd*, *acct_expired*, *session_err*, *cred_unavail*, *cred_expired*, *cred_err*, *no_module_data*, *conv_err*, *authtok_err*, *authtok_recover_err*, *authtok_lock_busy*, *authtok_disable_aging*, *try_again*, *ignore*, *abort*, *authtok_expired*, *module_unknown*, *bad_item*, *conv_again*, *incomplete*, and *default*.

The last of these, *default*, implies 'all *valueN*'s not mentioned explicitly. Note, the full list of PAM errors is available in /usr/include/security/_pam_types.h. The *actionN* can take one of the following forms:

ignore

when used with a stack of modules, the module's return status will not contribute to the return code the application obtains.

bad

this action indicates that the return code should be thought of as indicative of the module failing. If this module is the first in the stack to fail, its status value will be used for that of the whole stack.

die

equivalent to bad with the side effect of terminating the module stack and PAM immediately returning to the application.

ok

this tells PAM that the administrator thinks this return code should contribute directly to the return code of the full stack of modules. In other words, if the former state of the stack would lead to a return of *PAM_SUCCESS*, the module's return code will override this value. Note, if the former state of the stack holds some value that is indicative of a module's failure, this 'ok' value will not be used to override that value.

done

equivalent to ok with the side effect of terminating the module stack and PAM immediately returning to the application.

N (an unsigned integer)

jump over the next N modules in the stack. Note that N equal to 0 is not allowed, it would be treated as *ignore* in such case. The side effect depends on the PAM function call: for *pam_authenticate*, *pam_acct_mgmt*, *pam_chauthtok*, and *pam_open_session* it is *ignore*; for *pam_setcred* and *pam_close_session* it is one of *ignore*, *ok*, or *bad* depending on the module's return value.

reset

clear all memory of the state of the module stack and start again with the next stacked module.

Each of the four keywords: required; requisite; sufficient; and optional, have an equivalent expression in terms of the [...] syntax. They are as follows:

required

[success=ok new_authok_reqd=ok ignore=ignore default=bad]

requisite

[success=ok new_authok_reqd=ok ignore=ignore default=die]

sufficient

[success=done new_authok_reqd=done default=ignore]

optional

[success=ok new_authok_reqd=ok default=ignore]

module-path is either the full filename of the PAM to be used by the application (it begins with a '/'), or a relative pathname from the default module location: /lib/security/ or /lib64/security/, depending on the architecture.

module-arguments are a space separated list of tokens that can be used to modify the specific behavior of the given PAM. Such arguments will be documented for each individual module. Note, if you wish to include spaces in an argument, you should surround that argument with square brackets.

```
squid auth required pam_mysql.so user=passwd_query passwd=mada \
    db=eminence [query=select user_name from internet_service \
    where user_name='%u' and password=PASSWORD('%p') and \
    service='web_proxy']
```

When using this convention, you can include '[' characters inside the string, and if you wish to include a ']' character inside the string that will survive the argument parsing, you should use '\]'. In other words:

[..[.]..] --> ..[.]..

Any line in (one of) the configuration file(s), that is not formatted correctly, will generally tend (erring on the side of caution) to make the authentication process fail. A corresponding error is written to the system log files with a call to *syslog(3)*.

More flexible than the single configuration file is it to configure libpam via the contents of the /etc/pam.d/ directory. In this case the directory is filled with files each of which has a filename equal to a service-name (in lower-case): it is the personal configuration file for the named service.

The syntax of each file in /etc/pam.d/ is similar to that of the /etc/pam.conf file and is made up of lines of the following form:

```
type control module-path module-arguments
```

The only difference being that the service-name is not present. The service-name is of course the name of the given configuration file. For example, /etc/pam.d/login contains the configuration for the **login** service.

NAME

pam_access – PAM module for logdaemon style login access control

SYNOPSIS

pam_access.so [debug] [nodefgroup] [noaudit] [accessfile=*file*] [fieldsep=*sep*] [listsep=*sep*]

DESCRIPTION

The pam_access PAM module is mainly for access management. It provides logdaemon style login access control based on login names, host or domain names, internet addresses or network numbers, or on terminal line names, X \$DISPLAY values, or PAM service names in case of non-networked logins.

By default rules for access management are taken from config file /etc/security/access.conf if you don't specify another file. Then individual *.conf files from the /etc/security/access.d/ directory are read. The files are parsed one after another in the order of the system locale. The effect of the individual files is the same as if all the files were concatenated together in the order of parsing. This means that once a pattern is matched in some file no further files are parsed. If a config file is explicitly specified with the **accessfile** option the files in the above directory are not parsed.

If Linux PAM is compiled with audit support the module will report when it denies access based on origin (host, tty, etc.).

OPTIONS

accessfile=/path/to/access.conf

Indicate an alternative access.conf style configuration file to override the default. This can be useful when different services need different access lists.

debug

A lot of debug information is printed with **syslog(3)**.

noaudit

Do not report logins from disallowed hosts and ttys to the audit subsystem.

fieldsep=separators

This option modifies the field separator character that pam_access will recognize when parsing the access configuration file. For example: **fieldsep=|** will cause the default ':' character to be treated as part of a field value and '|' becomes the field separator. Doing this may be useful in conjunction with a system that wants to use pam_access with X based applications, since the **PAM_TTY** item is likely to be of the form "hostname:0" which includes a ':' character in its value. But you should not need this.

listsep=separators

This option modifies the list separator character that pam_access will recognize when parsing the access configuration file. For example: **listsep=,** will cause the default ' ' (space) and '\t' (tab) characters to be treated as part of a list element value and ',' becomes the only list element separator. Doing this may be useful on a system with group information obtained from a Windows domain, where the default built-in groups "Domain Users", "Domain Admins" contain a space.

nodefgroup

User tokens which are not enclosed in parentheses will not be matched against the group database. The backwards compatible default is to try the group database match even for tokens not enclosed in parentheses.

MODULE TYPES PROVIDED

All module types (**auth**, **account**, **password** and **session**) are provided.

RETURN VALUES

PAM_SUCCESS

Access was granted.

PAM_PERM_DENIED

Access was not granted.

PAM_IGNORE

pam_setcred was called which does nothing.

PAM_ABORT

Not all relevant data or options could be gotten.

PAM_USER_UNKNOWN

The user is not known to the system.

FILES

/etc/security/access.conf

Default configuration file

SEE ALSO

access.conf(5), pam.d(5), pam(7).

AUTHORS

The logdaemon style login access control scheme was designed and implemented by Wietse Venema. The pam_access PAM module was developed by Alexei Nogin <alexei@nogin.dnitz.ru>. The IPv6 support and the network(address) / netmask feature was developed and provided by Mike Becher <mike.becher@lrz-muenchen.de>.

NAME

pam_deny – The locking-out PAM module

SYNOPSIS

pam_deny.so

DESCRIPTION

This module can be used to deny access. It always indicates a failure to the application through the PAM framework. It might be suitable for using for default (the *OTHER*) entries.

OPTIONS

This module does not recognise any options.

MODULE TYPES PROVIDED

All module types (**account**, **auth**, **password** and **session**) are provided.

RETURN VALUES

PAM_AUTH_ERR

This is returned by the account and auth services.

PAM_CRED_ERR

This is returned by the setcred function.

PAM_AUTHTOK_ERR

This is returned by the password service.

PAM_SESSION_ERR

This is returned by the session service.

EXAMPLES

```
#%PAM-1.0
#
# If we don't have config entries for a service, the
# OTHER entries are used. To be secure, warn and deny
# access to everything.
other auth required pam_warn.so
other auth required pam_deny.so
other account required pam_warn.so
other account required pam_deny.so
other password required pam_warn.so
other password required pam_deny.so
other session required pam_warn.so
other session required pam_deny.so
```

SEE ALSO

pam.conf(5), **pam.d(5)**, **pam(7)**

AUTHOR

pam_deny was written by Andrew G. Morgan <morgan@kernel.org>

NAME

pam_env – PAM module to set/unset environment variables

SYNOPSIS

```
pam_env.so [debug] [conffile=conf-file] [envfile=env-file] [readenv=0/1] [user_envfile=env-file]
               [user_readenv=0/1]
```

DESCRIPTION

The pam_env PAM module allows the (un)setting of environment variables. Supported is the use of previously set environment variables as well as *PAM_ITEMS* such as *PAM_RHOST*.

By default rules for (un)setting of variables are taken from the config file /etc/security/pam_env.conf. An alternate file can be specified with the *conffile* option.

Second a file (/etc/environment by default) with simple *KEY=VAL* pairs on separate lines will be read. With the *envfile* option an alternate file can be specified. And with the *readenv* option this can be completely disabled.

Third it will read a user configuration file (\$HOME/.pam_environment by default). The default file can be changed with the *user_envfile* option and it can be turned on and off with the *user_readenv* option.

Since setting of PAM environment variables can have side effects to other modules, this module should be the last one on the stack.

OPTIONS

conffile=/path/to/pam_env.conf

Indicate an alternative pam_env.conf style configuration file to override the default. This can be useful when different services need different environments.

debug

A lot of debug information is printed with **syslog(3)**.

envfile=/path/to/environment

Indicate an alternative environment file to override the default. The syntax are simple *KEY=VAL* pairs on separate lines. The *export* instruction can be specified for bash compatibility, but will be ignored. This can be useful when different services need different environments.

readenv=0/1

Turns on or off the reading of the file specified by envfile (0 is off, 1 is on). By default this option is on.

user_envfile=filename

Indicate an alternative .pam_environment file to override the default. The syntax is the same as for /etc/security/pam_env.conf. The filename is relative to the user home directory. This can be useful when different services need different environments.

user_readenv=0/1

Turns on or off the reading of the user specific environment file. 0 is off, 1 is on. By default this option is off.

MODULE TYPES PROVIDED

The **auth** and **session** module types are provided.

RETURN VALUES

PAM_ABORT

Not all relevant data or options could be gotten.

PAM_BUF_ERR

Memory buffer error.

PAM_IGNORE

No pam_env.conf and environment file was found.

PAM_SUCCESS

Environment variables were set.

FILES

/etc/security/pam_env.conf
Default configuration file

/etc/environment
Default environment file

\$HOME/.pam_environment
User specific environment file

SEE ALSO

pam_env.conf(5), pam.d(5), pam(8), environ(7).

AUTHOR

pam_env was written by Dave Kinchlea <kinch@kinch.ark.com>.

NAME

pam_env.conf, environment – the environment variables config files

DESCRIPTION

The /etc/security/pam_env.conf file specifies the environment variables to be set, unset or modified by **pam_env(8)**. When someone logs in, this file is read and the environment variables are set according.

Each line starts with the variable name, there are then two possible options for each variable DEFAULT and OVERRIDE. DEFAULT allows an administrator to set the value of the variable to some default value, if none is supplied then the empty string is assumed. The OVERRIDE option tells pam_env that it should enter in its value (overriding the default value) if there is one to use. OVERRIDE is not used, "" is assumed and no override will be done.

VARIABLE [DEFAULT=[value]] [OVERRIDE=[value]]

(Possibly non-existent) environment variables may be used in values using the \${string} syntax and (possibly non-existent) PAM_ITEMS as well as HOME and SHELL may be used in values using the @{string} syntax. Both the \$ and @ characters can be backslash escaped to be used as literal values values can be delimited with "", escaped " not supported. Note that many environment variables that you would like to use may not be set by the time the module is called. For example, \${HOME} is used below several times, but many PAM applications don't make it available by the time you need it. The special variables @{HOME} and {@SHELL} are expanded to the values for the user from his *passwd* entry.

The "#" character at start of line (no space at front) can be used to mark this line as a comment line.

The /etc/environment file specifies the environment variables to be set. The file must consist of simple NAME=VALUE pairs on separate lines. The **pam_env(8)** module will read the file after the pam_env.conf file.

EXAMPLES

These are some example lines which might be specified in /etc/security/pam_env.conf.

Set the REMOTEHOST variable for any hosts that are remote, default to "localhost" rather than not being set at all

```
REMOTEHOST    DEFAULT=localhost OVERRIDE=@{PAM_RHOST}
```

Set the DISPLAY variable if it seems reasonable

```
DISPLAY      DEFAULT=${REMOTEHOST}:0.0 OVERRIDE=${DISPLAY}
```

Now some simple variables

```
PAGER        DEFAULT=less
MANPAGER     DEFAULT=less
LESS         DEFAULT="M q e h15 z23 b80"
NNTPSERVER   DEFAULT=localhost
PATH         DEFAULT=${HOME}/bin:/usr/local/bin:/bin\
:/usr/bin:/usr/local/bin/X11:/usr/bin/X11
XDG_DATA_HOME @${HOME}/share/
```

Silly examples of escaped variables, just to show how they work.

```
DOLLAR       DEFAULT=\$ 
DOLLARDOLLAR DEFAULT=    OVERRIDE=\${\$DOLLAR}
DOLLARPLUS   DEFAULT=\${REMOTEHOST}\${REMOTEHOST}
ATSIGN      DEFAULT=""   OVERRIDE=\@
```

NAME

pam_group – PAM module for group access

SYNOPSIS

pam_group.so

DESCRIPTION

The pam_group PAM module does not authenticate the user, but instead it grants group memberships (in the credential setting phase of the authentication module) to the user. Such memberships are based on the service they are applying for.

By default rules for group memberships are taken from config file /etc/security/group.conf.

This module's usefulness relies on the file-systems accessible to the user. The point being that once granted the membership of a group, the user may attempt to create a **setgid** binary with a restricted group ownership. Later, when the user is not given membership to this group, they can recover group membership with the precompiled binary. The reason that the file-systems that the user has access to are so significant, is the fact that when a system is mounted *nosuid* the user is unable to create or execute such a binary file. For this module to provide any level of security, all file-systems that the user has write access to should be mounted *nosuid*.

The pam_group module functions in parallel with the /etc/group file. If the user is granted any groups based on the behavior of this module, they are granted *in addition* to those entries /etc/group (or equivalent).

OPTIONS

This module does not recognise any options.

MODULE TYPES PROVIDED

Only the **auth** module type is provided.

RETURN VALUES

PAM_SUCCESS

group membership was granted.

PAM_ABORT

Not all relevant data could be gotten.

PAM_BUF_ERR

Memory buffer error.

PAM_CRED_ERR

Group membership was not granted.

PAM_IGNORE

pam_sm_authenticate was called which does nothing.

PAM_USER_UNKNOWN

The user is not known to the system.

FILES

/etc/security/group.conf

Default configuration file

SEE ALSO

group.conf(5), pam.d(5), pam(7).

pam_group was written by Andrew G. Morgan <morgan@kernel.org>.

NAME

parted – a partition manipulation program

SYNOPSIS

parted [options] [device [command [options...]]]

DESCRIPTION

parted is a program to manipulate disk partitions. It supports multiple partition table formats, including MS-DOS and GPT. It is useful for creating space for new operating systems, reorganising disk usage, and copying data to new hard disks.

This manual page documents **parted** briefly. Complete documentation is distributed with the package in GNU Info format.

OPTIONS

-h, --help

displays a help message

-l, --list lists partition layout on all block devices

-m, --machine

displays machine parseable output

-s, --script

never prompts for user intervention

-v, --version

displays the version

-a alignment-type, --align alignment-type

Set alignment for newly created partitions, valid alignment types are:

none Use the minimum alignment allowed by the disk type.

cylinder

Align partitions to cylinders.

minimal

Use minimum alignment as given by the disk topology information. This and the opt value will use layout information provided by the disk to align the logical partition table addresses to actual physical blocks on the disks. The min value is the minimum alignment needed to align the partition properly to physical blocks, which avoids performance degradation.

optimal Use optimum alignment as given by the disk topology information. This aligns to a multiple of the physical block size in a way that guarantees optimal performance.

COMMANDS

[device]

The block device to be used. When none is given, **parted** will use the first block device it finds.

[command [options]]

Specifies the command to be executed. If no command is given, **parted** will present a command prompt. Possible commands are:

help [command]

Print general help, or help on *command* if specified.

align-check type partition

Check if *partition* satisfies the alignment constraint of *type*. *type* must be "minimal" or "optimal".

mklabel *label-type*

Create a new disklabel (partition table) of *label-type*. *label-type* should be one of "aix", "amiga", "bsd", "dvh", "gpt", "loop", "mac", "msdos", "pc98", or "sun".

mkpart [*part-type name fs-type*] *start end*

Create a new partition. *part-type* may be specified only with msdos and dvh partition tables, it should be one of "primary", "logical", or "extended". *name* is required for GPT partition tables and *fs-type* is optional. *fs-type* can be one of "btrfs", "ext2", "ext3", "ext4", "fat16", "fat32", "hfs", "hfs+", "linux-swap", "ntfs", "reiserfs", "udf", or "xfs".

name *partition name*

Set the name of *partition* to *name*. This option works only on Mac, PC98, and GPT disklabels. The name can be placed in double quotes, if necessary. And depending on the shell may need to also be wrapped in single quotes so that the shell doesn't strip off the double quotes.

print

Display the partition table.

quit

Exit from **parted**.

rescue *start end*

Rescue a lost partition that was located somewhere between *start* and *end*. If a partition is found, **parted** will ask if you want to create an entry for it in the partition table.

resizepart *partition end*

Change the *end* position of *partition*. Note that this does not modify any filesystem present in the partition.

rm *partition*

Delete *partition*.

select *device*

Choose *device* as the current device to edit. *device* should usually be a Linux hard disk device, but it can be a partition, software raid device, or an LVM logical volume if necessary.

set *partition flag state*

Change the state of the *flag* on *partition* to *state*. Supported flags are: "boot", "root", "swap", "hidden", "raid", "lvm", "lba", "legacy_boot", "irst", "msftres", "esp", "chromeos_kernel", "bls_boot" and "palo". *state* should be either "on" or "off".

unit *unit*

Set *unit* as the unit to use when displaying locations and sizes, and for interpreting those given by the user when not suffixed with an explicit unit. *unit* can be one of "s" (sectors), "B" (bytes), "kB", "MB", "MiB", "GB", "GiB", "TB", "TiB", "%" (percentage of device size), "cyl" (cylinders), "chs" (cylinders, heads, sectors), or "compact" (megabytes for input, and a human-friendly form for output).

toggle *partition flag*

Toggle the state of *flag* on *partition*.

version

Display version information and a copyright message.

REPORTING BUGS

Report bugs to <bug-parted@gnu.org>

SEE ALSO

fdisk(8), **mkfs(8)**, The *parted* program is fully documented in the **info(1)** format *GNU partitioning software* manual which is distributed with the *parted-doc* Debian package.

AUTHOR

This manual page was written by Timshel Knoll <timshel@debian.org>, for the Debian GNU/Linux system (but may be used by others).

NAME

passwd – change user password

SYNOPSIS

passwd [*options*] [*LOGIN*]

DESCRIPTION

The **passwd** command changes passwords for user accounts. A normal user may only change the password for their own account, while the superuser may change the password for any account. **passwd** also changes the account or associated password validity period.

Password Changes

The user is first prompted for their old password, if one is present. This password is then encrypted and compared against the stored password. The user has only one chance to enter the correct password. The superuser is permitted to bypass this step so that forgotten passwords may be changed.

After the password has been entered, password aging information is checked to see if the user is permitted to change the password at this time. If not, **passwd** refuses to change the password and exits.

The user is then prompted twice for a replacement password. The second entry is compared against the first and both are required to match in order for the password to be changed.

Then, the password is tested for complexity. As a general guideline, passwords should consist of 6 to 8 characters including one or more characters from each of the following sets:

- lower case alphabetics
- digits 0 thru 9
- punctuation marks

Care must be taken not to include the system default erase or kill characters. **passwd** will reject any password which is not suitably complex.

Hints for user passwords

The security of a password depends upon the strength of the encryption algorithm and the size of the key space. The legacy *UNIX* System encryption method is based on the NBS DES algorithm. More recent methods are now recommended (see **ENCRYPT_METHOD**). The size of the key space depends upon the randomness of the password which is selected.

Compromises in password security normally result from careless password selection or handling. For this reason, you should not select a password which appears in a dictionary or which must be written down. The password should also not be a proper name, your license number, birth date, or street address. Any of these may be used as guesses to violate system security.

You can find advice on how to choose a strong password on http://en.wikipedia.org/wiki/Password_strength

OPTIONS

The options which apply to the **passwd** command are:

-a, --all

This option can be used only with **-S** and causes show status for all users.

-d, --delete

Delete a user's password (make it empty). This is a quick way to disable a password for an account. It will set the named account passwordless.

-e, --expire

Immediately expire an account's password. This in effect can force a user to change their password at the user's next login.

-h, --help

Display help message and exit.

-i, --inactive *INACTIVE*

This option is used to disable an account after the password has been expired for a number of days.

After a user account has had an expired password for *INACTIVE* days, the user may no longer sign on to the account.

-k, --keep-tokens

Indicate password change should be performed only for expired authentication tokens (passwords). The user wishes to keep their non-expired tokens as before.

-l, --lock

Lock the password of the named account. This option disables a password by changing it to a value which matches no possible encrypted value (it adds a '!' at the beginning of the password).

Note that this does not disable the account. The user may still be able to login using another authentication token (e.g. an SSH key). To disable the account, administrators should use **usermod --expiredate 1** (this set the account's expire date to Jan 2, 1970).

Users with a locked password are not allowed to change their password.

-n, --mindays MIN_DAYS

Set the minimum number of days between password changes to *MIN_DAYS*. A value of zero for this field indicates that the user may change their password at any time.

-q, --quiet

Quiet mode.

-r, --repository REPOSITORY

change password in *REPOSITORY* repository

-R, --root CHROOT_DIR

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-S, --status

Display account status information. The status information consists of 7 fields. The first field is the user's login name. The second field indicates if the user account has a locked password (L), has no password (NP), or has a usable password (P). The third field gives the date of the last password change. The next four fields are the minimum age, maximum age, warning period, and inactivity period for the password. These ages are expressed in days.

-u, --unlock

Unlock the password of the named account. This option re-enables a password by changing the password back to its previous value (to the value before using the **-l** option).

-w, --warndays WARN_DAYS

Set the number of days of warning before a password change is required. The *WARN_DAYS* option is the number of days prior to the password expiring that a user will be warned that their password is about to expire.

-x, --maxdays MAX_DAYS

Set the maximum number of days a password remains valid. After *MAX_DAYS*, the password is required to be changed.

Passing the number **-1** as *MAX_DAYS* will remove checking a password's validity.

CAVEATS

Password complexity checking may vary from site to site. The user is urged to select a password as complex as he or she feels comfortable with.

Users may not be able to change their password on a system if NIS is enabled and they are not logged into the NIS server.

passwd uses PAM to authenticate users and to change their passwords.

FILES

- /etc/passwd
User account information.
- /etc/shadow
Secure user account information.
- /etc/pam.d/passwd
PAM configuration for **passwd**.

EXIT VALUES

The **passwd** command exits with the following values:

- 0* success
- 1* permission denied
- 2* invalid combination of options
- 3* unexpected failure, nothing done
- 4* unexpected failure, passwd file missing
- 5* passwd file busy, try again
- 6* invalid argument to option

SEE ALSO

chpasswd(8), **passwd(5)**, **shadow(5)**, **usermod(8)**.

