Linux Filesystem Hierarchy

Version 0.65

Binh Nguyen

<linuxfilesystem@yahoo.com.au>

2004-07-30

This document outlines the set of requirements and guidelines for file and directory placement under the Linux operating system according to those of the FSSTND v2.3 final (January 29, 2004) and also its actual implementation on an arbitrary system. It is meant to be accessible to all members of the Linux community, be distribution independent and is intended to discuss the impact of the FSSTND and how it has managed to increase the efficiency of support interoperability of applications, system administration tools, development tools