NAME

`openssl-passwd`, `passwd` – compute password hashes

SYNOPSIS

```
openssl passwd [-help] [-crypt] [-1] [-apr1] [-aixmd5] [-5] [-6] [-salt string] [-in file] [-stdin]
[-noverify] [-quiet] [-table] [-rand file...] [-writerand file] {password}
```

DESCRIPTION

The **passwd** command computes the hash of a password typed at run-time or the hash of each password in a list. The password list is taken from the named file for option **-in file**, from stdin for option **-stdin**, or from the command line, or from the terminal otherwise.

OPTIONS**-help**

Print out a usage message.

-crypt

Use the **crypt** algorithm (default).

-1

Use the MD5 based BSD password algorithm **1**.

-apr1

Use the **apr1** algorithm (Apache variant of the BSD algorithm).

-aixmd5

Use the **AIX MD5** algorithm (AIX variant of the BSD algorithm).

-5

-6 Use the **SHA256** / **SHA512** based algorithms defined by Ulrich Drepper. See <<https://www.akkadia.org/drepper/SHA-crypt.txt>>.

-salt *string*

Use the specified salt. When reading a password from the terminal, this implies **-noverify**.

-in *file*

Read passwords from *file*.

-stdin

Read passwords from **stdin**.

-noverify

Don't verify when reading a password from the terminal.

-quiet

Don't output warnings when passwords given at the command line are truncated.

-table

In the output list, prepend the cleartext password and a TAB character to each password hash.

-rand *file...*

A file or files containing random data used to seed the random number generator. Multiple files can be specified separated by an OS-dependent character. The separator is ; for MS-W indows, , for OpenVMS, and : for all others.

[-writerand *file*]

Writes random data to the specified *file* upon exit. This can be used with a subsequent**-rand** flag.

EXAMPLES

```
% openssl passwd -crypt -salt xx password
xxj31ZMTZzkVA
```

```
% openssl passwd -1 -salt xxxxxxxx password
$1$xxxxxxxx$UYCIxa628.9qXjpQCjM4a.
```

```
% openssl passwd -apr1 -salt xxxxxxxx password
```

```
$apr1$xxxxxxxxx$dxHfLAs jHkDRmG83UXe8K0  
% openssl passwd -aixmd5 -salt xxxxxxxxx password  
xxxxxxxxx$8Oaipk/GPKhC64w/YVeFD/
```

NAME

passwd – password file

DESCRIPTION

The */etc/passwd* file is a text file that describes user login accounts for the system. It should have read permission allowed for all users (many utilities, like **ls(1)** use it to map user IDs to usernames), but write access only for the superuser.

In the good old days there was no great problem with this general read permission. Everybody could read the encrypted passwords, but the hardware was too slow to crack a well-chosen password, and moreover the basic assumption used to be that of a friendly user-community. These days many people run some version of the shadow password suite, where */etc/passwd* has an 'x' character in the password field, and the encrypted passwords are in */etc/shadow*, which is readable by the superuser only.

If the encrypted password, whether in */etc/passwd* or in */etc/shadow*, is an empty string, login is allowed without even asking for a password. Note that this functionality may be intentionally disabled in applications, or configurable (for example using the "**nullok**" or "**nonnull**" arguments to **pam_unix(8)**).

If the encrypted password in */etc/passwd* is "*NP*" (without the quotes), the shadow record should be obtained from an NIS+ server.

Regardless of whether shadow passwords are used, many system administrators use an asterisk (*) in the encrypted password field to make sure that this user can not authenticate themselves using a password. (But see NOTES below.)

If you create a new login, first put an asterisk (*) in the password field, then use **passwd(1)** to set it.

Each line of the file describes a single user, and contains seven colon-separated fields:

```
name :password:UID:GECOS:directory:shell
```

The field are as follows:

<i>name</i>	This is the user's login name. It should not contain capital letters.
<i>password</i>	This is either the encrypted user password, an asterisk (*), or the letter 'x'. (See pwconv(8) for an explanation of 'x').
<i>UID</i>	The privileged <i>root</i> login account (superuser) has the user ID 0.
<i>GID</i>	This is the numeric primary group ID for this user. (Additional groups for the user are defined in the system group file; see group(5)).
<i>GECOS</i>	This field (sometimes called the "comment field") is optional and used only for informational purposes. Usually, it contains the full username. Some programs (for example, finger(1)) display information from this field. GECOS stands for "General Electric Comprehensive Operating System", which was renamed to GCOS when GE's large systems division was sold to Honeywell. Dennis Ritchie has reported: "Sometimes we sent printer output or batch jobs to the GCOS machine. The gcos field in the password file was a place to stash the information for the \$IDENTcard. Not elegant."
<i>directory</i>	This is the user's home directory: the initial directory where the user is placed after logging in. The value in this field is used to set the HOME environment variable.
<i>shell</i>	This is the program to run at login (if empty, use <i>/bin/sh</i>). If set to a nonexistent executable, the user will be unable to login through login(1) . The value in this field is used to set the SHELL environment variable.

FILES

/etc/passwd

NOTES

If you want to create user groups, there must be an entry in */etc/group*, or no group will exist.

If the encrypted password is set to an asterisk (*), the user will be unable to login using **login(1)**, but may still login using **rlogin(1)**, run existing processes and initiate new ones through **rsh(1)**, **cron(8)**, **at(1)**, or mail filters, etc. Trying to lock an account by simply changing the shell field yields the same result and additionally allows the use of **su(1)**.

NAME

pgrep, **pkill**, **pidwait** – look up, signal, or wait for processes based on name and other attributes

SYNOPSIS

```
pgrep [options] pattern
pkill [options] pattern
pidwait [options] pattern
```

DESCRIPTION

pgrep looks through the currently running processes and lists the process IDs which match the selection criteria to stdout. All the criteria have to match. For example,

```
$ pgrep -u root sshd
```

will only list the processes called **sshd** AND owned by **root**. On the other hand,

```
$ pgrep -u root,daemon
```

will list the processes owned by **root** OR **daemon**.

pkill will send the specified signal (by default **SIGTERM**) to each process instead of listing them on stdout.

pidwait will wait for each process instead of listing them on stdout.

OPTIONS

-signal

--signal *signal*

Defines the signal to send to each matched process. Either the numeric or the symbolic signal name can be used. (**pkill** only.)

-c, --count

Suppress normal output; instead print a count of matching processes. When count does not match anything, e.g. returns zero, the command will return non-zero value. Note that for **pkill** and **pidwait**, the count is the number of matching processes, not the processes that were successfully signaled or waited for.

-d, --delimiter *delimiter*

Sets the string used to delimit each process ID in the output (by default a newline). (**pgrep** only.)

-e, --echo

Display name and PID of the process being killed. (**pkill** only.)

-f, --full

The *pattern* is normally only matched against the process name. When **-f** is set, the full command line is used.

-g, --pgroup *pgrp*...

Only match processes in the process group IDs listed. Process group 0 is translated into **pgrep**'s, **pkill**'s, or **pidwait**'s own process group.

-G, --group *gid*...

Only match processes whose real group ID is listed. Either the numerical or symbolical value may be used.

-i, --ignore-case

Match processes case-insensitively.

-l, --list-name

List the process name as well as the process ID. (**pgrep** only.)

-a, --list-full

List the full command line as well as the process ID. (**pgrep** only.)

- n, --newest**
Select only the newest (most recently started) of the matching processes.
- o, --oldest**
Select only the oldest (least recently started) of the matching processes.
- O, --older secs**
Select processes older than secs.
- P, --parent ppid,...**
Only match processes whose parent process ID is listed.
- s, --session sid,...**
Only match processes whose process session ID is listed. Session ID 0 is translated into **pgrep**'s, **pkill**'s, or **pidwait**'s own session ID.
- t, --terminal term,...**
Only match processes whose controlling terminal is listed. The terminal name should be specified without the "/dev/" prefix.
- u, --euid euid,...**
Only match processes whose effective user ID is listed. Either the numerical or symbolical value may be used.
- U, --uid uid,...**
Only match processes whose real user ID is listed. Either the numerical or symbolical value may be used.
- v, --inverse**
Negates the matching. This option is usually used in **pgrep**'s or **pidwait**'s context. In **pkill**'s context the short option is disabled to avoid accidental usage of the option.
- w, --lightweight**
Shows all thread ids instead of pids in **pgrep**'s or **pidwait**'s context. In **pkill**'s context this option is disabled.
- x, --exact**
Only match processes whose names (or command lines if **-f** is specified) **exactly** match the *pattern*.
- F, --pidfile file**
Read *PIDs* from *file*. This option is more useful for **pkill** or **pid** wait than **pgrep**.
- L, --logpidfile**
Fail if pidfile (see **-F**) not locked.
- r, --runstates D,R,S,Z,...**
Match only processes which match the process state.
- ns pid**
Match processes that belong to the same namespaces. Required to run as root to match processes from other users. See **--nslist** for how to limit which namespaces to match.
- nslist name,...**
Match only the provided namespaces. Available namespaces: ipc, mnt, net, pid, user, uts.
- q, --queue value**
Use **sigqueue(3)** rather than **kill(2)** and the value argument is used to specify an integer to be sent with the signal. If the receiving process has installed a handler for this signal using the SA_INFO flag to **sigaction(2)**, then it can obtain this data via the si_value field of the siginfo_t structure.
- V, --version**
Display version information and exit.

-h, --help

Display help and exit.

OPERANDS

pattern Specifies an Extended Regular Expression for matching against the process names or command lines.

EXAMPLES

Example 1: Find the process ID of the **named** daemon:

```
$ pgrep -u root named
```

Example 2: Make **syslog** reread its configuration file:

```
$ pkill -HUP syslogd
```

Example 3: Give detailed information on all **xterm** processes:

```
$ ps -fp $(pgrep -d, -x xterm)
```

Example 4: Make all **chrome** processes run nicer:

```
$ renice +4 $(pgrep chrome)
```

EXIT STATUS

- 0 One or more processes matched the criteria. For pkill and pidwait, one or more processes must also have been successfully signalled or waited for.
- 1 No processes matched or none of them could be signalled.
- 2 Syntax error in the command line.
- 3 Fatal error: out of memory etc.

NOTES

The process name used for matching is limited to the 15 characters present in the output of /proc/pid/stat. Use the **-f** option to match against the complete command line, /proc/pid/cmdline.

The running **pgrep**, **pkill**, or **pidwait** process will never report itself as a match.

BUGS

The options **-n** and **-o** and **-v** can not be combined. Let me know if you need to do this.

Defunct processes are reported.

NAME

plocate-build – generate index for plocate

SYNOPSIS

plocate-build [OPTION]... MLOCATE_DB PLOCATE_DB

DESCRIPTION

plocate-build creates an index from **plocate(1)** from an index earlier generated by **updatedb(8)** from the **mlocate(1)** package. Most users would rather want to use plocate's own **updatedb(8)**, which is more direct. If *PLOCATE_DB* already exists, it will be overwritten (non-atomically). The file is created such that it is not world-readable, as the final access check is done by **plocate(1)** during the search.

OPTIONS

-b, --block-size SIZE

Create blocks containing *SIZE* filenames each, compress them together, and treat them as the same element in the posting lists. This makes the index smaller (because the compression algorithm gets more context to work with, and because there are fewer elements in each posting list), but also makes posting lists less precise, moving more work to weeding out false positives after posting list intersection.

Making this number larger will make linear search (for **--regex**, or very short patterns) faster, with diminishing returns around 256 filenames per block. However, making it too large will cause more false positives, reducing overall performance for typical queries. The default value is 32. Setting it to 1 makes one (compressed) block per filename.

-p, --plaintext

Treat the input as plain text, with entries delimited by newlines, instead of an mlocate database.

--help Print out usage information, then exit successfully.

--version

Print out version information, then exit successfully.

NAME

plocate – find files by name, quickly

SYNOPSIS

plocate [*OPTION*]... *PATTERN*...

DESCRIPTION

plocate finds all files on the system matching the given pattern (or all of the patterns if multiple are given). It does this by means of an index made by **updatedb(8)** or (less commonly) converted from another index by **plocate-build(8)**.

plocate is largely argument-compatible with **mlocate(1)**, but is significantly faster. In particular, it rarely needs to scan through its entire database, unless the pattern is very short (less than three bytes) or you want to search for a regular expression. It does not try to maintain compatibility with BSD locate, or non-UTF-8 filenames and locales. Most I/O is done asynchronously, but the results are synchronized so that output comes in the same order every time.

When multiple patterns are given, **plocate** will search for files that match *all* of them. This is the main incompatibility with **mlocate(1)**, which searches for files that match one or more patterns, unless the **-A** option is given.

By default, patterns are taken to be substrings to search for. If at least one non-escaped globbing metacharacter (*, ?, or []) is given, that pattern is instead taken to be a glob pattern (which means it needs to start and end in * for a substring match). If **--regexp** is given, patterns are instead taken to be (non-anchored) POSIX basic regular expressions, and if **--regex** is given, patterns are taken to be POSIX extended regular expressions. All of this matches **mlocate(1)** behavior.

Like **mlocate(1)**, **plocate** shows all files visible to the calling user (by virtue of having read and execute permissions on all parent directories), and none that are not, by means of running with the setgid bit set to access the index (which is built as root), but by testing visibility as the calling user.

OPTIONS**-A, --all**

Ignored for compatibility with **mlocate(1)**.

-b, --basename

Match only against the file name portion of the path name, ie., the directory names will be excluded from the match (but still printed). This does not speed up the search, but can suppress uninteresting matches.

-c, --count

Do not print each match. Instead, count them, and print out a total number at the end.

-d, --database DBPATH

Find matches in the given database, instead of **/var/lib/plocate/plocate.db**. This argument can be given multiple times, to search multiple databases. It is also possible to give multiple databases in one argument, separated by :. (Any character, including :, and \, can be escaped by prepending a \.)

-e, --existing

Print only entries that refer to files existing at the time **locate** is run. Note that unlike **mlocate(1)**, symlinks are not followed by default (and indeed, there is no option to change this).

-i, --ignore-case

Do a case-insensitive match as given by the current locale (default is case-sensitive, byte-by-byte match). Note that **plocate** does not support the full range of Unicode case folding rules; in particular, searching for β will not give you matches on ss even in a German locale. Also note that this option will be somewhat slower than a case-sensitive match, since it needs to generate more candidates for searching the index.

-p, --ignore-spaces

Ignore punctuation and spaces when matching patterns.

-l, --limit LIMIT

Stop searching after *LIMIT* matches have been found. If **--count** is given, the number printed out will be at most *LIMIT*.

-N, --literal

Print entry names without quoting. Normally, **plocate** will escape special characters in filenames, so that they are safe for consumption by typical shells (similar to the GNU coreutils *shell-escape-always* quoting style), unless printing to a pipe, but this option will turn off such quoting.

-0, --null

Instead of writing a newline after every match, write a NUL (ASCII 0). This is useful for creating unambiguous output when it is to be processed by other tools (like **xargs(1)**), as filenames are allowed to contain embedded newlines.

-r, --regexp

Patterns are taken to be POSIX basic regular expressions. See **egrep(7)** for more information. Note that this forces a linear scan through the entire database, which is slow.

--regex

Like **--regexp**, but patterns are instead taken to be POSIX *extended* regular expressions.

-w, --wholename

Match against the entire path name. This is the default, so unless **-b** is given first (see above), it will not do anything. This option thus exists only as compatibility with **mlocate(1)**.

--help Print out usage information, then exit successfully.**--version**

Print out version information, then exit successfully.

ENVIRONMENT**LOCATE_PATH**

If given, appended after the list of **--database** paths (whether an explicit is given or the default is used). Colon-delimiting and character escaping follows the same rules as for **--database**.

SEE ALSO

plocate-build(8), mlocate(1), updatedb(8)

NAME

ps – report a snapshot of the current processes.

SYNOPSIS

ps [*options*]

DESCRIPTION

ps displays information about a selection of the active processes. If you want a repetitive update of the selection and the displayed information, use **top** instead.

This version of **ps** accepts several kinds of options:

- 1 UNIX options, which may be grouped and must be preceded by a dash.
- 2 BSD options, which may be grouped and must not be used with a dash.
- 3 GNU long options, which are preceded by two dashes.

Options of different types may be freely mixed, but conflicts can appear. There are some synonymous options, which are functionally identical, due to the many standards and **ps** implementations that this **ps** is compatible with.

Note that **ps -aux** is distinct from **ps aux**. The POSIX and UNIX standards require that **ps -aux** print all processes owned by a user named *x*, as well as printing all processes that would be selected by the **-a** option. If the user named *x* does not exist, this **ps** may interpret the command as **ps aux** instead and print a warning. This behavior is intended to aid in transitioning old scripts and habits. It is fragile, subject to change, and thus should not be relied upon.

By default, **ps** selects all processes with the same effective user ID (euid=EUID) as the current user and associated with the same terminal as the invoker. It displays the process ID (pid=PID), the terminal associated with the process (tname=TTY), the cumulated CPU time in [DD-]hh:mm:ss format (time=TIME), and the executable name (ucmd=CMD). Output is unsorted by default.

The use of BSD-style options will add process state (stat=STAT) to the default display and show the command args (args=COMMAND) instead of the executable name. You can override this with the **PS_FORMAT** environment variable. The use of BSD-style options will also change the process selection to include processes on other terminals (TTYs) that are owned by you; alternately, this may be described as setting the selection to be the set of all processes filtered to exclude processes owned by other users or not on a terminal. These effects are not considered when options are described as being "identical" below, so **-M** will be considered identical to **Z** and so on.

Except as described below, process selection options are additive. The default selection is discarded, and then the selected processes are added to the set of processes to be displayed. A process will thus be shown if it meets any of the given selection criteria.

EXAMPLES

To see every process on the system using standard syntax:

```
ps -e  
ps -ef  
ps -eF  
ps -ely
```

To see every process on the system using BSD syntax:

```
ps ax  
ps axu
```

To print a process tree:

```
ps -ejH  
ps axjf
```

To get info about threads:

```
ps -eLf  
ps axms
```

To get security info:

```
ps -eo euser,ruser,suser,fuser,f,comm,label
ps axZ
ps -eM
```

To see every process running as root (real & effective ID) in user format:

```
ps -U root -u root u
```

To see every process with a user-defined format:

```
ps -eo pid,tid,class,rtprio,ni,pri,psr,pcpu,stat,wchan:14,comm
ps axo stat,euid,ruid,tty,tpgid,ses,pgroup,ppid,pid,pcpu,comm
ps -Ao pid,tt,user,fnname,tmout,f,wchan
```

Print only the process IDs of syslogd:

```
ps -C syslogd -o pid=
```

Print only the name of PID 42:

```
ps -q 42 -o comm=
```

SIMPLE PROCESS SELECTION

- a** Lift the BSD-style "only yourself" restriction, which is imposed upon the set of all processes when some BSD-style (without "-") options are used or when the **ps** personality setting is BSD-like. The set of processes selected in this manner is in addition to the set of processes selected by other means. An alternate description is that this option causes **ps** to list all processes with a terminal (tty), or to list all processes when used together with the **x** option.
- A** Select all processes. Identical to **-e**.
- a** Select all processes except both session leaders (see *getsid(2)*) and processes not associated with a terminal.
- d** Select all processes except session leaders.
- deselect**
Select all processes except those that fulfill the specified conditions (negates the selection). Identical to **-N**.
- e** Select all processes. Identical to **-A**.
- g** Really all, even session leaders. This flag is obsolete and may be discontinued in a future release. It is normally implied by the **a** flag, and is only useful when operating in the sunos4 personality.
- N** Select all processes except those that fulfill the specified conditions (negates the selection). Identical to **--deselect**.
- T** Select all processes associated with this terminal. Identical to the **t** option without any argument.
- r** Restrict the selection to only running processes.
- x** Lift the BSD-style "must have a tty" restriction, which is imposed upon the set of all processes when some BSD-style (without "-") options are used or when the **ps** personality setting is BSD-like. The set of processes selected in this manner is in addition to the set of processes selected by other means. An alternate description is that this option causes **ps** to list all processes owned by you (same EUID as **ps**), or to list all processes when used together with the **a** option.

PROCESS SELECTION BY LIST

These options accept a single argument in the form of a blank-separated or comma-separated list. They can be used multiple times. For example: **ps -p "1 2" -p 3,4**

-123 Identical to **--pid 123**.

123 Identical to **--pid 123**.

-C cmdlist

Select by command name. This selects the processes whose executable name is given in *cmdlist*.
NOTE: The command name is not the same as the command line. Previous versions of procps and

the kernel truncated this command name to 15 characters. This limitation is no longer present in both. If you depended on matching only 15 characters, you may no longer get a match.

-G *grplist*

Select by real group ID (RGID) or name. This selects the processes whose real group name or ID is in the *grplist* list. The real group ID identifies the group of the user who created the process, see *getgid*(2).

-g *grplist*

Select by session OR by effective group name. Selection by session is specified by many standards, but selection by effective group is the logical behavior that several other operating systems use. This **ps** will select by session when the list is completely numeric (as sessions are). Group ID numbers will work only when some group names are also specified. See the **-s** and **--group** options.

--Group *grplist*

Select by real group ID (RGID) or name. Identical to **-G**.

--group *grplist*

Select by effective group ID (EGID) or name. This selects the processes whose effective group name or ID is in *grplist*. The effective group ID describes the group whose file access permissions are used by the process (see *getegid*(2)). The **-g** option is often an alternative to **--group**.

p *pidlist*

Select by process ID. Identical to **-p** and **--pid**.

-p *pidlist*

Select by PID. This selects the processes whose process ID numbers appear in *pidlist*. Identical to **p** and **--pid**.

--pid *pidlist*

Select by process ID. Identical to **-p** and **p**.

--ppid *pidlist*

Select by parent process ID. This selects the processes with a parent process ID in *pidlist*. That is, it selects processes that are children of those listed in *pidlist*.

q *pidlist*

Select by process ID (quick mode). Identical to **-q** and **--quick-pid**.

-q *pidlist*

Select by PID (quick mode). This selects the processes whose process ID numbers appear in *pidlist*. With this option **ps** reads the necessary info only for the pids listed in the *pidlist* and doesn't apply additional filtering rules. The order of pids is unsorted and preserved. No additional selection options, sorting and forest type listings are allowed in this mode. Identical to **q** and **--quick-pid**.

--quick-pid *pidlist*

Select by process ID (quick mode). Identical to **-q** and **q**.

-s *sesslist*

Select by session ID. This selects the processes with a session ID specified in *sesslist*.

--sid *sesslist*

Select by session ID. Identical to **-s**.

t *ttylist* Select by tty. Nearly identical to **-t** and **--tty**, but can also be used with an empty *ttylist* to indicate the terminal associated with **ps**. Using the **T** option is considered cleaner than using **t** with an empty *ttylist*.

-t *ttylist*

Select by tty. This selects the processes associated with the terminals given in *ttylist*. Terminals (ttys, or screens for text output) can be specified in several forms: /dev/ttyS1, ttyS1, S1. A plain

"–" may be used to select processes not attached to any terminal.

--tty *ttylist*

Select by terminal. Identical to **-t** and **t**.

U *userlist*

Select by effective user ID (EUID) or name. This selects the processes whose effective user name or ID is in *userlist*. The effective user ID describes the user whose file access permissions are used by the process (see *geteuid(2)*). Identical to **u** and **--user**.

-U *userlist*

Select by real user ID (RUID) or name. It selects the processes whose real user name or ID is in the *userlist* list. The real user ID identifies the user who created the process, see *getuid(2)*.

-u *userlist*

Select by effective user ID (EUID) or name. This selects the processes whose effective user name or ID is in *userlist*.

The effective user ID describes the user whose file access permissions are used by the process (see *geteuid(2)*). Identical to **U** and **--user**.

--User *userlist*

Select by real user ID (RUID) or name. Identical to **-U**.

--user *userlist*

Select by effective user ID (EUID) or name. Identical to **-u** and **U**.

OUTPUT FORMAT CONTROL

These options are used to choose the information displayed by **ps**. The output may differ by personality.

-c Show different scheduler information for the **-l** option.

--context

Display security context format (for SELinux).

-f Do full-format listing. This option can be combined with many other UNIX-style options to add additional columns. It also causes the command arguments to be printed. When used with **-L**, the NLWP (number of threads) and LWP (thread ID) columns will be added. See the **c** option, the format keyword **args**, and the format keyword **comm**.

-F Extra full format. See the **-f** option, which **-F** implies.

--format *format*

user-defined format. Identical to **-o** and **o**.

j BSD job control format.

-j Jobs format.

l Display BSD long format.

-l Long format. The **-y** option is often useful with this.

-M Add a column of security data. Identical to **Z** (for SELinux).

O *format*

is preloaded **o** (overloaded). The **BSDO** option can act like **e -O** (user-defined output format with some common fields predefined) or can be used to specify sort order. Heuristics are used to determine the behavior of this option. To ensure that the desired behavior is obtained (sorting or formatting), specify the option in some other way (e.g. with **-O** or **--sort**). When used as a formatting option, it is identical to **-O**, with the BSD personality.

-O *format*

Like **-o**, but preloaded with some default columns. Identical to **-o pid,format,state,tname,time,command** or **-o pid,format,tname,time,cmd**, see **-o** below.

o *format*

Specify user-defined format. Identical to **-o** and **--format**.

-o *format*

User-defined format. *format* is a single argument in the form of a blank-separated or comma-separated list, which offers a way to specify individual output columns. The recognized keywords are described in the **STANDARD FORMAT SPECIFIERS** section below. Headers may be renamed (**ps -o pid,ruser=RealUser -o comm=Command**) as desired. If all column headers are empty (**ps -o pid= -o comm=**) then the header line will not be output. Column width will increase as needed for wide headers; this may be used to widen up columns such as WCHAN (**ps -o pid,wchan=WIDE-WCHAN-COLUMN -o comm**). Explicit width control (**ps opid, wchan:42,cmd**) is offered too. The behavior of **ps -o pid=X,comm=Y** varies with personality; output may be one column named "X,comm=Y" or two columns named "X" and "Y". Use multiple **-o** options when in doubt. Use the **PS_FORMAT** environment variable to specify a default as desired; DefSysV and DefBSD are macros that may be used to choose the default UNIX or BSD columns.

s Display signal format.

u Display user-oriented format.

v Display virtual memory format.

X Register format.

-y Do not show flags; show rss in place of addr. This option can only be used with **-l**.

Z Add a column of security data. Identical to **-M** (for SELinux).

OUTPUT MODIFIERS

c Show the true command name. This is derived from the name of the executable file, rather than from the argv value. Command arguments and any modifications to them are thus not shown. This option effectively turns the **args** format keyword into the **comm** format keyword; it is useful with the **-f** format option and with the various BSD-style format options, which all normally display the command arguments. See the **-f** option, the format keyword **args**, and the format keyword **comm**.

--cols *n*

Set screen width.

--columns *n*

Set screen width.

--cumulative

Include some dead child process data (as a sum with the parent).

e Show the environment after the command.

f ASCII art process hierarchy (forest).

--forest

ASCII art process tree.

h No header. (or, one header per screen in the BSD personality). The **h** option is problematic.

Standard BSD **ps** uses this option to print a header on each page of output, but older Linux **ps** uses this option to totally disable the header. This version of **ps** follows the Linux usage of not printing the header unless the BSD personality has been selected, in which case it prints a header on each page of output. Regardless of the current personality, you can use the long options **--headers** and **--no-headers** to enable printing headers each page or disable headers entirely, respectively.

-H Show process hierarchy (forest).

--headers

Repeat header lines, one per page of output.

k spec Specify sorting order. Sorting syntax is `[+|-]key[,[+|-]key[,...]]`. Choose a multi-letter key from the **STANDARD FORMAT SPECIFIERS** section. The "+" is optional since default direction is increasing numerical or lexicographic order. Identical to—**sort**.

Examples:

```
ps jaxkuid,-ppid,+pid
ps axk comm o comm,args
ps kstart_time -ef
```

—lines n

Set screen height.

n Numeric output for WCHAN and USER (including all types of UID and GID).

—no-headers

Print no header line at all. —**no-heading** is an alias for this option.

O order

Sorting order (overloaded). The **BSDO** option can act like —**O** (user-defined output format with some common fields predefined) or can be used to specify sort order. Heuristics are used to determine the behavior of this option. To ensure that the desired behavior is obtained (sorting or formatting), specify the option in some other way (e.g. with —**O** or —**sort**).

For sorting, obsolete BSD **O** option syntax is `O[+|-]k1[,[+|-]k2[,...]]`. It orders the processes listing according to the multilevel sort specified by the sequence of one-letter short keys *k1,k2,...* described in the **OBSOLETE SORT KEYS** section below. The "+" is currently optional, merely re-iterating the default direction on a key, but may help to distinguish an **O** sort from an **O** format. The "--" reverses direction only on the key it precedes.

—rows n

Set screen height.

S Sum up some information, such as CPU usage, from dead child processes into their parent. This is useful for examining a system where a parent process repeatedly forks off short-lived children to do work.

—sort spec

Specify sorting order. Sorting syntax is `[+|-]key[,[+|-]key[,...]]`. Choose a multi-letter key from the **STANDARD FORMAT SPECIFIERS** section. The "+" is optional since default direction is increasing numerical or lexicographic order. Identical to **k**. For example: `ps jax --sort=uid,-ppid,+pid`

w Wide output. Use this option twice for unlimited width.

-w Wide output. Use this option twice for unlimited width.

—width n

Set screen width.

THREAD DISPLAY

H Show threads as if they were processes.

-L Show threads, possibly with LWP and NLWP columns.

m Show threads after processes.

-m Show threads after processes.

-T Show threads, possibly with SPID column.

OTHER INFORMATION

—help section

Print a help message. The *section* argument can be one of *simple*, *list*, *output*, *threads*, *misc*, or *all*. The argument can be shortened to one of the underlined letters as in: `s|l|o|t|m|a`.

--info Print debugging info.
L List all format specifiers.
V Print the procps-ng version.
-V Print the procps-ng version.
--version
Print the procps-ng version.

NOTES

This **ps** works by reading the virtual files in /proc. This **ps** does not need to be setuid kmem or have any privileges to run. Do not give this **ps** any special permissions.

CPU usage is currently expressed as the percentage of time spent running during the entire lifetime of a process. This is not ideal, and it does not conform to the standards that **ps** otherwise conforms to. CPU usage is unlikely to add up to exactly 100%.

The SIZE and RSS fields don't count some parts of a process including the page tables, kernel stack, struct thread_info, and struct task_struct. This is usually at least 20 KiB of memory that is always resident. SIZE is the virtual size of the process (code+data+stack).

Processes marked <defunct> are dead processes (so-called "zombies") that remain because their parent has not destroyed them properly. These processes will be destroyed by *init*(8) if the parent process exits.

If the length of the username is greater than the length of the display column, the username will be truncated. See the **-o** and **-O** formatting options to customize length.

Commands options such as **ps -aux** are not recommended as it is a confusion of two different standards. According to the POSIX and UNIX standards, the above command asks to display all processes with a TTY (generally the commands users are running) plus all processes owned by a user named *x*. If that user doesn't exist, then **ps** will assume you really meant **ps aux**.

PROCESS FLAGS

The sum of these values is displayed in the "F" column, which is provided by the **flags** output specifier:

- 1 forked but didn't exec
- 4 used super-user privileges

PROCESS STATE CODES

Here are the different values that the **s**, **stat** and **state** output specifiers (header "STAT" or "S") will display to describe the state of a process:

- D uninterruptible sleep (usually IO)
- I Idle kernel thread
- R running or runnable (on run queue)
- S interruptible sleep (waiting for an event to complete)
- T stopped by job control signal
- t stopped by debugger during the tracing
- W paging (not valid since the 2.6.xx kernel)
- X dead (should never be seen)
- Z defunct ("zombie") process, terminated but not reaped by its parent

For BSD formats and when the **stat** keyword is used, additional characters may be displayed:

- < high-priority (not nice to other users)
- N low-priority (nice to other users)
- L has pages locked into memory (for real-time and custom IO)
- s is a session leader
- l is multi-threaded (using CLONE_THREAD, like NPTL pthreads do)
- +
- is in the foreground process group

OBSOLETE SORT KEYS

These keys are used by the BSD **O** option (when it is used for sorting). The GNU **--sort** option doesn't use these keys, but the specifiers described below in the **STANDARD FORMAT SPECIFIERS** section. Note that the values used in sorting are the internal values **ps** uses and not the "cooked" values used in some of the output format fields (e.g. sorting on **tty** will sort into device number, not according to the terminal name displayed). Pipe **ps** output into the **sort(1)** command if you want to sort the cooked values.

KEY	LONG	DESCRIPTION
c	cmd	simple name of executable
C	pcpu	cpu utilization
f	flags	flags as in long format F field
g	pgrp	process group ID
G	tpgid	controlling tty process group ID
j	cutime	cumulative user time
J	cstime	cumulative system time
k	utime	user time
m	min_flt	number of minor page faults
M	maj_flt	number of major page faults
n	cmin_flt	cumulative minor page faults
N	cmaj_flt	cumulative major page faults
o	session	session ID
p	pid	process ID
P	ppid	parent process ID
r	rss	resident set size
R	resident	resident pages
s	size	memory size in kilobytes
S	share	amount of shared pages
t	tty	the device number of the controlling tty
T	start_time	time process was started
U	uid	user ID number
u	user	user name
v	vsize	total VM size in KiB
y	priority	kernel scheduling priority

AIX FORMAT DESCRIPTORS

This **ps** supports AIX format descriptors, which work somewhat like the formatting codes of *printf(1)* and *printf(3)*. For example, the normal default output can be produced with this: **ps -eo "%p %y %x %c"**. The **NORMAL** codes are described in the next section.

CODE	NORMAL	HEADER
%C	pcpu	%CPU
%G	group	GROUP
%P	ppid	PPID
%U	user	USER
%a	args	COMMAND
%c	comm	COMMAND
%g	rgroup	RGROUP
%n	nice	NI
%p	pid	PID
%r	pgid	PGID
%t	etime	ELAPSED
%u	ruser	RUSER
%x	time	TIME
%y	tty	TTY
%z	vsz	VSZ

STANDARD FORMAT SPECIFIERS

Here are the different keywords that may be used to control the output format (e.g., with option **-o**) or to sort the selected processes with the GNU-style **--sort** option.

For example: **ps -eo pid,user,args --sort user**

This version of **ps** tries to recognize most of the keywords used in other implementations of **ps**.

The following user-defined format specifiers may contain spaces: **args**, **cmd**, **comm**, **command**, **fname**, **ucmd**, **ucomm**, **lstart**, **bsdstart**, **start**.

Some keywords may not be available for sorting.

CODE	HEADER	DESCRIPTION
%cpu	%CPU	cpu utilization of the process in "##.#" format. Currently, it is the CPU time used divided by the time the process has been running (cputime realtime ratio), expressed as a percentage. It will not add up to 100% unless you are lucky. (alias pcpu).
%mem	%MEM	ratio of the process's resident set size to the physical memory on the machine, expressed as a percentage. (alias pmem).
args	COMMAND	command with all its arguments as a string. Modifications to the arguments may be shown. The output in this column may contain spaces. A process marked <defunct> is partly dead, waiting to be fully destroyed by its parent. Sometimes the process args will be unavailable; when this happens, ps will instead print the executable name in brackets. (alias cmd , command). See also the comm format keyword, the -f option, and the c option. When specified last, this column will extend to the edge of the display. If ps can not determine display width, as when output is redirected (piped) into a file or another command, the output width is undefined (it may be 80, unlimited, determined by the TERM variable, and so on). The COLUMNS environment variable or --cols option may be used to exactly determine the width in this case. The w or -w option may be also be used to adjust width.
blocked	BLOCKED	mask of the blocked signals, see <i>signal(7)</i> . According to the width of the field, a 32 or 64-bit mask in hexadecimal format is displayed. (alias sig_block , sigmask).
bsdstart	START	time the command started. If the process was started less than 24 hours ago, the output format is " HH:MM", else it is " Mmm:SS" (where Mmm is the three letters of the month). See also lstart , start , start_time , and stime .
bsdtime	TIME	accumulated cpu time, user + system. The display format is usually "MMM:SS", but can be shifted to the right if the process used more than 999 minutes of cpu time.
c	C	processor utilization. Currently, this is the integer value of the percent usage over the lifetime of the process. (see %cpu).
caught	CAUGHT	mask of the caught signals, see <i>signal(7)</i> . According to the width of the field, a 32 or 64 bits mask in hexadecimal format is displayed. (alias sig_catch , sigcatch).

cgroup	CGROUP	display control groups to which the process belongs.																		
class	CLS	scheduling class of the process. (alias policy , cls). Field's possible values are:																		
		<table> <tbody> <tr><td>-</td><td>not reported</td></tr> <tr><td>TS</td><td>SCED_OTHER</td></tr> <tr><td>FF</td><td>SCED_FIFO</td></tr> <tr><td>RR</td><td>SCED_RR</td></tr> <tr><td>B</td><td>SCED_BATCH</td></tr> <tr><td>ISO</td><td>SCED_ISO</td></tr> <tr><td>IDL</td><td>SCED_IDLE</td></tr> <tr><td>DLN</td><td>SCED_DEADLINE</td></tr> <tr><td>?</td><td>unknown value</td></tr> </tbody> </table>	-	not reported	TS	SCED_OTHER	FF	SCED_FIFO	RR	SCED_RR	B	SCED_BATCH	ISO	SCED_ISO	IDL	SCED_IDLE	DLN	SCED_DEADLINE	?	unknown value
-	not reported																			
TS	SCED_OTHER																			
FF	SCED_FIFO																			
RR	SCED_RR																			
B	SCED_BATCH																			
ISO	SCED_ISO																			
IDL	SCED_IDLE																			
DLN	SCED_DEADLINE																			
?	unknown value																			
cls	CLS	scheduling class of the process. (alias policy , cls). Field's possible values are:																		
		<table> <tbody> <tr><td>-</td><td>not reported</td></tr> <tr><td>TS</td><td>SCED_OTHER</td></tr> <tr><td>FF</td><td>SCED_FIFO</td></tr> <tr><td>RR</td><td>SCED_RR</td></tr> <tr><td>B</td><td>SCED_BATCH</td></tr> <tr><td>ISO</td><td>SCED_ISO</td></tr> <tr><td>IDL</td><td>SCED_IDLE</td></tr> <tr><td>DLN</td><td>SCED_DEADLINE</td></tr> <tr><td>?</td><td>unknown value</td></tr> </tbody> </table>	-	not reported	TS	SCED_OTHER	FF	SCED_FIFO	RR	SCED_RR	B	SCED_BATCH	ISO	SCED_ISO	IDL	SCED_IDLE	DLN	SCED_DEADLINE	?	unknown value
-	not reported																			
TS	SCED_OTHER																			
FF	SCED_FIFO																			
RR	SCED_RR																			
B	SCED_BATCH																			
ISO	SCED_ISO																			
IDL	SCED_IDLE																			
DLN	SCED_DEADLINE																			
?	unknown value																			
cmd	CMD	see args . (alias gs , command).																		
comm	COMMAND	command name (only the executable name). Modifications to the command name will not be shown. A process marked <defunct> is partly dead, waiting to be fully destroyed by its parent. The output in this column may contain spaces. (alias ucmd , ucomm). See also the ar gs format keyword, the -f option, and the c option. When specified last, this column will extend to the edge of the display. If ps can not determine display width, as when output is redirected (piped) into a file or another command, the output width is undefined (it may be 80, unlimited, determined by the TERM variable, and so on). The COLUMNS environment variable or --cols option may be used to exactly determine the width in this case. The w or -w option may be also be used to adjust width.																		
command	COMMAND	See args . (alias gs , command).																		
cp	CP	per-mill (tenths of a percent) CPU usage. (see %cpu).																		
cputime	TIME	cumulative CPU time, "[DD-]hh:mm:ss" format. (alias time).																		
cputimes	TIME	cumulative CPU time in seconds (alias times).																		
drs	DRS	data resident set size, the amount of physical memory devoted to other than executable code.																		

egid	EGID	effective group ID number of the process as a decimal integer. (alias gid).
egroup	EGROUP	effective group ID of the process. This will be the textual group ID, if it can be obtained and the field width permits, or a decimal representation otherwise. (alias group).
eip	EIP	instruction pointer.
esp	ESP	stack pointer.
etime	ELAPSED	elapsed time since the process was started, in the form [[DD–]hh:]mm:ss.
etimes	ELAPSED	elapsed time since the process was started, in seconds.
euid	EUID	effective user ID (alias uid).
euser	EUSER	effective user name. This will be the textual user ID, if it can be obtained and the field width permits, or a decimal representation otherwise. The n option can be used to force the decimal representation. (alias uname , user).
exe	EXE	path to the executable. Useful if path cannot be printed via cmd , comm or args format options.
f	F	flags associated with the process, see the PROCESS FLAGS section. (alias flag , flags).
fgid	FGID	filesystem access group ID. (alias fsgid).
fgroup	FGROUP	filesystem access group ID. This will be the textual group ID, if it can be obtained and the field width permits, or a decimal representation otherwise. (alias fsgroup).
flag	F	see f . (alias f , flags).
flags	F	see f . (alias f , flag).
fname	COMMAND	first 8 bytes of the base name of the process's executable file. The output in this column may contain spaces.
fuid	FUID	filesystem access user ID. (alias fsuid).
fuser	FUSER	filesystem access user ID. This will be the textual user ID, if it can be obtained and the field width permits, or a decimal representation otherwise.
gid	GID	see egid . (alias egid).
group	GROUP	see egroup . (alias egroup).
ignored	IGNORED	mask of the ignored signals, see <i>signal(7)</i> . According to the width of the field, a 32 or 64 bits mask in hexadecimal format is displayed. (alias sig_ignore , sigignore).

ipcns	IPCNS	Unique inode number describing the namespace the process belongs to. See <i>namespaces(7)</i> .
label	LABEL	security label, most commonly used for SELinux context data. This is for the <i>Mandatory Access Control</i> ("MAC") found on high-security systems.
lstart	STARTED	time the command started. See also bsdstart , start , start_time , and stime .
lsession	SESSION	displays the login session identifier of a process, if systemd support has been included.
luid	LUID	displays Login ID associated with a process.
lwp	LWP	light weight process (thread) ID of the dispatchable entity (alias spid , tid). See tid for additional information.
lxc	LXC	The name of the lxc container within which a task is running. If a process is not running inside a container, a dash ('-') will be shown.
machine	MACHINE	displays the machine name for processes assigned to VM or container, if systemd support has been included.
maj_flt	MAJFLT	The number of major page faults that have occurred with this process.
min_flt	MINFLT	The number of minor page faults that have occurred with this process.
mntns	MNTNS	Unique inode number describing the namespace the process belongs to. See <i>namespaces(7)</i> .
netns	NETNS	Unique inode number describing the namespace the process belongs to. See <i>namespaces(7)</i> .
ni	NI	nice value. This ranges from 19 (nicest) to -20 (not nice to others), see <i>nice(1)</i> . (alias nice).
nice	NI	see ni.(alias ni) .
nlwp	NLWP	number of lwps (threads) in the process. (alias thcount).
numa	NUMA	The node associated with the most recently used processor. A -1 means that NUMA information is unavailable.
nwchan	WCHAN	address of the kernel function where the process is sleeping (use wchan if you want the kernel function name). Running tasks will display a dash ('-') in this column.
ouid	OWNER	displays the Unix user identifier of the owner of the session of a process, if systemd support has been included.
pcpu	%CPU	see %cpu . (alias %cpu).

pending	PENDING	mask of the pending signals. See <i>signal(7)</i> . Signals pending on the process are distinct from signals pending on individual threads. Use the m option or the -m option to see both. According to the width of the field, a 32 or 64 bits mask in hexadecimal format is displayed. (alias sig).																		
pgid	PGID	process group ID or, equivalently, the process ID of the process group leader. (alias pgrp).																		
pgrp	PGRP	see pgid . (alias pgid).																		
pid	PID	a number representing the process ID (alias tgid).																		
pidns	PIDNS	Unique inode number describing the namespace the process belongs to. See <i>namespaces(7)</i> .																		
pmem	%MEM	see %mem . (alias %mem).																		
policy	POL	scheduling class of the process. (alias class , cls). Possible values are:																		
		<table> <tr><td>–</td><td>not reported</td></tr> <tr><td>TS</td><td>SCED_OTHER</td></tr> <tr><td>FF</td><td>SCED_FIFO</td></tr> <tr><td>RR</td><td>SCED_RR</td></tr> <tr><td>B</td><td>SCED_BATCH</td></tr> <tr><td>ISO</td><td>SCED_ISO</td></tr> <tr><td>IDL</td><td>SCED_IDLE</td></tr> <tr><td>DLN</td><td>SCED_DEADLINE</td></tr> <tr><td>?</td><td>unknown value</td></tr> </table>	–	not reported	TS	SCED_OTHER	FF	SCED_FIFO	RR	SCED_RR	B	SCED_BATCH	ISO	SCED_ISO	IDL	SCED_IDLE	DLN	SCED_DEADLINE	?	unknown value
–	not reported																			
TS	SCED_OTHER																			
FF	SCED_FIFO																			
RR	SCED_RR																			
B	SCED_BATCH																			
ISO	SCED_ISO																			
IDL	SCED_IDLE																			
DLN	SCED_DEADLINE																			
?	unknown value																			
ppid	PPID	parent process ID.																		
pri	PRI	priority of the process. Higher number means lower priority.																		
psr	PSR	processor that process is currently assigned to.																		
rgid	RGID	real group ID.																		
rgroup	RGROUP	real group name. This will be the textual group ID, if it can be obtained and the field width permits, or a decimal representation otherwise.																		
rss	RSS	resident set size, the non-swapped physical memory that a task has used (in kilobytes). (alias rssize , rsz).																		
rssize	RSS	see rss . (alias rss , rsz).																		
rsz	RSZ	see rss . (alias rss , rssize).																		
rtprio	RTPRIO	realtime priority.																		
ruid	RUID	real user ID.																		
ruser	RUSER	real user ID. This will be the textual user ID, if it can be obtained and the field width permits, or a decimal representation otherwise.																		

s	S	minimal state display (one character). See section PROCESS STATE CODES for the different values. See also stat if you want additional information displayed. (alias state).
sched	SCH	scheduling policy of the process. The policies SCHED_OTHER (SCHED_NORMAL), SCHED_FIFO, SCHED_RR, SCHED_BATCH, SCHED_ISO, SCHED_IDLE and SCHED_DEADLINE are respectively displayed as 0, 1, 2, 3, 4, 5 and 6.
seat	SEAT	displays the identifier associated with all hardware devices assigned to a specific workplace, if systemd support has been included.
sess	SESS	session ID or, equivalently, the process ID of the session leader. (alias session , sid).
sgi_p	P	processor that the process is currently executing on. Displays "*" if the process is not currently running or runnable.
sgid	SGID	saved group ID. (alias svgid).
sgroup	SGROUP	saved group name. This will be the textual group ID, if it can be obtained and the field width permits, or a decimal representation otherwise.
sid	SID	see sess . (alias session).
sig	PENDING	see pending . (alias pending , sig_pend).
sigcatch	CAUGHT	see caught . (alias caught , sig_catch).
sigignore	IGNORED	see ignored . (alias ignored , sig_ignore).
sigmask	BLOCKED	see blocked . (alias block , sig_block).
size	SIZE	approximate amount of swap space that would be required if the process were to dirty all writable pages and then be swapped out. This number is very rough!
slice	SLICE	displays the slice unit which a process belongs to, if systemd support has been included.
spid	SPID	see lwp . (alias lwp , tid).
stackp	STACKP	address of the bottom (start) of stack for the process.
start	STARTED	time the command started. If the process was started less than 24 hours ago, the output format is "HH:MM:SS", else it is " Mmm dd" (where Mmm is a three-letter month name). See also lstart , bsdstart , start_time , and stime .
start_time	START	starting time or date of the process. Only the year will be displayed if the process was not started the same year ps was invoked, or "MmmDD" if it was not started the same day, or "HH:MM" otherwise. See also bsdstart , start , lstart , and stime .

stat	STAT	multi-character process state. See section PROCESS STATE CODES for the different values meaning. See also s and state if you just want the first character displayed.
state	S	see s . (alias s).
stime	STIME	see start_time . (alias start_time).
suid	SUID	saved user ID. (alias svuid).
supgid	SUPGID	group ids of supplementary groups, if any. See getgr oups(2) .
supgrp	SUPGRP	group names of supplementary groups, if any. See getgr oups(2) .
suser	SUSER	saved user name. This will be the textual user ID, if it can be obtained and the field width permits, or a decimal representation otherwise. (alias svuser).
svgid	SVGID	see sgid . (alias sgid).
svuid	SVUID	see suid . (alias suid).
sz	SZ	size in physical pages of the core image of the process. This includes text, data, and stack space. Device mappings are currently excluded; this is subject to change. See vsz and rss .
tgid	TGID	a number representing the thread group to which a task belongs (alias pid). It is the process ID of the thread group leader.
thcount	THCNT	see nlwp . (alias nlwp). number of kernel threads owned by the process.
tid	TID	the unique number representing a dispatchable entity (alias lwp , spid). This value may also appear as: a process ID (pid); a process group ID (pgrp); a session ID for the session leader (sid); a thread group ID for the thread group leader (tgid); and a tty process group ID for the process group leader (tpgid).
time	TIME	cumulative CPU time, "[DD-]HH:MM:SS" format. (alias cpu_time).
times	TIME	cumulative CPU time in seconds (alias cpu_times).
tname	TTY	controlling tty (terminal). (alias tt , tty).
tpgid	TPGID	ID of the foreground process group on the tty (terminal) that the process is connected to, or -1 if the process is not connected to a tty.
trs	TRS	text resident set size, the amount of physical memory devoted to executable code.
tt	TT	controlling tty (terminal). (alias tname , tty).
tty	TT	controlling tty (terminal). (alias tname , tt).
ucmd	CMD	see comm . (alias comm , ucomm).

ucomm	COMMAND	see comm . (alias comm , ucmd).
uid	UID	see euid . (alias euid).
uname	USER	see euser . (alias euser , user).
unit	UNIT	displays unit which a process belongs to, if systemd support has been included.
user	USER	see euser . (alias euser , uname).
usersns	USERNS	Unique inode number describing the namespace the process belongs to. See <i>namespaces(7)</i> .
utsns	UTSNS	Unique inode number describing the namespace the process belongs to. See <i>namespaces(7)</i> .
uunit	UUNIT	displays user unit which a process belongs to, if systemd support has been included.
vsize	VSZ	see vsz . (alias vsz).
vsz	VSZ	virtual memory size of the process in KiB (1024–byte units). Device mappings are currently excluded; this is subject to change. (alias vsize).
wchan	WCHAN	name of the kernel function in which the process is sleeping, a “–” if the process is running, or a “*” if the process is multi-threaded and ps is not displaying threads.

ENVIRONMENT VARIABLES

The following environment variables could affect **ps**:

COLUMNS

Override default display width.

LINES

Override default display height.

PS_PERSONALITY

Set to one of posix, old, linux, bsd, sun, digital... (see section **PERSONALITY** below).

CMD_ENV

Set to one of posix, old, linux, bsd, sun, digital... (see section **PERSONALITY** below).

I_WANT_A_BROKEN_PS

Force obsolete command line interpretation.

LC_TIME

Date format.

PS_COLORS

Not currently supported.

PS_FORMAT

Default output format override. You may set this to a format string of the type used for the **-o** option.

The **DefSysV** and **DefBSD** values are particularly useful.

POSIXLY_CORRECT

Don't find excuses to ignore bad "features".

POSIX2

When set to "on", acts as **POSIXLY_CORRECT**.

UNIX95

Don't find excuses to ignore bad "features".

XPG

Cancel **CMD_ENV=irix** non-standard behavior.

In general, it is a bad idea to set these variables. The one exception is **CMD_ENV** or **PS_PERSONALITY**, which could be set to Linux for normal systems. Without that setting, **ps** follows the useless and bad parts of the Unix98 standard.

PERSONALITY

390	like the OS/390 OpenEdition ps
aix	like AIX ps
bsd	like FreeBSD ps (totally non-standard)
compaq	like Digital Unix ps
debian	like the old Debian ps
digital	like Tru64 (was Digital Unix, was OSF/1) ps
gnu	like the old Debian ps
hp	like HP-UX ps
hpx	like HP-UX ps
irix	like Irix ps
linux	***** recommended *****
old	like the original Linux ps (totally non-standard)
os390	like OS/390 Open Edition ps
posix	standard
s390	like OS/390 Open Edition ps
sco	like SCO ps
sgi	like Irix ps
solaris2	like Solaris 2+ (SunOS 5) ps
sunos4	like SunOS 4 (Solaris 1) ps (totally non-standard)
svr4	standard
sysv	standard
tru64	like Tru64 (was Digital Unix, was OSF/1) ps
unix	standard
unix95	standard
unix98	standard

SEE ALSO

pgrep(1), pstree(1), top(1), proc(5).

STANDARDS

This **ps** conforms to:

- 1 Version 2 of the Single Unix Specification
- 2 The Open Group Technical Standard Base Specifications, Issue 6
- 3 IEEE Std 1003.1, 2004 Edition
- 4 X/Open System Interfaces Extension [UP XSI]
- 5 ISO/IEC 9945:2003

AUTHOR

ps was originally written by Branko Lankester <lankeste@fwi.uva.nl>. Michael K. Johnson<johnsonm@redhat.com> re-wrote it significantly to use the proc filesystem, changing a few things in the process. Michael Shields <mjshield@nyx.cs.du.edu> added the pid-list feature. Charles Blake <cblake@bbn.com> added multi-level sorting, the dirent-style library, the device name-to-number mmaped database, the

approximate binary search directly on System.map, and many code and documentation cleanups. David Mossberger-Tang wrote the generic BFD support for psupdate. Albert Cahalan <albert@users.sf.net> rewrote ps for full Unix98 and BSD support, along with some ugly hacks for obsolete and foreign syntax.

Please send bug reports to <procps@freelists.org>. No subscription is required or suggested.

NAME

pval – print BER values in ASN.1 value notation

SYNOPSIS

```
pval -T <tt file name> [-m <module name>] -n <type name>  
<BER value file list>
```

DESCRIPTION

pval prints the given BER values in their value notation. You must specify the type name and optionally the module name of the type in the given BER files.

OPTIONS

-T *file*Use the type table in the file to look for the named types definition.

-m *modulename*Specifies the module in which the named type is defined. If the module name is not specified with this option, pval looks for the first occurrence of the named type in the modules in the given type table.

-n *typename*Specifies the type of the values in the given BER files. If you give the wrong type name, decoding errors will occur.

FILES

snacc/tbl-tools/pval/ Source code for the pval program

NAME

posix_memalign, **aligned_alloc**, **memalign**, **valloc**, **pvalloc** – allocate aligned memory

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <stdlib.h>
int posix_memalign(void **memptr, size_t alignment, size_t size);
void *aligned_alloc(size_t alignment, size_t size);
void *valloc(size_t size);

#include <malloc.h>
void *memalign(size_t alignment, size_t size);
void *pvalloc(size_t size);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
posix_memalign():
    _POSIX_C_SOURCE >= 200112L

aligned_alloc():
    _ISOC11_SOURCE

valloc():
    Since glibc 2.12:
        (_XOPEN_SOURCE >= 500) && !(_POSIX_C_SOURCE >= 200112L)
        || /* glibc >= 2.19: */ _DEFAULT_SOURCE
        || /* glibc <= 2.19: */ _SVID_SOURCE || _BSD_SOURCE

Before glibc 2.12:
    _BSD_SOURCE || _XOPEN_SOURCE >= 500
```

DESCRIPTION

The function **posix_memalign()** allocates *size* bytes and places the address of the allocated memory in **memptr*. The address of the allocated memory will be a multiple of *alignment*, which must be a power of two and a multiple of *sizeof(void *)*. This address can later be successfully passed to **free(3)**. If *size* is 0, then the value placed in **memptr* is either NULL or a unique pointer value.

The obsolete function **memalign()** allocates *size* bytes and returns a pointer to the allocated memory. The memory address will be a multiple of *alignment*, which must be a power of two.

The function **aligned_alloc()** is the same as **memalign()**, except for the added restriction that *size* should be a multiple of *alignment*.

The obsolete function **valloc()** allocates *size* bytes and returns a pointer to the allocated memory. The memory address will be a multiple of the page size. It is equivalent to **memalign(sysconf(_SC_PAGESIZE), size)**.

The obsolete function **pvalloc()** is similar to **valloc()**, but rounds the size of the allocation up to the next multiple of the system page size.

For all of these functions, the memory is not zeroed.

RETURN VALUE

aligned_alloc(), **memalign()**, **valloc()**, and **pvalloc()** return a pointer to the allocated memory on success. On error, NULL is returned, and *errno* is set to indicate the error.

posix_memalign() returns zero on success, or one of the error values listed in the next section on failure. The value of *errno* is not set. On Linux (and other systems), **posix_memalign()** does not modify *memptr* on failure. A requirement standardizing this behavior was added in POSIX.1-2008 TC2.

ERRORS

EINVAL

The *alignment* argument was not a power of two, or was not a multiple of *sizeof(void *)*.

ENOMEM

There was insufficient memory to fulfill the allocation request.

VERSIONS

The functions **memalign()**, **valloc()**, and **pvalloc()** have been available since at least glibc 2.0.

The function **aligned_alloc()** was added in glibc 2.16.

The function **posix_memalign()** is available since glibc 2.1.91.

ATTRIBUTES

For an explanation of the terms used in this section, see **attributes(7)**.

Interface	Attribute	Value
aligned_alloc() , memalign() , posix_memalign()	Thread safety	MT-Safe
valloc() , pvalloc()	Thread safety	MT-Unsafe init

STANDARDS

The function **valloc()** appeared in 3.0BSD. It is documented as being obsolete in 4.3BSD, and as legacy in SUSv2. It does not appear in POSIX.1.

The function **pvalloc()** is a GNU extension.

The function **memalign()** appears in SunOS 4.1.3 but not in 4.4BSD.

The function **posix_memalign()** comes from POSIX.1d and is specified in POSIX.1-2001 and POSIX.1-2008.

The function **aligned_alloc()** is specified in the C11 standard.

Headers

Everybody agrees that **posix_memalign()** is declared in `<stdlib.h>`.

On some systems **memalign()** is declared in `<stdlib.h>` instead of `<malloc.h>`.

According to SUSv2, **valloc()** is declared in `<stdlib.h>`. glibc declares it in `<malloc.h>`, and also in `<stdlib.h>` if suitable feature test macros are defined (see above).

NOTES

On many systems there are alignment restrictions, for example, on buffers used for direct block device I/O. POSIX specifies the *pathconf(path, _PC_REC_XFER_ALIGN)* call that tells what alignment is needed. Now one can use **posix_memalign()** to satisfy this requirement.

posix_memalign() verifies that *alignment* matches the requirements detailed above. **memalign()** may not check that the *alignment* argument is correct.

POSIX requires that memory obtained from **posix_memalign()** can be freed using **free(3)**. Some systems provide no way to reclaim memory allocated with **memalign()** or **valloc()** (because one can pass to **free(3)** only a pointer obtained from **malloc(3)**, while, for example, **memalign()** would call **malloc(3)** and then align the obtained value). The glibc implementation allows memory obtained from any of these functions to be reclaimed with **free(3)**.

The glibc **malloc(3)** always returns 8-byte aligned memory addresses, so these functions are needed only if you require larger alignment values.

NAME

pvchange – Change attributes of physical volume(s)

SYNOPSIS

```
pvchange option_args position_args
      [ option_args ]
```

DESCRIPTION

pvchange changes PV attributes in the VG.

For options listed in parentheses, any one is required, after which the others are optional.

USAGE

Change properties of all PVs.

```
pvchange -a|--all
      ( -x|--allocatable y|n,
        -u|--uuid,
        --addtag Tag,
        --deltag Tag,
        --metadataignore y|n )
      [ COMMON_OPTIONS ]
```

Change properties of specified PVs.

```
pvchange
      ( -x|--allocatable y|n,
        -u|--uuid,
        --addtag Tag,
        --deltag Tag,
        --metadataignore y|n )
      PV|Select ...
      [ -S|--select String ]
      [ COMMON_OPTIONS ]
```

Common options for command:

```
[ -A|--autobackup y|n ]
[ -f|--force ]
[ -u|--uuid ]
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--addtag *Tag*

Adds a tag to a PV, VG or LV. This option can be repeated to add multiple tags at once. See **lvm(8)** for information about tags.

-a|--all

Change all visible PVs.

-x|--allocatable *y|n*

Enable or disable allocation of physical extents on this PV.

-A|--autobackup *y|n*

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--deletag *Tag*

Deletes a tag from a PV, VG or LV. This option can be repeated to delete multiple tags at once. See **lvm(8)** for information about tags.

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--metadataignore *y|n*

Specifies the metadataignore property of a PV. If yes, metadata areas on the PV are ignored, and lvm will not store metadata in the metadata areas of the PV. If no, lvm will store metadata on the PV.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat **basic|json**

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one

report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-S|--select *String*

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by **--select help** and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See **--options help** for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-u|--uuid

Generate new random UUID for specified PVs.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **-qq**.)

VARIABLES

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

Select

Select indicates that a required positional parameter can be omitted if the **--select** option is used. No arg appears in this position.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Disallow the allocation of physical extents on a PV (e.g. because of disk errors, or because it will be removed after freeing it).

pvchange -x n /dev/sdk1

      --repairtype pv_header|metadata|label_header
      --settings String
      -t|--test
      -v|--verbose
      --version
      -y|--yes
```

DESCRIPTION

pvck checks and repairs LVM metadata on PVs.

Dump options**headers**

Print LVM on-disk headers and structures: label_header, pv_header, mda_header(s), and metadata text. Warnings are printed if any values are incorrect. The label_header and pv_header both exist in a 512 byte sector, usually the second sector of the device. An mda_header exists in a 512 byte sector at offset 4096 bytes. A second mda_header can optionally exist near the end of the device. The metadata text exists in an area (about 1MiB by default) immediately following the mda_header sector. The metadata text is checked but not printed (see other options).

metadata

Print the current LVM VG metadata text (or save to a file), using headers to locate the latest copy of metadata. If headers are damaged, metadata may not be found (see metadata_search). Use --settings "mda_num=2" to look in mda2 (the second mda at the end of the device, if used). The metadata text is printed to stdout or saved to a file with --file.

metadata_all

List all versions of VG metadata found in the metadata area, using headers to locate metadata. Full copies of all metadata are saved to a file with the --file option. If headers are damaged, metadata may not be found (see metadata_search). Use --settings "mda_num=2" as above. Use -v to include descriptions and dates when listing metadata versions.

metadata_search

List all versions of VG metadata found in the metadata area, searching common locations so metadata can be found if headers are damaged. Full copies of all metadata are saved to a file with the --file option. To

save one specific version of metadata, use `--settings "metadata_offset=<offset>"`, where the offset is taken from the list of versions found. Use `-v` to include descriptions and dates when listing metadata versions.

metadata_area

Save the entire text metadata area to a file without processing.

Repair options**--repair**

Repair headers and metadata on a PV. This uses a metadata input file that was extracted by `--dump`, or a backup file (from `/etc/lvm/backup`). When possible, use metadata saved by `--dump` from another PV in the same VG (or from a second metadata area on the PV).

There are cases where the PV UUID needs to be specified for the PV being repaired. It is specified using `--settings "pv_uuid=<UUID>"`. In particular, if the device name for the PV being repaired does not match the previous device name of the PV, then LVM may not be able to determine the correct PV UUID. When headers are damaged on more than one PV in a VG, it is important for the user to determine the correct PV UUID and specify it in `--settings`. Otherwise, the wrong PV UUID could be used if device names have been swapped since the metadata was last written.

If a PV has no metadata areas and the `pv_header` is damaged, then the repair will not know to create no metadata areas during repair. It will by default repair metadata in `mda1`. To repair with no metadata areas, use `--settings "mda_offset=0 mda_size=0"`.

There are cases where repair should be run on all PVs in the VG (using the same metadata file): if all PVs in the VG are damaged, if using an old metadata version, or if a backup file is used instead of raw metadata (taken from `pvck dump`.)

Using `--repair` is equivalent to running `--repairtype pv_header` followed by `--repairtype metadata`.

--repairtype pv_header

Repairs the header sector, containing the `pv_header` and `label_header`.

--repairtype metadata

Repairs the `mda_header` and metadata text. It requires the headers to be correct (having been undamaged or already repaired).

--repairtype label_header

Repairs `label_header` fields, leaving the `pv_header` (in the same sector) unchanged. (`repairtype pv_header` should usually be used instead.)

Settings

The `--settings` option controls or overrides certain dump or repair behaviors. All offset and size values in settings are in bytes (units are not recognized.) These settings are subject to change.

mda_num=1|2

Select which metadata area should be used. By default the first metadata area (1) is used. `mda1` is always located at offset 4096. `mda2`, at the end of the device, often does not exist (it's not created by default.) If `mda1` is erased, `mda2`, if it exists, will often still have metadata.

metadata_offset=bytes

Select metadata text at this offset. Use with `metadata_search` to print/save one instance of metadata text.

mda_offset=bytes mda_size=bytes

Refers to a metadata area (mda) location and size. An mda includes an `mda_header` and circular metadata

text buffer. Setting this forces metadata_search look for metadata in the given area instead of the standard locations. When set to zero with repair, it indicates no metadata areas should exist.

mda2_offset=bytes mda2_size=bytes

When repairing a pv_header, this forces a specific offset and size for mda2 that should be recorded in the pv_header.

pv_uuid=uuid

Specify the PV UUID of the device being repaired. When not specified, repair will attempt to determine the correct PV UUID by matching a device name in the metadata.

device_size=bytes

data_offset=bytes

When repairing a pv_header, the device_size, data_offset, and pvid can all be specified directly, in which case these values are not taken from a metadata file (where they usually come from), and the metadata file can be omitted. data_offset is the starting location of the first physical extent (data), which follows the first metadata area.

USAGE

Check for metadata on a device

```
pvck PV ...
    [ COMMON_OPTIONS ]
```

Check and print LVM headers and metadata on a device

```
pvck --dump headers|metadata|metadata_all|metadata_search PV
    [ -f|--file String ]
    [ --settings String ]
    [ --[pv]metadatacopies 0|1|2 ]
    [ COMMON_OPTIONS ]
```

Repair LVM headers or metadata on a device

```
pvck --repairtype pv_header|metadata|label_header PV
    [ -f|--file String ]
    [ --settings String ]
    [ COMMON_OPTIONS ]
```

Repair LVM headers and metadata on a device

```
pvck --repair -f|--file String PV
    [ --settings String ]
    [ COMMON_OPTIONS ]
```

Common options for command:

```
[ --labelsector Number ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
```

```
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--dump headers|metadata|metadata_all|metadata_search

Dump headers and metadata from a PV for debugging and repair. Option values include: **headers** to print and check LVM headers, **metadata** to print or save the current text metadata, **meta-data_all** to list or save all versions of metadata, **metadata_search** to list or save all versions of metadata, searching standard locations in case of damaged headers, **metadata_area** to save an entire text metadata area to a file.

-f|--file *String*

Metadata file to read or write.

-h|--help

Display help text.

--labelsector *Number*

By default the PV is labelled with an LVM2 identifier in its second sector (sector 1). This lets you use a different sector near the start of the disk (between 0 and 3 inclusive – see LABEL_SCAN_SECTORS in the source). Use with care.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

--[pv]metadatacopies 0|1|2

The number of metadata areas to set aside on a PV for storing VG metadata. When 2, one copy of the VG metadata is stored at the front of the PV and a second copy is stored at the end. When 1,

one copy of the VG metadata is stored at the front of the PV. When 0, no copies of the VG metadata are stored on the given PV. This may be useful in VGs containing many PVs (this places limitations on the ability to use vgsplit later.)

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--repair

Repair headers and metadata on a PV.

--repairtype *pv_header|metadata|label_header*

Repair headers and metadata on a PV. See command description.

--settings *String*

Specifies command specific settings in "Key = Value" form. Combine multiple settings in quotes, or repeat the settings option for each.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

If the partition table is corrupted or lost on /dev/sda, and you suspect there was an LVM partition at approximately 100 MiB, then this area of the disk can be scanned using the --labelsector parameter with a value of 204800 ($100 * 1024 * 1024 / 512 = 204800$).

pvck --labelsector 204800 /dev/sda

NAME

pvcreate – Initialize physical volume(s) for use by LVM

SYNOPSIS

```
pvcreate position_args
      [ option_args ]
```

DESCRIPTION

pvcreate initializes a Physical Volume (PV) on a device so the device is recognized as belonging to LVM. This allows the PV to be used in a Volume Group (VG). An LVM disk label is written to the device, and LVM metadata areas are initialized. A PV can be placed on a whole device or partition.

Use **vgcreate(8)** to create a new VG on the PV, or **vgextend(8)** to add the PV to an existing VG. Use **pvr e-move(8)** to remove the LVM disk label from the device.

The force option will create a PV without confirmation. Repeating the force option (**-ff**) will forcibly create a PV, overriding checks that normally prevent it, e.g. if the PV is already in a VG.

Metadata location, size, and alignment

The LVM disk label begins 512 bytes from the start of the device, and is 512 bytes in size.

The LVM metadata area begins at an offset (from the start of the device) equal to the page size of the machine creating the PV (often 4 KiB.) The metadata area contains a 512 byte header and a multi-KiB circular buffer that holds text copies of the VG metadata.

With default settings, the first physical extent (PE), which contains LV data, is 1 MiB from the start of the device. This location is controlled by **default_data_alignment** in lvm.conf, which is set to 1 (MiB) by default. The pe_start will be a multiple of this many MiB. This location can be checked with:

```
pvs -o pe_start PV
```

The size of the LVM metadata area is the space between the the start of the metadata area and the first PE. When metadata begins at 4 KiB and the first PE is at 1024 KiB, the metadata area size is 1020 KiB. This can be checked with:

```
pvs -o mda_size PV
```

The mda_size cannot be increased after **pvcreate**, so if larger metadata is needed, it must be set during **pvcreate**. Two copies of the VG metadata must always fit within the metadata area, so the maximum VG metadata size is around half the mda_size. This can be checked with:

```
vgs -o mda_free VG
```

A larger metadata area can be set with **--metadatasize**. The resulting mda_size may be larger than specified due to **default_data_alignment** placing pe_start on a MiB boundary, and the fact that the metadata area extends to the first PE. With metadata starting at 4 KiB and **default_data_alignment** 1 (MiB), setting **--metadatasize** 2048k results in pe_start of 3 MiB and mda_size of 3068 KiB. Alternatively, **--metadatasize** 2044k results in pe_start at 2 MiB and mda_size of 2044 KiB.

The alignment of pe_start described above may be automatically overriden based on md device properties or device i/o properties reported in sysfs. These automatic adjustments can be enabled/disabled using lvm.conf settings **md_chunk_alignment** and **data_alignment_offset_detection**.

To use a different pe_start alignment, use the **--dataalignment** option. The **--metadatasize** option would also typically be used in this case because the metadata area size also determines the location of pe_start. When using these two options together, pe_start is calculated as: metadata area start (page size), plus the specified **--metadatasize**, rounded up to the next multiple of **--dataalignment**. With metadata starting at 4 KiB, **--metadatasize** 2048k, and **--dataalignment** 128k, pe_start is 2176 KiB and mda_size is 2172 KiB.

The pe_start of 2176 KiB is the nearest even multiple of 128 KiB that provides at least 2048 KiB of metadata space. Always check the resulting alignment and metadata size when using these options.

To shift an aligned pe_start value, use the --dataalignmentoffset option. The pe_start alignment is calculated as described above, and then the value specified with --dataalignmentoffset is added to produce the final pe_start value.

USAGE

```
pvcreate PV ...
[ -f|--force ]
[ -M|--metadatatype lvm2 ]
[ -u|--uuid String ]
[ -Z|--zero y|n ]
[ --dataalignment Size[k|UNIT] ]
[ --dataalignmentoffset Size[k|UNIT] ]
[ --bootloaderareasize Size[m|UNIT] ]
[ --labelsector Number ]
[ --[pv]metadatacopies 0|1|2 ]
[ --metadatasize Size[m|UNIT] ]
[ --metadataignore y|n ]
[ --norestorefile ]
[ --setphysicalvolumesize Size[m|UNIT] ]
[ --reportformat basic|json ]
[ --restorefile String ]
[ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--bootloaderareasize Size[m|UNIT]

Reserve space for the bootloader between the LVM metadata area and the first PE. The bootloader area is reserved for bootloaders to embed their own data or metadata; LVM will not use it. The bootloader area begins where the first PE would otherwise be located. The first PE is moved out by the size of the bootloader area, and then moved out further if necessary to match the data alignment. The start of the bootloader area is always aligned, see also --dataalignment and --dataalignmentoffset. The bootloader area may be larger than requested due to the alignment, but it's never less than the requested size. To see the bootloader area start and size of an existing PV use pvs -o +pv_ba_start,pv_ba_size.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--dataalignment *Size[k|UNIT]*

Align the start of a PV data area with a multiple of this number. To see the location of the first Physical Extent (PE) of an existing PV, use pvs -o +pe_start. In addition, it may be shifted by an alignment offset, see --dataalignmentoffset. Also specify an appropriate PE size when creating a VG.

--dataalignmentoffset *Size[k|UNIT]*

Shift the start of the PV data area by this additional offset.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--labelsector *Number*

By default the PV is labelled with an LVM2 identifier in its second sector (sector 1). This lets you use a different sector near the start of the disk (between 0 and 3 inclusive – see LA-BEL_SCAN_SECTORS in the source). Use with care.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--metadataignore *y|n*

Specifies the metadataignore property of a PV. If yes, metadata areas on the PV are ignored, and lvm will not store metadata in the metadata areas of the PV. If no, lvm will store metadata on the PV.

--metadatasize *Size[m|UNIT]*

The approximate amount of space used for each VG metadata area. The size may be rounded.

-M|--metadatatype *lvm2*

Specifies the type of on-disk metadata to use. **lvm2** (or just **2**) is the current, standard format. **lvm1** (or just **1**) is no longer used.

--nolocking

Disable locking.

--norestorefile

In conjunction with --uuid, this allows a uuid to be specified without also requiring that a backup of the metadata be provided.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

--[pv]metadatacopies *0|1|2*

The number of metadata areas to set aside on a PV for storing VG metadata. When 2, one copy of the VG metadata is stored at the front of the PV and a second copy is stored at the end. When 1, one copy of the VG metadata is stored at the front of the PV. When 0, no copies of the VG

metadata are stored on the given PV. This may be useful in VGs containing many PVs (this places limitations on the ability to use vgsplit later.)

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--restorefile String

In conjunction with --uuid, this reads the file (produced by vgcfgbackup), extracts the location and size of the data on the PV, and ensures that the metadata produced by the program is consistent with the contents of the file, i.e. the physical extents will be in the same place and not be overwritten by new metadata. This provides a mechanism to upgrade the metadata format or to add/remove metadata areas. Use with care.

--setphysicalvolumesize Size[m|UNIT]

Overrides the automatically detected size of the PV. Use with care, or prior to reducing the physical size of the device.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-u|--uuid String

Specify a UUID for the device. Without this option, a random UUID is generated. This option is needed before restoring a backup of LVM metadata onto a replacement device; see **vgcfgrestore(8)**. As such, use of --restorefile is compulsory unless the --norestorefile is used. All PVs must have unique UUIDs, and LVM will prevent certain operations if multiple devices are seen with the same UUID. See **vgimportclone(8)** for more information.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

-Z|--zero y|n

Controls if the first 4 sectors (2048 bytes) of the device are wiped. The default is to wipe these sectors unless either or both of --restorefile or --uuid are specified.

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

EXAMPLES

Initialize a partition and a full device.

```
pvcreate /dev/sdc4 /dev/sde
```

If a device is a 4KiB sector drive that compensates for windows partitioning (sector 7 is the lowest aligned logical block, the 4KiB sectors start at LBA -1, and consequently sector 63 is aligned on a 4KiB boundary) manually account for this when initializing for use by LVM.

```
pvcreate --dataalignmentoffset 7s /dev/sdb
```

NAME

pvdisplay – Display various attributes of physical volume(s)

SYNOPSIS

```
pvdisplay
  [ option_args ]
  [ position_args ]
```

DESCRIPTION

pvdisplay shows the attributes of PVs, like size, physical extent size, space used for the VG descriptor area, etc.

pvs(8) is a preferred alternative that shows the same information and more, using a more compact and configurable output format.

USAGE

```
pvdisplay
  [ -a|--all ]
  [ -c|--colon ]
  [ -C|--columns ]
  [ -m|--maps ]
  [ -o|--options String ]
  [ -S|--select String ]
  [ -s|--short ]
  [ -O|--sort String ]
  [ --aligned ]
  [ --binary ]
  [ --configreport log|vg|lv|pv|pvseg|seg ]
  [ --foreign ]
  [ --ignorelockingfailure ]
  [ --logonly ]
  [ --noheadings ]
  [ --nosuffix ]
  [ --readonly ]
  [ --reportformat basic|json ]
  [ --separator String ]
  [ --shared ]
  [ --unbuffered ]
  [ --units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E ]
  [ COMMON_OPTIONS ]
  [ PV|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
```

[--version]

OPTIONS

--aligned

Use with --separator to align the output columns

-a|--all

Show information about devices that have not been initialized by LVM, i.e. they are not PVs.

--binary

Use binary values "0" or "1" instead of descriptive literal values for columns that have exactly two valid values to report (not counting the "unknown" value which denotes that the value could not be determined).

-c|--colon

Generate colon separated output for easier parsing in scripts or programs. Also see **vgs(8)** which provides considerably more control over the output.

-C|--columns

Display output in columns, the equivalent of **vgs(8)**. Options listed are the same as options given in **vgs(8)**.

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--configreport log|vg|lv|pv|pvseg|seg

See **lvmreport(7)**.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--logonly

Suppress command report and display only log report.

--longhelp

Display long help text.

-m|--maps

Display the mapping of physical extents to LVs and logical extents.

--noheadings

Suppress the headings line that is normally the first line of output. Useful if grepping the output.

--nolocking

Disable locking.

--nosuffix

Suppress the suffix on output sizes. Use with --units (except h and H) if processing the output.

-o|--options String

Comma-separated, ordered list of fields to display in columns. String arg syntax is:

[+|-#]Field1[,Field2 ...] The prefix + will append the specified fields to the default fields, - will remove the specified fields from the default fields, and # will compact specified fields (removing them when empty for all rows.) Use **-o help** to view the list of all available fields. Use separate lists of fields to add, remove or compact by repeating the -o option: -o+field1,field2 -o-field3,field4 -o#field5. These lists are evaluated from left to right. Use field name **lv_all** to view all LV fields, **vg_all** all VG fields, **pv_all** all PV fields, **pvseg_all** all PV segment fields, **seg_all** all LV segment fields, and **pvseg_all** all PV segment columns. See the lvm.conf report section for more config options. See **lvmreport(7)** for more information about reporting.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-S|--select String

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--separator String

String to use to separate each column. Useful if grepping the output.

--shared

Report/display shared VGs that would otherwise be skipped when lvmlockd is not being used on the host. See **lvmlockd(8)** for more information about shared VGs.

-s|--short

Only display the size of the given PVs.

-O|--sort String

Comma-separated ordered list of columns to sort by. Replaces the default selection. Precede any column with - for a reverse sort on that column.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes

has changed but hasn't.

--unbuffered

Produce output immediately without sorting or aligning the columns properly.

--units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E

All sizes are output in these units: human-(r)eadable with '<' rounding indicator, (h)uman-read-able, (b)ytes, (s)ectors, (k)ilobytes, (m)egabytes, (g)igabytes, (t)erabytes, (p)etabytes, (e)xabytes.

Capitalise to use multiples of 1000 (S.I.) instead of 1024. Custom units can be specified, e.g.
--units 3M.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES

PV

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

Tag

Tag name. See lvm(8) for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See lvm(8) for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

pvmove – Move extents from one physical volume to another

SYNOPSIS

```
pvmove position_args
      [ option_args ]
      [ position_args ]
```

DESCRIPTION

pvmove moves the allocated physical extents (PEs) on a source PV to one or more destination PVs. You can optionally specify a source LV in which case only extents used by that LV will be moved to free (or specified) extents on the destination PV. If no destination PV is specified, the normal allocation rules for the VG are used.

If **pvmove** is interrupted for any reason (e.g. the machine crashes) then run **pvmove** again without any PV arguments to restart any operations that were in progress from the last checkpoint. Alternatively, use the abort option at any time to abort the operation. The resulting location of LVs after an abort depends on whether the atomic option was used.

More than one **pvmove** can run concurrently if they are moving data from different source PVs, but additional **pvmoves** will ignore any LVs already in the process of being changed, so some data might not get moved.

USAGE

Move PV extents.

```
pvmove PV
      [ -A|--autobackup y|n ]
      [ -n|--name LV ]
      [ --alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit ]
      [ --atomic ]
      [ --noudevsync ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
      [ PV ... ]
```

Continue or abort existing **pvmove** operations.

```
pvmove
      [ COMMON_OPTIONS ]
```

Common options for command:

```
[ -b|--background ]
[ -i|--interval Number ]
[ --abort ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
```

```
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**--abort**

Abort any pvmove operations in progress. If a pvmove was started with the --atomic option, then all LVs will remain on the source PV. Otherwise, segments that have been moved will remain on the destination PV, while unmoved segments will remain on the source PV.

--alloc contiguous|cling|cling_by_tags|normal|anywhere|inherit

Determines the allocation policy when a command needs to allocate Physical Extents (PEs) from the VG. Each VG and LV has an allocation policy which can be changed with vgchange/lvchange, or overridden on the command line. **normal** applies common sense rules such as not placing parallel stripes on the same PV. **inherit** applies the VG policy to an LV. **contiguous** requires new PEs be placed adjacent to existing PEs. **cling** places new PEs on the same PV as existing PEs in the same stripe of the LV. If there are sufficient PEs for an allocation, but normal does not use them, **anywhere** will use them even if it reduces performance, e.g. by placing two stripes on the same PV. Optional positional PV args on the command line can also be used to limit which PVs the command will use for allocation. See **lvm(8)** for more information about allocation.

--atomic

Makes a pvmove operation atomic, ensuring that all affected LVs are moved to the destination PV, or none are if the operation is aborted.

-A|--autobackup y|n

Specifies if metadata should be backed up automatically after a change. Enabling this is strongly advised! See **vgcfgbackup(8)** for more information.

-b|--background

If the operation requires polling, this option causes the command to return before the operation is complete, and polling is done in the background.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

-i|--interval Number

Report progress at regular intervals.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-n|--name *String*

Move only the extents belonging to the named LV.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat **basic|json**

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NOTES

pvmove works as follows:

1. A temporary 'pvmove' LV is created to store details of all the data movements required.
2. Every LV in the VG is searched for contiguous data that need moving according to the command line arguments. For each piece of data found, a new segment is added to the end of the pvmove LV. This segment takes the form of a temporary mirror to copy the data from the original location to a newly allocated location. The original LV is updated to use the new temporary mirror segment in the pvmove LV instead of accessing the data directly.
3. The VG metadata is updated on disk.
4. The first segment of the pvmove LV is activated and starts to mirror the first part of the data. Only one segment is mirrored at once as this is usually more efficient.
5. A daemon repeatedly checks progress at the specified time interval. When it detects that the first temporary mirror is in sync, it breaks that mirror so that only the new location for that data gets used and writes a checkpoint into the VG metadata on disk. Then it activates the mirror for the next segment of the pvmove LV.
6. When there are no more segments left to be mirrored, the temporary LV is removed and the VG metadata is updated so that the LVs reflect the new data locations.

Note that this new process cannot support the original LVM1 type of on-disk metadata. Metadata can be converted using **vgconvert(8)**.

If the **--atomic** option is used, a slightly different approach is used for the move. Again, a temporary 'pvmove' LV is created to store the details of all the data movements required. This temporary LV contains all the segments of the various LVs that need to be moved. However, in this case, an identical LV is allocated that contains the same number of segments and a mirror is created to copy the contents from the first temporary LV to the second. After a complete copy is made, the temporary LVs are removed, leaving behind the segments on the destination PV. If an abort is issued during the move, all LVs being moved will remain on the source PV.

EXAMPLES

Move all physical extents that are used by simple LVs on the specified PV to free physical extents elsewhere in the VG.

pvmove /dev/sdb1

Use a specific destination PV when moving physical extents.

pvmove /dev/sdb1 /dev/sdc1

Move extents belonging to a single LV.

pvmove -n lvol1 /dev/sdb1 /dev/sdc1

Rather than moving the contents of an entire device, it is possible to move a range of physical extents, for example numbers 1000 to 1999 inclusive on the specified PV.

pvmove /dev/sdb1:1000-1999

A range of physical extents to move can be specified as start+length. For example, starting from PE 1000.

(Counting starts from 0, so this refers to the 1001st to the 2000th PE inclusive.)

pvmmove /dev/sdb1:1000+1000

Move a range of physical extents to a specific PV (which must have sufficient free extents).

pvmmove /dev/sdb1:1000-1999 /dev/sdc1

Move a range of physical extents to specific new extents on a new PV.

pvmmove /dev/sdb1:1000-1999 /dev/sdc1:0-999

If the source and destination are on the same disk, the **anywhere** allocation policy is needed.

pvmmove --alloc anywhere /dev/sdb1:1000-1999 /dev/sdb1:0-999

The part of a specific LV present within in a range of physical extents can also be picked out and moved.

pvmmove -n lvol1 /dev/sdb1:1000-1999 /dev/sdc1

NAME

pvremove – Remove LVM label(s) from physical volume(s)

SYNOPSIS

```
pvremove position_args
      [ option_args ]
```

DESCRIPTION

pvremove wipes the label on a device so that LVM will no longer recognise it as a PV.

A PV cannot be removed from a VG while it is used by an active LV.

Repeat the force option (**-ff**) to forcibly remove a PV belonging to an existing VG. Normally, **vgreduce(8)** should be used instead.

USAGE

```
pvremove PV ...
      [ -f|--force ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**--commandprofile** *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded *y|n*

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-f|--force ...

Override various checks, confirmations and protections. Use with extreme caution.

-h|--help

Display help text.

--lockopt *String*
 Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp
 Display long help text.

--nolocking
 Disable locking.

--profile *String*
 An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...
 Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json
 Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-t|--test
 Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...
 Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version
 Display version information.

-y|--yes
 Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES

PV
String
 Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String
 See the option description for information about the string content.

Size[UNIT]
 Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

pvresize – Resize physical volume(s)

SYNOPSIS

```
pvresize position_args
      [ option_args ]
```

DESCRIPTION

pvresize resizes a PV. The PV may already be in a VG and may have active LVs allocated on it.

USAGE

```
pvresize PV ...
      [ --setphysicalvolumesize Size[m|UNIT] ]
      [ --reportformat basic|json ]
      [ COMMON_OPTIONS ]
```

Common options for lvm:

```
[ --d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded **y|n**

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-h|--help

Display help text.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

--nolocking

Disable locking.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--setphysicalvolumesize *Size[m|UNIT]*

Overrides the automatically detected size of the PV. Use with care, or prior to reducing the physical size of the device.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control --units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NOTES

pvresize will refuse to shrink a PV if it has allocated extents beyond the new end.

EXAMPLES

Expand a PV after enlarging the partition.

```
pvresize /dev/sda1
```

Shrink a PV prior to shrinking the partition (ensure that the PV size is appropriate for the intended new partition size).

```
pvresize --setphysicalvolumesize 40G /dev/sda1
```

NAME

pvs – Display information about physical volumes

SYNOPSIS

```
pvs
  [ option_args ]
  [ position_args ]
```

DESCRIPTION

pvs produces formatted output about PVs.

USAGE

```
pvs
  [ -a|--all ]
  [ -o|--options String ]
  [ -S|--select String ]
  [ -O|--sort String ]
  [ --segments ]
  [ --aligned ]
  [ --binary ]
  [ --configreport log|vg|lv|pv|pvseg|seg ]
  [ --foreign ]
  [ --ignorelockingfailure ]
  [ --logonly ]
  [ --nameprefixes ]
  [ --noheadings ]
  [ --nosuffix ]
  [ --readonly ]
  [ --reportformat basic|json ]
  [ --rows ]
  [ --separator String ]
  [ --shared ]
  [ --unbuffered ]
  [ --units r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E ]
  [ --unquoted ]
  [ COMMON_OPTIONS ]
  [ PV|Tag ... ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS**--aligned**

Use with **--separator** to align the output columns

-a|--all

Show information about devices that have not been initialized by LVM, i.e. they are not PVs.

--binary

Use binary values "0" or "1" instead of descriptive literal values for columns that have exactly two valid values to report (not counting the "unknown" value which denotes that the value could not be determined).

--commandprofile *String*

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config *String*

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

--configreport log|vg|lv|pv|pvseg|seg

See **lvmreport(7)**.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

--foreign

Report/display foreign VGs that would otherwise be skipped. See **lvmsystemid(7)** for more information about foreign VGs.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt *String*

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--logonly

Suppress command report and display only log report.

--longhelp

Display long help text.

--nameprefixes

Add an "LVM2_" prefix plus the field name to the output. Useful with --noheadings to produce a list of field=value pairs that can be used to set environment variables (for example, in udev rules).

--noheadings

Suppress the headings line that is normally the first line of output. Useful if grepping the output.

--nolocking

Disable locking.

--nosuffix

Suppress the suffix on output sizes. Use with --units (except h and H) if processing the output.

-o|--options *String*

Comma-separated, ordered list of fields to display in columns. String arg syntax is:
`[+|-#]Field1[,Field2 ...]` The prefix + will append the specified fields to the default fields, - will remove the specified fields from the default fields, and # will compact specified fields (removing them when empty for all rows.) Use **-o help** to view the list of all available fields. Use separate lists of fields to add, remove or compact by repeating the -o option: `-o+field1,field2 -o-`

field3,field4 -o#field5. These lists are evaluated from left to right. Use field name **lv_all** to view all LV fields, **vg_all** all VG fields, **pv_all** all PV fields, **pvseg_all** all PV segment fields, **seg_all** all LV segment fields, and **pvseg_all** all PV segment columns. See the lvm.conf report section for more config options. See **lvmreport(7)** for more information about reporting.

--profile *String*

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--readonly

Run the command in a special read-only mode which will read on-disk metadata without needing to take any locks. This can be used to peek inside metadata used by a virtual machine image while the virtual machine is running. No attempt will be made to communicate with the device-mapper kernel driver, so this option is unable to report whether or not LVs are actually in use.

--reportformat **basic|json**

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

--rows

Output columns as rows.

--segments

Produces one line of output for each contiguous allocation of space on each PV, showing the start (pvseg_start) and length (pvseg_size) in units of physical extents.

-S|--select *String*

Select objects for processing and reporting based on specified criteria. The criteria syntax is described by --select help and **lvmreport(7)**. For reporting commands, one row is displayed for each object matching the criteria. See --options help for selectable object fields. Rows can be displayed with an additional "selected" field (-o selected) showing 1 if the row matches the selection and 0 otherwise. For non-reporting commands which process LVM entities, the selection is used to choose items to process.

--separator *String*

String to use to separate each column. Useful if grepping the output.

--shared

Report/display shared VGs that would otherwise be skipped when lvmlockd is not being used on the host. See **lvmlockd(8)** for more information about shared VGs.

-O|--sort *String*

Comma-separated ordered list of columns to sort by. Replaces the default selection. Precede any column with - for a reverse sort on that column.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

--unbuffered

Produce output immediately without sorting or aligning the columns properly.

--units **r|R|h|H|b|B|s|S|k|K|m|M|g|G|t|T|p|P|e|E**

All sizes are output in these units: human-(r)eadable with '<' rounding indicator, (h)uman-readable, (b)ytes, (s)ectors, (k)ilobytes, (m)egabytes, (g)igabytes, (t)erabytes, (p)etabytes, (e)xabytes.

Capitalise to use multiples of 1000 (S.I.) instead of 1024. Custom units can be specified, e.g.
—units 3M.

--unquoted

When used with --nameprefixes, output values in the field=value pairs are not quoted.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see -qq.)

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE–PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

Tag

Tag name. See **lvm(8)** for information about tag names and using tags in place of a VG, LV or PV.

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control —units, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **lvm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NOTES

The pv_attr bits are:

- 1 (d)uplicate, (a)llocatable, (u)sed
- 2 e(x)ported
- 3 (m)issing

NAME

pvscan – List all physical volumes

SYNOPSIS

```
pvscan option_args
      [ option_args ]
      [ position_args ]
```

DESCRIPTION

When called without the **--cache** option, **pvscan** lists PVs on the system, like **pvs(8)** or **pvdisplay(8)**.

When the **--cache** and **-aay** options are used, **pvscan** records which PVs are available on the system, and activates LVs in completed VGs. A VG is complete when **pvscan** sees that the final PV in the VG has appeared. This is used by event-based system startup (systemd, udev) to activate LVs.

The four main variations of this are:

pvscan --cache device

If *device* is present, lvm adds a record that the PV on *device* is online. If *device* is not present, lvm removes the online record for the PV. In most cases, the **pvscan** will only read the named devices.

pvscan --cache -aay device...

This begins by performing the same steps as above. Afterward, if the VG for the specified PV is complete, then **pvscan** will activate LVs in the VG (the same as **vgchange -aay vgname** would do.)

pvscan --cache

This first clears all existing PV online records, then scans all devices on the system, adding PV online records for any PVs that are found.

pvscan --cache -aay

This begins by performing the same steps as **pvscan --cache**. Afterward, it activates LVs in any complete VGs.

To prevent devices from being scanned by **pvscan --cache**, add them to **lvm.conf(5) devices/global_filter**. For more information, see:

lvmconfig --withcomments devices/global_filter

Auto-activation of VGs or LVs can be enabled/disabled using:

lvm.conf(5) activation/auto_activation_volume_list

For more information, see:

lvmconfig --withcomments activation/auto_activation_volume_list

To disable auto-activation, explicitly set this list to an empty list, i.e. **auto_activation_volume_list = []**.

When this setting is undefined (e.g. commented), then all LVs are auto-activated.

USAGE

Display PV information.

```
pvscan
      [ -e|--exported ]
```

```
[ -n|--novolumegroup ]
[ -s|--short ]
[ -u|--uuid ]
[ COMMON_OPTIONS ]
```

Autoactivate a VG when all PVs are online.

```
pvscan --cache
[ -a|--activate ay ]
[ -j|--major Number ]
[ --minor Number ]
[ --noudevsync ]
[ COMMON_OPTIONS ]
[ String|PV ... ]
```

Common options for command:

```
[ --ignorelockingfailure ]
[ --reportformat basic|json ]
```

Common options for lvm:

```
[ -d|--debug ]
[ -h|--help ]
[ -q|--quiet ]
[ -t|--test ]
[ -v|--verbose ]
[ -y|--yes ]
[ --commandprofile String ]
[ --config String ]
[ --driverloaded y|n ]
[ --lockopt String ]
[ --longhelp ]
[ --nolocking ]
[ --profile String ]
[ --version ]
```

OPTIONS

-a|--activate y|n|ay

Auto-activate LVs in a VG when the PVs scanned have completed the VG. (Only **ay** is applicable.)

--cache

Scan one or more devices and record that they are online.

--commandprofile String

The command profile to use for command configuration. See **lvm.conf(5)** for more information about profiles.

--config String

Config settings for the command. These override lvm.conf settings. The String arg uses the same format as lvm.conf, or may use section/field syntax. See **lvm.conf(5)** for more information about config.

-d|--debug ...

Set debug level. Repeat from 1 to 6 times to increase the detail of messages sent to the log file and/or syslog (if configured).

--driverloaded y|n

If set to no, the command will not attempt to use device-mapper. For testing and debugging.

-e|--exported

Only show PVs belonging to exported VGs.

-h|--help

Display help text.

--ignorelockingfailure

Allows a command to continue with read-only metadata operations after locking failures.

--lockopt String

Used to pass options for special cases to lvmlockd. See **lvmlockd(8)** for more information.

--longhelp

Display long help text.

-j|--major Number

The major number of a device.

--minor Number

The minor number of a device.

--nolocking

Disable locking.

--noudevsync

Disables udev synchronisation. The process will not wait for notification from udev. It will continue irrespective of any possible udev processing in the background. Only use this if udev is not running or has rules that ignore the devices LVM creates.

-n|--novolumegroup

Only show PVs not belonging to any VG.

--profile String

An alias for --commandprofile or --metadataprofile, depending on the command.

-q|--quiet ...

Suppress output and log messages. Overrides --debug and --verbose. Repeat once to also suppress any prompts with answer 'no'.

--reportformat basic|json

Overrides current output format for reports which is defined globally by the report/output_format setting in lvm.conf. **basic** is the original format with columns and rows. If there is more than one report per command, each report is prefixed with the report name for identification. **json** produces report output in JSON format. See **lvmreport(7)** for more information.

-s|--short

Short listing format.

-t|--test

Run in test mode. Commands will not update metadata. This is implemented by disabling all metadata writing but nevertheless returning success to the calling function. This may lead to unusual error messages in multi-stage operations if a tool relies on reading back metadata it believes has changed but hasn't.

-u|--uuid

Show UUIDs in addition to device names.

-v|--verbose ...

Set verbose level. Repeat from 1 to 4 times to increase the detail of messages sent to stdout and stderr.

--version

Display version information.

-y|--yes

Do not prompt for confirmation interactively but always assume the answer yes. Use with extreme caution. (For automatic no, see **--qq**.)

VARIABLES*PV*

Physical Volume name, a device path under /dev. For commands managing physical extents, a PV positional arg generally accepts a suffix indicating a range (or multiple ranges) of physical extents (PEs). When the first PE is omitted, it defaults to the start of the device, and when the last PE is omitted it defaults to end. Start and end range (inclusive): *PV[:PE-PE]...* Start and length range (counting from 0): *PV[:PE+PE]...*

String

See the option description for information about the string content.

Size[UNIT]

Size is an input number that accepts an optional unit. Input units are always treated as base two values, regardless of capitalization, e.g. 'k' and 'K' both refer to 1024. The default input unit is specified by letter, followed by |UNIT. UNIT represents other possible input units:**bBsSkMmMg-GtTpPeE**. b|B is bytes, s|S is sectors of 512 bytes, k|K is KiB, m|M is MiB, g|G is GiB, t|T is TiB, p|P is PiB, e|E is EiB. (This should not be confused with the output control **--units**, where capital letters mean multiple of 1000.)

ENVIRONMENT VARIABLES

See **Ivm(8)** for information about environment variables used by lvm. For example, LVM_VG_NAME can generally be substituted for a required VG parameter.

NAME

pwck – verify integrity of password files

SYNOPSIS

pwck [options] [*passwd* [*shadow*]]

DESCRIPTION

The **pwck** command verifies the integrity of the users and authentication information. It checks that all entries in /etc/passwd and /etc/shadow have the proper format and contain valid data. The user is prompted to delete entries that are improperly formatted or which have other uncorrectable errors.

Checks are made to verify that each entry has:

- the correct number of fields
- a unique and valid user name
- a valid user and group identifier
- a valid primary group
- a valid home directory
- a valid login shell

shadow checks are enabled when a second file parameter is specified or when /etc/shadow exists on the system.

These checks are the following:

- every passwd entry has a matching shadow entry, and every shadow entry has a matching passwd entry
- passwords are specified in the shadowed file
- shadow entries have the correct number of fields
- shadow entries are unique in shadow
- the last password changes are not in the future

The checks for correct number of fields and unique user name are fatal. If the entry has the wrong number of fields, the user will be prompted to delete the entire line. If the user does not answer affirmatively, all further checks are bypassed. An entry with a duplicated user name is prompted for deletion, but the remaining checks will still be made. All other errors are warning and the user is encouraged to run the **usermod** command to correct the error.

The commands which operate on the /etc/passwd file are not able to alter corrupted or duplicated entries. **pwck** should be used in those circumstances to remove the offending entry.

OPTIONS

The **-r** and **-s** options cannot be combined.

The options which apply to the **pwck** command are:

--badname

Allow names that do not conform to standards.

-h, --help

Display help message and exit.

-q, --quiet

Report errors only. The warnings which do not require any action from the user won't be displayed.

-r, --read-only

Execute the **pwck** command in read-only mode.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR*

directory.

-s, --sort

Sort entries in /etc/passwd and /etc/shadow by UID.

By default, **pwck** operates on the files /etc/passwd and /etc/shadow. The user may select alternate files with the *passwd* and *shadow* parameters.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

PASS_MAX_DAYS (number)

The maximum number of days a password may be used. If the password is older than this, a password change will be forced. If not specified, -1 will be assumed (which disables the restriction).

PASS_MIN_DAYS (number)

The minimum number of days allowed between password changes. Any password changes attempted sooner than this will be rejected. If not specified, -1 will be assumed (which disables the restriction).

PASS_WARN_AGE (number)

The number of days warning given before a password expires. A zero means warning is given only upon the day of expiration, a negative value means no warning is given. If not specified, no warning will be provided.

FILES

/etc/group

Group account information.

/etc/passwd

User account information.

/etc/shadow

Secure user account information.

EXIT VALUES

The **pwck** command exits with the following values:

0

success

1

invalid command syntax

2

one or more bad password entries

3

can't open password files

4

can't lock password files

5

can't update password files

6

can't sort password files

NAME

rarp – manipulate the system RARP table

SYNOPSIS

```
rarp [-V] [--version] [-h] [--help]
rarp -a
rarp [-v] -d hostname ...
rarp [-v] [-t type] -s hostname hw_addr
```

NOTE

This program is obsolete. From version 2.3, the Linux kernel no longer contains RARP support. For a replacement RARP daemon, see <ftp://ftp.dementia.org/pub/net-tools>

DESCRIPTION

Rarp manipulates the kernel's RARP table in various ways. The primary options are clearing an address mapping entry and manually setting up one. For debugging purposes, the **rarp** program also allows a complete dump of the RARP table.

OPTIONS

- V** Display the version of RARP in use.
- v** Tell the user what is going on by being verbose.
- t type** When setting or reading the RARP table, this optional parameter tells **rarp** which class of entries it should check for. The default value of this parameter is **ether** (i.e. hardware code **0x01** for **IEEE 802.3 10Mbps Ethernet**). Other values might include network technologies such as **AX.25** (**ax25**) and **NET/ROM (netrom)**.
- a**
- list** Lists the entries in the RARP table.
- d hostname**
- delete hostname**
Remove all RARP entries for the specified host.
- s hostname hw_addr**
- set hostname hw_addr**
Create a RARP address mapping entry for host **hostname** with hardware address set to **hw_addr**.
The format of the hardware address is dependent on the hardware class, but for most classes one can assume that the usual presentation can be used. For the Ethernet class, this is 6 bytes in hexadecimal, separated by colons.

WARNING

Some systems (notably older Suns) assume that the host replying to a RARP query can also provide other remote boot services. Therefore never gratuitously add rarp entries unless you wish to meet the wrath of the network administrator.

FILES

/proc/net/rarp,

NAME

systemd-rc-local-generator, rc-local.service – Compatibility generator and service to start /etc/rc.local during boot

SYNOPSIS

```
/lib/systemd/system-generators/systemd-rc-local-generator  
rc-local.service
```

DESCRIPTION

systemd-rc-local-generator is a generator that checks whether /etc/rc.local exists and is executable, and if it is, pulls the rc-local.service unit into the boot process. This unit is responsible for running this script during late boot. The script is run after network.target, but in parallel with most other regular system services.

Note that rc-local.service runs with slightly different semantics than the original System V version, which was executed "last" in the boot process, which is a concept that does not translate to systemd.

Also note that rc-local.service is ordered after network.target, which does not mean that the network is functional, see **systemd.special(7)**. If the script requires a configured network connection, it may be desirable to pull in and order it after network-online.target with a drop-in:

```
# /etc/systemd/system/rc-local.service.d/network.conf  
[Unit]  
Wants=network-online.target  
After=network-online.target
```

Support for /etc/rc.local is provided for compatibility with specific System V systems only. However, it is strongly recommended to avoid making use of this script today, and instead provide proper unit files with appropriate dependencies for any scripts to run during the boot process. Note that the path to the script is set at compile time and varies between distributions.

systemd-rc-local-generator implements **systemd.generator(7)**.

NAME

`regcomp`, `regexec`, `reerror`, `regfree` – POSIX regex functions

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <regex.h>

int regcomp(regex_t *restrict preg, const char *restrict regex,
            int cflags);
int regexec(const regex_t *restrict preg, const char *restrict string,
            size_t nmatch, regmatch_t pmatch[restrict .nmatch],
            int eflags);
size_t reerror(int errcode, const regex_t *restrict preg,
               char errbuf[restrict .errbuf_size], size_t errbuf_size);
void regfree(regex_t *preg);
```

DESCRIPTION**POSIX regex compiling**

`regcomp()` is used to compile a regular expression into a form that is suitable for subsequent `regexec()` searches.

`regcomp()` is supplied with *preg*, a pointer to a pattern buffer storage area; *regex*, a pointer to the null-terminated string and *cflags*, flags used to determine the type of compilation.

All regular expression searching must be done via a compiled pattern buffer, thus `regexec()` must always be supplied with the address of a `regcomp()`-initialized pattern buffer.

cflags is the bitwise-**or** of zero or more of the following:

REG_EXTENDED

Use **POSIX** Extended Regular Expression syntax when interpreting *regex*. If not set, **POSIX** Basic Regular Expression syntax is used.

REG_ICASE

Do not differentiate case. Subsequent `regexec()` searches using this pattern buffer will be case insensitive.

REG_NOSUB

Do not report position of matches. The *nmatch* and *pmatch* arguments to `regexec()` are ignored if the pattern buffer supplied was compiled with this flag set.

REG_NEWLINE

Match-any-character operators don't match a newline.

A nonmatching list ([^...]) not containing a newline does not match a newline.

Match-beginning-of-line operator (^) matches the empty string immediately after a newline, regardless of whether *eflags*, the execution flags of `regexec()`, contains **REG_NOTBOL**.

Match-end-of-line operator (\$) matches the empty string immediately before a newline, regardless of whether *eflags* contains **REG_NOTEOL**.

POSIX regex matching

`regexec()` is used to match a null-terminated string against the precompiled pattern buffer, *preg*. *nmatch* and *pmatch* are used to provide information regarding the location of any matches. *eflags* is the bitwise-**or** of zero or more of the following flags:

REG_NOTBOL

The match-beginning-of-line operator always fails to match (but see the compilation flag **REG_NEWLINE** above). This flag may be used when different portions of a string are passed to `regexec()` and the beginning of the string should not be interpreted as the beginning of the line.

REG_NOTEOL

The match-end-of-line operator always fails to match (but see the compilation flag **REG_NEWLINE** above).

REG_STARTEND

Use *pmatch[0]* on the input string, starting at byte *pmatch[0].rm_so* and ending before byte *pmatch[0].rm_eo*. This allows matching embedded NUL bytes and avoids a **strlen(3)** on large strings. It does not use *nmatch* on input, and does not change **REG_NOTBOL** or **REG_NEWLINE** processing. This flag is a BSD extension, not present in POSIX.

Byte offsets

Unless **REG_NOSUB** was set for the compilation of the pattern buffer, it is possible to obtain match addressing information. *pmatch* must be dimensioned to have at least *nmatch* elements. These are filled in by **regexec()** with substring match addresses. The offsets of the subexpression starting at the *i*th open parenthesis are stored in *pmatch[i]*. The entire regular expression's match addresses are stored in *pmatch[0]*. (Note that to return the offsets of *N* subexpression matches, *nmatch* must be at least *N+1*.) Any unused structure elements will contain the value -1.

The *regmatch_t* structure which is the type of *pmatch* is defined in *<regex.h>*.

```
typedef struct {
    regoff_t rm_so;
    regoff_t rm_eo;
} regmatch_t;
```

Each *rm_so* element that is not -1 indicates the start offset of the next largest substring match within the string. The relative *rm_eo* element indicates the end offset of the match, which is the offset of the first character after the matching text.

POSIX error reporting

reerror() is used to turn the error codes that can be returned by both **regcomp()** and **regexec()** into error message strings.

reerror() is passed the error code, *errcode*, the pattern buffer, *preg*, a pointer to a character string buffer, *errbuf*, and the size of the string buffer, *errbuf_size*. It returns the size of the *errbuf* required to contain the null-terminated error message string. If both *errbuf* and *errbuf_size* are nonzero, *errbuf* is filled in with the first *errbuf_size* - 1 characters of the error message and a terminating null byte ('\0').

POSIX pattern buffer freeing

Supplying **regfree()** with a precompiled pattern buffer, *preg*, will free the memory allocated to the pattern buffer by the compiling process, **regcomp()**.

RETURN VALUE

regcomp() returns zero for a successful compilation or an error code for failure.

regexec() returns zero for a successful match or **REG_NOMATCH** for failure.

ERRORS

The following errors can be returned by **regcomp()**:

REG_BADBR

Invalid use of back reference operator.

REG_BADPAT

Invalid use of pattern operators such as group or list.

REG_BADRPT

Invalid use of repetition operators such as using '*' as the first character.

REG_EBRACE

Un-matched brace interval operators.

REG_EBRACK

Un-matched bracket list operators.

REG_ECOLLATE

Invalid collating element.

REG_ECTYPE

Unknown character class name.

REG_EEND

Nonspecific error. This is not defined by POSIX.2.

REG_EESCAPE

Trailing backslash.

REG_EPAREN

Un-matched parenthesis group operators.

REG_ERANGE

Invalid use of the range operator; for example, the ending point of the range occurs prior to the starting point.

REG_ESIZE

Compiled regular expression requires a pattern buffer larger than 64 kB. This is not defined by POSIX.2.

REG_ESPACE

The regex routines ran out of memory.

REG_ESUBREG

Invalid back reference to a subexpression.

ATTRIBUTES

For an explanation of the terms used in this section, see **attributes(7)**.

Interface	Attribute	Value
<code>regcomp()</code> , <code>regexec()</code>	Thread safety	MT-Safe locale
<code>regerror()</code>	Thread safety	MT-Safe env
<code>regfree()</code>	Thread safety	MT-Safe

STANDARDS

POSIX.1-2001, POSIX.1-2008.

EXAMPLES

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <regex.h>

#define ARRAY_SIZE(arr) (sizeof((arr)) / sizeof((arr)[0]))

static const char *const str =
    "1) John Driverhacker;\n2) John Doe;\n3) John Foo;\n";
static const char *const re = "John.*o";

int main(void)
{
    static const char *s = str;
    regex_t      regex;
    regmatch_t   pmatch[1];
    regoff_t     off, len;
```

```
if (regcomp(&regex, re, REG_NEWLINE))
    exit(EXIT_FAILURE);

printf("String = \"%s\"\n", str);
printf("Matches:\n");

for (unsigned int i = 0; ; i++) {
    if (regexec(&regex, s, ARRAY_SIZE(pmatch), pmatch, 0))
        break;

    off = pmatch[0].rm_so + (s - str);
    len = pmatch[0].rm_eo - pmatch[0].rm_so;
    printf("#%zu:\n", i);
    printf("offset = %jd; length = %jd\n", (intmax_t) off,
           (intmax_t) len);
    printf("substring = \"%.*s\"\n", len, s + pmatch[0].rm_so);

    s += pmatch[0].rm_eo;
}

exit(EXIT_SUCCESS);
}
```

The glibc manual section, *Regular Expressions*

NAME

regex – POSIX.2 regular expressions

DESCRIPTION

Regular expressions ("RE"s), as defined in POSIX.2, come in two forms: modern REs (roughly those of *egrep*; POSIX.2 calls these "extended" REs) and obsolete REs (roughly those of *ed*(1); POSIX.2 "basic" REs). Obsolete REs mostly exist for backward compatibility in some old programs; they will be discussed at the end. POSIX.2 leaves some aspects of RE syntax and semantics open; "†" marks decisions on these aspects that may not be fully portable to other POSIX.2 implementations.

A (modern) RE is one† or more nonempty† *branches*, separated by '|'. It matches anything that matches one of the branches.

A branch is one† or more *pieces*, concatenated. It matches a match for the first, followed by a match for the second, and so on.

A piece is an *atom* possibly followed by a single† '*', '+', '?', or *bound*. An atom followed by '*' matches a sequence of 0 or more matches of the atom. An atom followed by '+' matches a sequence of 1 or more matches of the atom. An atom followed by '?' matches a sequence of 0 or 1 matches of the atom.

A *bound* is '{' followed by an unsigned decimal integer, possibly followed by ',' possibly followed by another unsigned decimal integer, always followed by '}'. The integers must lie between 0 and **RE_DUP_MAX** (255†) inclusive, and if there are two of them, the first may not exceed the second. An atom followed by a bound containing one integer *i* and no comma matches a sequence of exactly *i* matches of the atom. An atom followed by a bound containing one integer *i* and a comma matches a sequence of *i* or more matches of the atom. An atom followed by a bound containing two integers *i* and *j* matches a sequence of *i* through *j* (inclusive) matches of the atom.

An atom is a regular expression enclosed in "()" (matching a match for the regular expression), an empty set of "()" (matching the null string)†, a *bracket expression* (see below), '.' (matching any single character), '^' (matching the null string at the beginning of a line), '\$' (matching the null string at the end of a line), a '\' followed by one of the characters ".[\$()/*+?/]" (matching that character taken as an ordinary character), a '\' followed by any other character† (matching that character taken as an ordinary character, as if the '\' had not been present†), or a single character with no other significance (matching that character). A '{' followed by a character other than a digit is an ordinary character, not the beginning of a bound†. It is illegal to end an RE with '\'.

A *bracket expression* is a list of characters enclosed in "[]". It normally matches any single character from the list (but see below). If the list begins with '^', it matches any single character (but see below) *not* from the rest of the list. If two characters in the list are separated by '-', this is shorthand for the full *range* of characters between those two (inclusive) in the collating sequence, for example, "[0-9]" in ASCII matches any decimal digit. It is illegal† for two ranges to share an endpoint, for example, "a-c-e". Ranges are very collating-sequence-dependent, and portable programs should avoid relying on them.

To include a literal ']' in the list, make it the first character (following a possible '^'). To include a literal '-', make it the first or last character, or the second endpoint of a range. To use a literal '-' as the first endpoint of a range, enclose it in "[." and ".]" to make it a collating element (see below). With the exception of these and some combinations using '[' (see next paragraphs), all other special characters, including '\', lose their special significance within a bracket expression.

Within a bracket expression, a collating element (a character, a multicharacter sequence that collates as if it were a single character, or a collating-sequence name for either) enclosed in "[." and ".]" stands for the sequence of characters of that collating element. The sequence is a single element of the bracket expression's list. A bracket expression containing a multicharacter collating element can thus match more than one character, for example, if the collating sequence includes a "ch" collating element, then the RE "[.ch.]*c" matches the first five characters of "chchcc".

Within a bracket expression, a collating element enclosed in "[=" and "=]" is an equivalence class, standing for the sequences of characters of all collating elements equivalent to that one, including itself. (If there are no other equivalent collating elements, the treatment is as if the enclosing delimiters were "[." and ".]" .)

For example, if o and ô are the members of an equivalence class, then "[=o=]", "[=ô=]", and "[oô]" are all synonymous. An equivalence class may not† be an endpoint of a range.

Within a bracket expression, the name of a *character class* enclosed in ":" and ":" stands for the list of all characters belonging to that class. Standard character class names are:

alnum	digit	punct
alpha	graph	space
blank	lower	upper
cntrl	print	xdigit

These stand for the character classes defined in **wctype(3)**. A locale may provide others. A character class may not be used as an endpoint of a range.

In the event that an RE could match more than one substring of a given string, the RE matches the one starting earliest in the string. If the RE could match more than one substring starting at that point, it matches the longest. Subexpressions also match the longest possible substrings, subject to the constraint that the whole match be as long as possible, with subexpressions starting earlier in the RE taking priority over ones starting later. Note that higher-level subexpressions thus take priority over their lower-level component subexpressions.

Match lengths are measured in characters, not collating elements. A null string is considered longer than no match at all. For example, "bb*" matches the three middle characters of "abbbc", "(wee/week)(knights/nights)" matches all ten characters of "weeknights", when "(.*).*?" is matched against "abc" the parenthesized subexpression matches all three characters, and when "(a*)*?" is matched against "bc" both the whole RE and the parenthesized subexpression match the null string.

If case-independent matching is specified, the effect is much as if all case distinctions had vanished from the alphabet. When an alphabetic that exists in multiple cases appears as an ordinary character outside a bracket expression, it is effectively transformed into a bracket expression containing both cases, for example, 'x' becomes "[xX]". When it appears inside a bracket expression, all case counterparts of it are added to the bracket expression, so that, for example, "[x]" becomes "[xX]" and "[^x]" becomes "[^xX]".

No particular limit is imposed on the length of REs†. Programs intended to be portable should not employ REs longer than 256 bytes, as an implementation can refuse to accept such REs and remain POSIX-compliant.

Obsolete ("basic") regular expressions differ in several respects. '|', '+', and '?' are ordinary characters and there is no equivalent for their functionality. The delimiters for bounds are "\/" and "\/", with '{' and '}' by themselves ordinary characters. The parentheses for nested subexpressions are "\(" and "\)", with '(' and ')' by themselves ordinary characters. '^' is an ordinary character except at the beginning of the RE or† the beginning of a parenthesized subexpression, '\$' is an ordinary character except at the end of the RE or† the end of a parenthesized subexpression, and '*' is an ordinary character if it appears at the beginning of the RE or the beginning of a parenthesized subexpression (after a possible leading '^').

Finally, there is one new type of atom, a *back reference*: '\' followed by a nonzero decimal digit d matches the same sequence of characters matched by the dth parenthesized subexpression (numbering subexpressions by the positions of their opening parentheses, left to right), so that, for example, "\([bc]\)\I" matches "bb" or "cc" but not "bc".

BUGS

Having two kinds of REs is a botch.

The current POSIX.2 spec says that ')' is an ordinary character in the absence of an unmatched '('; this was an unintentional result of a wording error, and change is likely. Avoid relying on it.

Back references are a dreadful botch, posing major problems for efficient implementations. They are also somewhat vaguely defined (does "a\(\(b\)\)*2\)*d" match "abbbd"?). Avoid using them.

POSIX.2's specification of case-independent matching is vague. The "one case implies all cases" definition given above is current consensus among implementors as to the right interpretation.

For further information about this structure, see [aio\(7\)](#).

Conforming to: POSIX.1-2001 and later.

See also: [aio_cancel\(3\)](#), [aio_error\(3\)](#), [aio_fsync\(3\)](#), [aio_read\(3\)](#), [aio_return\(3\)](#), [aio_suspend\(3\)](#), [aio_write\(3\)](#), [lio_listio\(3\)](#)

clock_t

Include: `<time.h>` or `<sys/types.h>`. Alternatively, `<sys/time.h>`.

Used for system time in clock ticks or **CLOCKS_PER_SEC** (defined in `<time.h>`). According to POSIX, it shall be an integer type or a real-floating type.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: [times\(2\)](#), [clock\(3\)](#)

clockid_t

Include: `<sys/types.h>`. Alternatively, `<time.h>`.

Used for clock ID type in the clock and timer functions. According to POSIX, it shall be defined as an arithmetic type.

Conforming to: POSIX.1-2001 and later.

See also: [clock_adjtime\(2\)](#), [clock_getres\(2\)](#), [clock_nanosleep\(2\)](#), [timer_create\(2\)](#), [clock_getcpuclockid\(3\)](#)

dev_t

Include: `<sys/types.h>`. Alternatively, `<sys/stat.h>`.

Used for device IDs. According to POSIX, it shall be an integer type. For further details of this type, see [makedev\(3\)](#).

Conforming to: POSIX.1-2001 and later.

See also: [mknod\(2\)](#), [stat\(2\)](#)

div_t

Include: `<stdlib.h>`.

```
typedef struct {
    int quot; /* Quotient */
    int rem; /* Remainder */
} div_t;
```

It is the type of the value returned by the [div\(3\)](#) function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: [div\(3\)](#)

double_t

Include: <math.h>.

The implementation's most efficient floating type at least as wide as *double*. Its type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <float.h>):

- 0 *double_t* is *double*.
- 1 *double_t* is *double*.
- 2 *double_t* is *long double*.

For other values of **FLT_EVAL_METHOD**, the type of *double_t* is implementation-defined.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *float_t* type in this page.

fd_set

Include: <sys/select.h>. Alternatively, <sys/time.h>.

A structure type that can represent a set of file descriptors. According to POSIX, the maximum number of file descriptors in an *fd_set* structure is the value of the macro **FD_SETSIZE**.

Conforming to: POSIX.1-2001 and later.

See also: **select**(2)

fenv_t

Include: <fenv.h>.

This type represents the entire floating-point environment, including control modes and status flags; for further details, see **fenv**(3).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fenv**(3)

fexcept_t

Include: <fenv.h>.

This type represents the floating-point status flags collectively; for further details see **fenv**(3).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fenv**(3)

FILE

Include: <stdio.h>. Alternatively, <wchar.h>.

An object type used for streams.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fclose**(3), **flockfile**(3), **fopen**(3), **fprintf**(3), **fread**(3), **fscanf**(3), **stdin**(3), **stdio**(3)

float_t

Include: <math.h>.

The implementation's most efficient floating type at least as wide as *float*. Its type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <float.h>):

- 0 *float_t* is *float*.
- 1 *float_t* is *double*.
- 2 *float_t* is *long double*.

For other values of **FLT_EVAL_METHOD**, the type of *float_t* is implementation-defined.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *double_t* type in this page.

gid_t

Include: <sys/types.h>. Alternatively, <grp.h>, <pwd.h>, <signal.h>, <stropts.h>, <sys/ipc.h>, <sys/stat.h>, or <unistd.h>.

A type used to hold group IDs. According to POSIX, this shall be an integer type.

Conforming to: POSIX.1-2001 and later.

See also: chown(2), getgid(2), getegid(2), getgroups(2), getresgid(2), getgrnam(2), credentials(7)

id_t

Include: <sys/types.h>. Alternatively, <sys/resource.h>.

A type used to hold a general identifier. According to POSIX, this shall be an integer type that can be used to contain a *pid_t*, *uid_t*, or *gid_t*.

Conforming to: POSIX.1-2001 and later.

See also: getpriority(2), waitid(2)

imaxdiv_t

Include: <inttypes.h>.

```
typedef struct {
    intmax_t      quot; /* Quotient */
    intmax_t      rem;   /* Remainder */
} imaxdiv_t;
```

It is the type of the value returned by the imaxdiv(3) function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: imaxdiv(3)

intmax_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

A signed integer type capable of representing any value of any signed integer type supported by the implementation. According to the C language standard, it shall be capable of storing values in the range [INTMAX_MIN, INTMAX_MAX].

The macro INTMAX_C() expands its argument to an integer constant of type *intmax_t*.

The length modifier for *intmax_t* for the printf(3) and the scanf(3) families of functions is **j**; resulting commonly in %**jd** or %**ji** for printing *intmax_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

Bugs: *intmax_t* is not large enough to represent values of type __int128 in implementations where __int128 is defined and long long is less than 128 bits wide.

See also: the *uintmax_t* type in this page.

intN_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

int8_t, *int16_t*, *int32_t*, *int64_t*

A signed integer type of a fixed width of exactly N bits, N being the value specified in its type name. According to the C language standard, they shall be capable of storing values in the range [INTN_MIN, INTN_MAX], substituting N by the appropriate number.

According to POSIX, *int8_t*, *int16_t*, and *int32_t* are required; *int64_t* is only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The length modifiers for the *intN_t* types for the printf(3) family of functions are expanded by macros of the forms **PRIIdN** and **PRIiN** (defined in <inttypes.h>); resulting for example in %"**PRI64**" or %"**PRIi64**" for printing *int64_t* values. The length modifiers for the *intN_t*

types for the **scanf**(3) family of functions are expanded by macros of the forms **SCNdN** and **SCNiN**, (defined in *<inttypes.h>*); resulting for example in **%"SCNd8"** or **%"SCNi8"** for scanning *int8_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intmax_t*, *uintN_t*, and *uintmax_t* types in this page.

intptr_t

Include: *<stdint.h>*. Alternatively, *<inttypes.h>*.

A signed integer type such that any valid (*void **) value can be converted to this type and back. According to the C language standard, it shall be capable of storing values in the range [**INTPTR_MIN**, **INTPTR_MAX**].

The length modifier for *intptr_t* for the **printf**(3) family of functions is expanded by the macros **PRIIdPTR** and **PRIiPTR** (defined in *<inttypes.h>*); resulting commonly in **%"PRIIdPTR"** or **%"PRIiPTR"** for printing *intptr_t* values. The length modifier for *intptr_t* for the **scanf**(3) family of functions is expanded by the macros **SCNdPTR** and **SCNiPTR**, (defined in *<inttypes.h>*); resulting commonly in **%"SCNdPTR"** or **%"SCNiPTR"** for scanning *intptr_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *uintptr_t* and *void ** types in this page.

lconv

Include: *<locale.h>*.

```
struct lconv {                                /* Values in the "C" locale: */
    char    *decimal_point;                  /* ". " */
    char    *thousands_sep;                 /* " " */
    char    *grouping;                      /* " " */
    char    *mon_decimal_point;             /* " " */
    char    *mon_thousands_sep;             /* " " */
    char    *mon_grouping;                  /* " " */
    char    *positive_sign;                 /* " " */
    char    *negative_sign;                 /* " " */
    char    *currency_symbol;               /* " " */
    char    frac_digits;                   /* CHAR_MAX */
    char    p_cs_precedes;                 /* CHAR_MAX */
    char    n_cs_precedes;                 /* CHAR_MAX */
    char    p_sep_by_space;                /* CHAR_MAX */
    char    n_sep_by_space;                /* CHAR_MAX */
    char    p_sign_posn;                   /* CHAR_MAX */
    char    n_sign_posn;                   /* CHAR_MAX */
    char    *int_curr_symbol;              /* " " */
    char    int_frac_digits;               /* CHAR_MAX */
    char    int_p_cs_precedes;             /* CHAR_MAX */
    char    int_n_cs_precedes;             /* CHAR_MAX */
    char    int_p_sep_by_space;             /* CHAR_MAX */
    char    int_n_sep_by_space;             /* CHAR_MAX */
    char    int_p_sign_posn;                /* CHAR_MAX */
    char    int_n_sign_posn;                /* CHAR_MAX */
};
```

Contains members related to the formatting of numeric values. In the "C" locale, its members have the values shown in the comments above.

Conforming to: C11 and later; POSIX.1-2001 and later.

See also: **setlocale**(3), **localeconv**(3), **charsets**(5), **locale**(7)

ldiv_t

Include: <stdlib.h>.

```
typedef struct {
    long      quot; /* Quotient */
    long      rem;   /* Remainder */
} ldiv_t;
```

It is the type of the value returned by the **ldiv(3)** function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **ldiv(3)**

lldiv_t

Include: <stdlib.h>.

```
typedef struct {
    long long  quot; /* Quotient */
    long long  rem;  /* Remainder */
} lldiv_t;
```

It is the type of the value returned by the **lldiv(3)** function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **lldiv(3)**

off_t

Include: <sys/types.h>. Alternatively, <aio.h>, <fcntl.h>, <stdio.h>, <sys/mman.h>, <sys/stat.h>, or <unistd.h>.

Used for file sizes. According to POSIX, this shall be a signed integer type.

Versions: <aio.h> and <stdio.h> define *off_t* since POSIX.1-2008.

Conforming to: POSIX.1-2001 and later.

Notes: On some architectures, the width of this type can be controlled with the feature test macro **_FILE_OFFSET_BITS**.

See also: **lseek(2)**, **mmap(2)**, **posix_fadvise(2)**, **pread(2)**, **truncate(2)**, **fseeko(3)**, **lockf(3)**, **posix_fallocate(3)**, **feature_test_macros(7)**

pid_t

Include: <sys/types.h>. Alternatively, <fcntl.h>, <sched.h>, <signal.h>, <spawn.h>, <sys/msg.h>, <sys/sem.h>, <sys/shm.h>, <sys/wait.h>, <termios.h>, <time.h>, <unistd.h>, or <utmpx.h>.

This type is used for storing process IDs, process group IDs, and session IDs. According to POSIX, it shall be a signed integer type, and the implementation shall support one or more programming environments where the width of *pid_t* is no greater than the width of the type *long*.

Conforming to: POSIX.1-2001 and later.

See also: **fork(2)**, **getpid(2)**, **getppid(2)**, **getsid(2)**, **gettid(2)**, **getpgid(2)**, **kill(2)**, **pidfd_open(2)**, **sched_setscheduler(2)**, **waitpid(2)**, **sigqueue(3)**, **credentials(7)**,

ptrdiff_t

Include: <stddef.h>.

Used for a count of elements, and array indices. It is the result of subtracting two pointers. According to the C language standard, it shall be a signed integer type capable of storing values in the range [**PTRDIFF_MIN**, **PTRDIFF_MAX**].

The length modifier for *ptrdiff_t* for the **printf(3)** and the **scanf(3)** families of functions is **t**; resulting commonly in **%td** or **%ti** for printing *ptrdiff_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the `size_t` and `ssize_t` types in this page.

`regex_t`

Include: `<regex.h>`.

```
typedef struct {
    size_t re_nsub; /* Number of parenthesized subexpressions. */
} regex_t;
```

This is a structure type used in regular expression matching. It holds a compiled regular expression, compiled with `regcomp(3)`.

Conforming to: POSIX.1-2001 and later.

See also: `regex(3)`

`regmatch_t`

Include: `<regex.h>`.

```
typedef struct {
    regoff_t rm_so; /* Byte offset from start of string
                      to start of substring */
    regoff_t rm_eo; /* Byte offset from start of string of
                      the first character after the end of
                      substring */
} regmatch_t;
```

This is a structure type used in regular expression matching.

Conforming to: POSIX.1-2001 and later.

See also: `regexec(3)`

`regoff_t`

Include: `<regex.h>`.

According to POSIX, it shall be a signed integer type capable of storing the largest value that can be stored in either a `ptrdiff_t` type or a `ssize_t` type.

Versions: Prior to POSIX.1-2008, the type was capable of storing the largest value that can be stored in either an `off_t` type or a `ssize_t` type.

Conforming to: POSIX.1-2001 and later.

See also: the `regmatch_t` structure and the `ptrdiff_t` and `ssize_t` types in this page.

`sigevent`

Include: `<signal.h>`. Alternatively, `<aio.h>`, `<mqueue.h>`, or `<time.h>`.

```
struct sigevent {
    int           sigev_notify; /* Notification type */
    int           sigev_signo;  /* Signal number */
    union sigval  sigev_value; /* Signal value */
    void         (*sigev_notify_function)(union sigval);
                 /* Notification function */
    pthread_attr_t *sigev_notify_attributes;
                 /* Notification attributes */
};
```

For further details about this type, see `sigevent(7)`.

Versions: `<aio.h>` and `<time.h>` define `sigevent` since POSIX.1-2008.

Conforming to: POSIX.1-2001 and later.

See also: `timer_create(2)`, `getaddrinfo_a(3)`, `lio_listio(3)`, `mq_notify(3)`

See also the *aiocb* structure in this page.

siginfo_t

Include: <signal.h>. Alternatively, <sys/wait.h>.

```
typedef struct {
    int      si_signo; /* Signal number */
    int      si_code;  /* Signal code */
    pid_t   si_pid;   /* Sending process ID */
    uid_t   si_uid;   /* Real user ID of sending process */
    void    *si_addr; /* Address of faulting instruction */
    int     si_status; /* Exit value or signal */
    union sigval si_value; /* Signal value */
} siginfo_t;
```

Information associated with a signal. For further details on this structure (including additional, Linux-specific fields), see **sigaction**(2).

Conforming to: POSIX.1-2001 and later.

See also: **pidfd_send_signal**(2), **rt_sigqueueinfo**(2), **sigaction**(2), **sigwaitinfo**(2), **psiginfo**(3)

sigset_t

Include: <signal.h>. Alternatively, <spawn.h>, or <sys/select.h>.

This is a type that represents a set of signals. According to POSIX, this shall be an integer or structure type.

Conforming to: POSIX.1-2001 and later.

See also: **epoll_pwait**(2), **ppoll**(2), **pselect**(2), **sigaction**(2), **signalfd**(2), **sigpending**(2), **sigprocmask**(2), **sigsuspend**(2), **sigwaitinfo**(2), **signal**(7)

sigval

Include: <signal.h>.

```
union sigval {
    int     sigval_int; /* Integer value */
    void   *sigval_ptr; /* Pointer value */
};
```

Data passed with a signal.

Conforming to: POSIX.1-2001 and later.

See also: **pthread_sigqueue**(3), **sigqueue**(3), **sigevent**(7)

See also the *sigevent* structure and the *siginfo_t* type in this page.

size_t

Include: <stddef.h> or <sys/types.h>. Alternatively, <aio.h>, <glob.h>, <grp.h>, <iconv.h>, <monetary.h>, <mqueue.h>, <ndbm.h>, <pwd.h>, <regex.h>, <search.h>, <signal.h>, <stdio.h>, <stdlib.h>, <string.h>, <strings.h>, <sys/mman.h>, <sys/msg.h>, <sys/sem.h>, <sys/shm.h>, <sys/socket.h>, <sys/uio.h>, <time.h>, <unistd.h>, <wchar.h>, or <wctype.h>.

Used for a count of bytes. It is the result of the *sizeof* operator. According to the C language standard, it shall be an unsigned integer type capable of storing values in the range [0, **SIZE_MAX**]. According to POSIX, the implementation shall support one or more programming environments where the width of *size_t* is no greater than the width of the type *long*.

The length modifier for *size_t* for the **printf**(3) and the **scanf**(3) families of functions is **z**; resulting commonly in **%zu** or **%zx** for printing *size_t* values.

Versions: <aio.h>, <glob.h>, <grp.h>, <iconv.h>, <mqueue.h>, <pwd.h>, <signal.h>, and <sys/socket.h> define *size_t* since POSIX.1-2008.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **read(2)**, **write(2)**, **fread(3)**, **fwrite(3)**, **memcmp(3)**, **memcpy(3)**, **memset(3)**, **off-setof(3)**

See also the *ptrdiff_t* and *ssize_t* types in this page.

ssize_t

Include: <sys/types.h>. Alternatively, <aio.h>, <monetary.h>, <mqueue.h>, <stdio.h>, <sys/msg.h>, <sys/socket.h>, <sys/uio.h>, or <unistd.h>.

Used for a count of bytes or an error indication. According to POSIX, it shall be a signed integer type capable of storing values at least in the range [-1, **SSIZE_MAX**], and the implementation shall support one or more programming environments where the width of *ssize_t* is no greater than the width of the type *long*.

Glibc and most other implementations provide a length modifier for *ssize_t* for the **printf(3)** and the **scanf(3)** families of functions, which is **z**; resulting commonly in **%zd** or **%zi** for printing *ssize_t* values. Although **z** works for *ssize_t* on most implementations, portable POSIX programs should avoid using it—for example, by converting the value to *intmax_t* and using its length modifier (**j**).

Conforming to: POSIX.1-2001 and later.

See also: **read(2)**, **readlink(2)**, **readv(2)**, **recv(2)**, **send(2)**, **write(2)**

See also the *ptrdiff_t* and *size_t* types in this page.

suseconds_t

Include: <sys/types.h>. Alternatively, <sys/select.h>, or <sys/time.h>.

Used for time in microseconds. According to POSIX, it shall be a signed integer type capable of storing values at least in the range [-1, 1000000], and the implementation shall support one or more programming environments where the width of *suseconds_t* is no greater than the width of the type *long*.

Conforming to: POSIX.1-2001 and later.

See also: the *timeval* structure in this page.

time_t

Include: <time.h> or <sys/types.h>. Alternatively, <sched.h>, <sys/msg.h>, <sys/select.h>, <sys/sem.h>, <sys/shm.h>, <sys/stat.h>, <sys/time.h>, or <utime.h>.

Used for time in seconds. According to POSIX, it shall be an integer type.

Versions: <sched.h> defines *time_t* since POSIX.1-2008.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **stime(2)**, **time(2)**, **ctime(3)**, **difftime(3)**

timer_t

Include: <sys/types.h>. Alternatively, <time.h>.

Used for timer ID returned by **timer_create(2)**. According to POSIX, there are no defined comparison or assignment operators for this type.

Conforming to: POSIX.1-2001 and later.

See also: **timer_create(2)**, **timer_delete(2)**, **timer_getoverrun(2)**, **timer_settime(2)**

timespec

Include: <time.h>. Alternatively, <aio.h>, <mqueue.h>, <sched.h>, <signal.h>, <sys/select.h>, or <sys/stat.h>.

```
struct timespec {
    time_t tv_sec; /* Seconds */
```

```
    long      tv_nsec; /* Nanoseconds */
}
```

Describes times in seconds and nanoseconds.

Conforming to: C11 and later; POSIX.1-2001 and later.

See also: **clock_gettime(2)**, **clock_nanosleep(2)**, **nanosleep(2)**, **timerfd_gettime(2)**, **timer_gettime(2)**

timeval

Include: <sys/time.h>. Alternatively, <sys/resource.h>, <sys/select.h>, or <utmpx.h>.

```
struct timeval {
    time_t      tv_sec;   /* Seconds */
    suseconds_t tv_usec; /* Microseconds */
};
```

Describes times in seconds and microseconds.

Conforming to: POSIX.1-2001 and later.

See also: **gettimeofday(2)**, **select(2)**, **utimes(2)**, **adjtime(3)**, **futimes(3)**, **timeradd(3)**

uid_t

Include: <sys/types.h>. Alternatively, <pwd.h>, <signal.h>, <stropts.h>, <sys/ipc.h>, <sys/stat.h>, or <unistd.h>.

A type used to hold user IDs. According to POSIX, this shall be an integer type.

Conforming to: POSIX.1-2001 and later.

See also: **chown(2)**, **getuid(2)**, **geteuid(2)**, **getresuid(2)**, **getpwnam(2)**, **credentials(7)**

uintmax_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

An unsigned integer type capable of representing any value of any unsigned integer type supported by the implementation. According to the C language standard, it shall be capable of storing values in the range [0, **UINTMAX_MAX**].

The macro **UINTMAX_C()** expands its argument to an integer constant of type *uintmax_t*.

The length modifier for *uintmax_t* for the **printf(3)** and the **scanf(3)** families of functions is **j**; resulting commonly in **%ju** or **%jx** for printing *uintmax_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

Bugs: *uintmax_t* is not large enough to represent values of type *unsigned __int128* in implementations where *unsigned __int128* is defined and *unsigned long long* is less than 128 bits wide.

See also: the *intmax_t* type in this page.

uintN_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

uint8_t, *uint16_t*, *uint32_t*, *uint64_t*

An unsigned integer type of a fixed width of exactly N bits, N being the value specified in its type name. According to the C language standard, they shall be capable of storing values in the range [0, **UINTN_MAX**], substituting N by the appropriate number.

According to POSIX, *uint8_t*, *uint16_t*, and *uint32_t* are required; *uint64_t* is only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The length modifiers for the *uintN_t* types for the **printf(3)** family of functions are expanded by macros of the forms **PRIuN**, **PRIoN**, **PRIxN**, and **PRIXN** (defined in <inttypes.h>); resulting for example in **%"PRIu32"** or **%"PRIx32"** for printing *uint32_t* values. The length modifiers for

the *uintN_t* types for the **scanf**(3) family of functions are expanded by macros of the forms **SCNuN**, **SCNoN**, **SCNxN**, and **SCNXN** (defined in *<inttypes.h>*); resulting for example in **%"SCNu16"** or **%"SCNx16"** for scanning *uint16_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intmax_t*, *intN_t*, and *uintmax_t* types in this page.

uintptr_t

Include: *<stdint.h>*. Alternatively, *<inttypes.h>*.

An unsigned integer type such that any valid (*void **) value can be converted to this type and back. According to the C language standard, it shall be capable of storing values in the range [0, **UINTPTR_MAX**].

The length modifier for *uintptr_t* for the **printf**(3) family of functions is expanded by the macros **PRIupTR**, **PRIoPTR**, **PRIxPTR**, and **PRIxPTR** (defined in *<inttypes.h>*); resulting commonly in **%"PRIupTR"** or **%"PRIxPTR"** for printing *uintptr_t* values. The length modifier for *uintptr_t* for the **scanf**(3) family of functions is expanded by the macros **SCNuPTR**, **SCNoPTR**, **SCNxPTR**, and **SCNXPTR** (defined in *<inttypes.h>*); resulting commonly in **%"SCNuPTR"** or **%"SCNxPTR"** for scanning *uintptr_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intptr_t* and *void ** types in this page.

va_list

Include: *<stdarg.h>*. Alternatively, *<stdio.h>*, or *<wchar.h>*.

Used by functions with a varying number of arguments of varying types. The function must declare an object of type *va_list* which is used by the macros **va_start**(3), **va_arg**(3), **va_copy**(3), and **va_end**(3) to traverse the list of arguments.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **va_start**(3), **va_arg**(3), **va_copy**(3), **va_end**(3)

*void **

According to the C language standard, a pointer to any object type may be converted to a pointer to *void* and back. POSIX further requires that any pointer, including pointers to functions, may be converted to a pointer to *void* and back.

Conversions from and to any other pointer type are done implicitly, not requiring casts at all. Note that this feature prevents any kind of type checking: the programmer should be careful not to convert a *void ** value to a type incompatible to that of the underlying data, because that would result in undefined behavior.

This type is useful in function parameters and return value to allow passing values of any type. The function will typically use some mechanism to know the real type of the data being passed via a pointer to *void*.

A value of this type can't be dereferenced, as it would give a value of type *void*, which is not possible. Likewise, pointer arithmetic is not possible with this type. However, in GNU C, pointer arithmetic is allowed as an extension to the standard; this is done by treating the size of a *void* or of a function as 1. A consequence of this is that *sizeof* is also allowed on *void* and on function types, and returns 1.

The conversion specifier for *void ** for the **printf**(3) and the **scanf**(3) families of functions is **p**.

Versions: The POSIX requirement about compatibility between *void ** and function pointers was added in POSIX.1-2008 Technical Corrigendum 1 (2013).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **malloc**(3), **memcmp**(3), **memcpy**(3), **memset**(3)

See also the *intptr_t* and *uintptr_t* types in this page.

NOTES

The structures described in this manual page shall contain, at least, the members shown in their definition, in no particular order.

Most of the integer types described in this page don't have a corresponding length modifier for the `printf(3)` and the `scanf(3)` families of functions. To print a value of an integer type that doesn't have a length modifier, it should be converted to `intmax_t` or `uintmax_t` by an explicit cast. To scan into a variable of an integer type that doesn't have a length modifier, an intermediate temporary variable of type `intmax_t` or `uintmax_t` should be used. When copying from the temporary variable to the destination variable, the value could overflow. If the type has upper and lower limits, the user should check that the value is within those limits, before actually copying the value. The example below shows how these conversions should be done.

Conventions used in this page

In "Conforming to" we only concern ourselves with C99 and later and POSIX.1-2001 and later. Some types may be specified in earlier versions of one of these standards, but in the interests of simplicity we omit details from earlier standards.

In "Include", we first note the "primary" header(s) that define the type according to either the C or POSIX.1 standards. Under "Alternatively", we note additional headers that the standards specify shall define the type.

EXAMPLES

The program shown below scans from a string and prints a value stored in a variable of an integer type that doesn't have a length modifier. The appropriate conversions from and to `intmax_t`, and the appropriate range checks, are used as explained in the notes section above.

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>

int
main (void)
{
    static const char *const str = "500000 us in half a second";
    suseconds_t us;
    intmax_t tmp;

    /* Scan the number from the string into the temporary variable */

    sscanf(str, "%jd", &tmp);

    /* Check that the value is within the valid range of suseconds_t */

    if (tmp < -1 || tmp > 1000000) {
        fprintf(stderr, "Scanned value outside valid range!\n");
        exit(EXIT_FAILURE);
    }

    /* Copy the value to the suseconds_t variable 'us' */

    us = tmp;

    /* Even though suseconds_t can hold the value -1, this isn't
       a sensible number of microseconds */
}
```

```
if (us < 0) {
    fprintf(stderr, "Scanned value shouldn't be negative!\n");
    exit(EXIT_FAILURE);
}

/* Print the value */

printf("There are %jd microseconds in half a second.\n",
       (intmax_t) us);

exit(EXIT_SUCCESS);
}
```

NAME

renice – alter priority of running processes

SYNOPSIS

renice [**-n**] *priority* [**-g|-p|-u**] *identifier...*

DESCRIPTION

renice alters the scheduling priority of one or more running processes. The first argument is the *priority* value to be used. The other arguments are interpreted as process IDs (by default), process group IDs, user IDs, or user names. **renice**'ing a process group causes all processes in the process group to have their scheduling priority altered. **renice**'ing a user causes all processes owned by the user to have their scheduling priority altered.

OPTIONS

-n, --priority *priority*

Specify the scheduling *priority* to be used for the process, process group, or user. Use of the option **-n** or **--priority** is optional, but when used it must be the first argument.

-g, --pgrp

Interpret the succeeding arguments as process group IDs.

-p, --pid

Interpret the succeeding arguments as process IDs (the default).

-u, --user

Interpret the succeeding arguments as usernames or UIDs.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

FILES

/etc/passwd

to map user names to user IDs

NOTES

Users other than the superuser may only alter the priority of processes they own. Furthermore, an unprivileged user can only *increase* the "nice value" (i.e., choose a lower priority) and such changes are irreversible unless (since Linux 2.6.12) the user has a suitable "nice" resource limit (see **ulimit(1p)** and **getrlimit(2)**).

The superuser may alter the priority of any process and set the priority to any value in the range -20 to 19. Useful priorities are: 19 (the affected processes will run only when nothing else in the system wants to), 0 (the "base" scheduling priority), anything negative (to make things go very fast).

HISTORY

The **renice** command appeared in 4.0BSD.

EXAMPLES

The following command would change the priority of the processes with PIDs 987 and 32, plus all processes owned by the users daemon and root:

```
renice +1 987 -u daemon root -p 32
```

SEE ALSO

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The `renice` command is part of the `util-linux` package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

rfkill – tool for enabling and disabling wireless devices

SYNOPSIS

rfkill [options] [*command*] [*ID|type ...*]

DESCRIPTION

rfkill lists, enabling and disabling wireless devices.

The command "list" output format is deprecated and maintained for backward compatibility only. The new output format is the default when no command is specified or when the option **--output** is used.

The default output is subject to change. So whenever possible, you should avoid using default outputs in your scripts. Always explicitly define expected columns by using the **--output** option together with a columns list in environments where a stable output is required.

OPTIONS

-J, --json

Use JSON output format.

-n, --noheadings

Do not print a header line.

-o, --output

Specify which output columns to print. Use **--help** to get a list of available columns.

--output-all

Output all available columns.

-r, --raw

Use the raw output format.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

COMMANDS

help

Display help text and exit.

event

Listen for rfkill events and display them on stdout.

list [*id|type ...*]

List the current state of all available devices. The command output format is deprecated, see the **DESCRIPTION** section. It is a good idea to check with **list** command *id* or *type* scope is appropriate before setting **block** or **unblock**. Special *all* type string will match everything. Use of multiple *ID* or *type* arguments is supported.

block *id|type [...]*

Disable the corresponding device.

unblock *id|type [...]*

Enable the corresponding device. If the device is hard-blocked, for example via a hardware switch, it will remain unavailable though it is now soft-unblocked.

toggle *id|type* [...]
Enable or disable the corresponding device.

EXAMPLE

```
rfkill --output ID,TYPE  
rfkill block all  
rfkill unblock wlan  
rfkill block bluetooth uwb wimax wwan gps fm nfc
```

AUTHORS

rfkill was originally written by [Johannes Berg](#) <johannes@sipsolutions.net> and [Marcel Holtmann](#) <marcel@holtmann.org>. The code has been later modified by [Sami Kerola](#) <kerolasa@iki.fi> and [Karel Zak](#) <kzak@redhat.com> for the util-linux project.

This manual page was written by [Darren Salt](#) <linux@youmustbejoking.demon.co.uk> for the Debian project (and may be used by others).

AVAILABILITY

The **rfkill** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](#) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

rm – remove files or directories

SYNOPSIS

rm [*OPTION*]... [*FILE*]...

DESCRIPTION

This manual page documents the GNU version of **rm**. **rm** removes each specified file. By default, it does not remove directories.

If the **-I** or **--interactive=once** option is given, and there are more than three files or the **-r**, **-R**, or **--recursive** are given, then **rm** prompts the user for whether to proceed with the entire operation. If the response is not affirmative, the entire command is aborted.

Otherwise, if a file is unwritable, standard input is a terminal, and the **-f** or **--force** option is not given, or the **-i** or **--interactive=always** option is given, **rm** prompts the user for whether to remove the file. If the response is not affirmative, the file is skipped.

OPTIONS

Remove (unlink) the FILE(s).

-f, --force

ignore nonexistent files and arguments, never prompt

-i

prompt before every removal

-I

prompt once before removing more than three files, or when removing recursively; less intrusive than **-i**, while still giving protection against most mistakes

--interactive[=*WHEN*]

prompt according to *WHEN*: never, once (**-I**), or always (**-i**); without *WHEN*, prompt always

--one-file-system

when removing a hierarchy recursively, skip any directory that is on a file system different from that of the corresponding command line argument

--no-preserve-root

do not treat '/' specially

--preserve-root[=*all*]

do not remove '/' (default); with 'all', reject any command line argument on a separate device from its parent

-r, -R, --recursive

remove directories and their contents recursively

-d, --dir

remove empty directories

-v, --verbose

explain what is being done

--help

display this help and exit

--version

output version information and exit

By default, **rm** does not remove directories. Use the **--recursive** (**-r** or **-R**) option to remove each listed directory, too, along with all of its contents.

To remove a file whose name starts with a '**-**', for example '**-foo**', use one of these commands:

```
rm -- -foo
```

```
rm ./-foo
```

Note that if you use **rm** to remove a file, it might be possible to recover some of its contents, given sufficient expertise and/or time. For greater assurance that the contents are truly unrecoverable, consider using **shred**.

NAME

rmdir – remove empty directories

SYNOPSIS

rmdir [*OPTION*]... *DIRECTORY*...

DESCRIPTION

Remove the *DIRECTORY*(ies), if they are empty.

--ignore-fail-on-non-empty

ignore each failure that is solely because a directory
is non-empty

-p, --parents

remove *DIRECTORY* and its ancestors; e.g., '**rmdir -p a/b/c**' is similar to '**rmdir a/b/c a/b a**'

-v, --verbose

output a diagnostic for every directory processed

--help display this help and exit

--version

output version information and exit

NAME

rmdir – delete a directory

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <unistd.h>
int rmdir(const char *pathname);
```

DESCRIPTION

rmdir() deletes a directory, which must be empty.

RETURN VALUE

On success, zero is returned. On error, **-1** is returned, and *errno* is set to indicate the error.

ERRORS**EACCES**

Write access to the directory containing *pathname* was not allowed, or one of the directories in the path prefix of *pathname* did not allow search permission. (See also **path_resolution(7)**.)

EBUSY

pathname is currently in use by the system or some process that prevents its removal. On Linux, this means *pathname* is currently used as a mount point or is the root directory of the calling process.

EFAULT

pathname points outside your accessible address space.

EINVAL

pathname has **.** as last component.

ELOOP

Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG

pathname was too long.

ENOENT

A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOMEM

Insufficient kernel memory was available.

ENOTDIR

pathname, or a component used as a directory in *pathname*, is not, in fact, a directory.

ENOTEMPTY

pathname contains entries other than **.** and **..**; or, *pathname* has **..** as its final component. POSIX.1 also allows **EXIST** for this condition.

EPERM

The directory containing *pathname* has the sticky bit (**S_ISVTX**) set and the process's effective user ID is neither the user ID of the file to be deleted nor that of the directory containing it, and the process is not privileged (Linux: does not have the **CAP_FOWNER** capability).

EPEERM

The filesystem containing *pathname* does not support the removal of directories.

EROFS

pathname refers to a directory on a read-only filesystem.

STANDARDS

POSIX.1-2001, POSIX.1-2008, SVr4, 4.3BSD.

BUGS

Infelicities in the protocol underlying NFS can cause the unexpected disappearance of directories which are still being used.

NAME

rmmod – Simple program to remove a module from the Linux Kernel

SYNOPSIS

rmmod [**-f**] [**-s**] [**-v**] [*modulename*]

DESCRIPTION

rmmod is a trivial program to remove a module (when module unloading support is provided) from the kernel. Most users will want to use **modprobe(8)** with the **-r** option instead.

OPTIONS**-v, --verbose**

Print messages about what the program is doing. Usually **rmmod** prints messages only if something goes wrong.

-f, --force

This option can be extremely dangerous: it has no effect unless **CONFIG_MODULE_FORCE_UNLOAD** was set when the kernel was compiled. With this option, you can remove modules which are being used, or which are not designed to be removed, or have been marked as unsafe (see **lsmod(8)**).

-s, --syslog

Send errors to syslog instead of standard error.

-V --version

Show version of program and exit.

COPYRIGHT

This manual page originally Copyright 2002, Rusty Russell, IBM Corporation. Maintained by Jon Masters and others.

NAME

route – show / manipulate the IP routing table

SYNOPSIS

```
route [-CFvnNee] [-A family |-4|-6]
route  [-v] [-A family |-4|-6] add [-net|-host] target [netmask Nm] [gw Gw] [metric N] [mss M]
       [window W] [irtt I] [reject] [mod] [dyn] [reinstate] [[dev] If]
route   [-v] [-A family |-4|-6] del [-net|-host] target [gw Gw] [netmask Nm] [metric M] [[dev] If]
route   [-V] [--version] [-h] [--help]
```

DESCRIPTION

Route manipulates the kernel's IP routing tables. Its primary use is to set up static routes to specific hosts or networks via an interface after it has been configured with the **ifconfig(8)** program.

When the **add** or **del** options are used, **route** modifies the routing tables. Without these options, **route** displays the current contents of the routing tables.

OPTIONS**-A** *family*

use the specified address family (eg ‘inet’). Use **route --help** for a full list. You can use **-6** as an alias for **--inet6** and **-4** as an alias for **-A inet**

-F operate on the kernel's FIB (Forwarding Information Base) routing table. This is the default.

-C operate on the kernel's routing cache.

-v select verbose operation.

-n show numerical addresses instead of trying to determine symbolic host names. This is useful if you are trying to determine why the route to your nameserver has vanished.

-e use **netstat(8)**-format for displaying the routing table. **-ee** will generate a very long line with all parameters from the routing table.

del delete a route.

add add a new route.

target the destination network or host. You can provide an addresses or symbolic network or host name. Optionally you can use */prefixlen* notation instead of using the **netmask** option.

-net the *target* is a network.

-host the *target* is a host.

netmask *NM*

when adding a network route, the netmask to be used.

gw *GW* route packets via a gateway.

NOTE: The specified gateway must be reachable first. This usually means that you have to set up a static route to the gateway beforehand. If you specify the address of one of your local interfaces, it will be used to decide about the interface to which the packets should be routed to. This is a BS-Dism compatibility hack.

metric *M*

set the metric field in the routing table (used by routing daemons) to *M*. If this option is not specified the metric for inet6 (IPv6) address family defaults to '1', for inet (IPv4) it defaults to '0'. You should always specify an explicit metric value to not rely on those defaults - they also differ from iproute2.

mss *M* sets MTU (Maximum Transmission Unit) of the route to *M* bytes. Note that the current implementation of the route command does not allow the option to set the Maximum Segment Size (MSS).

window *W*

set the TCP window size for connections over this route to *W* bytes. This is typically only used on AX.25 networks and with drivers unable to handle back to back frames.

irtt *I* set the initial round trip time (irtt) for TCP connections over this route to *I* milliseconds (1-12000). This is typically only used on AX.25 networks. If omitted the RFC 1122 default of 300ms is used.

reject install a blocking route, which will force a route lookup to fail. This is for example used to mask out networks before using the default route. This is NOT for firewalling.

mod, dyn, reinstate

install a dynamic or modified route. These flags are for diagnostic purposes, and are generally only set by routing daemons.

dev *If* force the route to be associated with the specified device, as the kernel will otherwise try to determine the device on its own (by checking already existing routes and device specifications, and where the route is added to). In most normal networks you won't need this.

If **dev *If*** is the last option on the command line, the word **dev** may be omitted, as it's the default. Otherwise the order of the route modifiers (**metric netmask gw dev**) doesn't matter.

EXAMPLES

route add -net 127.0.0.0 netmask 255.0.0.0 metric 1024 dev lo

adds the normal loopback entry, using netmask 255.0.0.0 and associated with the "lo" device (assuming this device was previously set up correctly with **ifconfig(8)**).

route add -net 192.56.76.0 netmask 255.255.255.0 metric 1024 dev eth0

adds a route to the local network 192.56.76.x via "eth0". The word "dev" can be omitted here.

route del default

deletes the current default route, which is labeled "default" or 0.0.0.0 in the destination field of the current routing table.

route del -net 192.56.76.0 netmask 255.255.255.0

deletes the route. Since the Linux routing kernel uses classless addressing, you pretty much always have to specify the netmask that is same as as seen in 'route -n' listing.

route add default gw mango

adds a default route (which will be used if no other route matches). All packets using this route will be gatewayed through the address of a node named "mango". The device which will actually be used for that route depends on how we can reach "mango" - "mango" must be on directly reachable route.

route add mango sl0

Adds the route to the host named "mango" via the SLIP interface (assuming that "mango" is the SLIP host).

route add -net 192.57.66.0 netmask 255.255.255.0 gw mango

This command adds the net "192.57.66.x" to be gatewayed through the former route to the SLIP interface.

route add -net 224.0.0.0 netmask 240.0.0.0 dev eth0

This is an obscure one documented so people know how to do it. This sets all of the class D (multicast) IP routes to go via "eth0". This is the correct normal configuration line with a multicasting kernel.

route add -net 10.0.0.0 netmask 255.0.0.0 metric 1024 reject

This installs a rejecting route for the private network "10.x.x.x."

route -6 add 2001:0002::/48 metric 1 dev eth0

This adds a IPv6 route with the specified metric to be directly reachable via eth0.

OUTPUT

The output of the kernel routing table is organized in the following columns

Destination

The destination network or destination host.

Gateway

The gateway address or '*' if none set.

Genmask

The netmask for the destination net; '255.255.255.255' for a host destination and '0.0.0.0' for the **default** route.

Flags

Possible flags include
U (route is **up**)
H (target is a **host**)
G (use **gateway**)
R (**reinstate** route for dynamic routing)
D (**dynamically** installed by daemon or redirect)
M (**modified** from routing daemon or redirect)
A (installed by **addrconf**)
C (**cache** entry)
! (**reject** route)

Metric

The 'distance' to the target (usually counted in hops).

Ref

Number of references to this route. (Not used in the Linux kernel.)

Use

Count of lookups for the route. Depending on the use of -F and -C this will be either route cache misses (-F) or hits (-C).

Iface

Interface to which packets for this route will be sent.

MSS

Default maximum segment size for TCP connections over this route.

Window

Default window size for TCP connections over this route.

irtt

Initial RTT (Round Trip Time). The kernel uses this to guess about the best TCP protocol parameters without waiting on (possibly slow) answers.

HH (cached only)

The number of ARP entries and cached routes that refer to the hardware header cache for the cached route. This will be -1 if a hardware address is not needed for the interface of the cached route (e.g. lo).

Arp (cached only)

Whether or not the hardware address for the cached route is up to date.

FILES

*/proc/net/ipv6_route
/proc/net/route
/proc/net/rt_cache*

SEE ALSO
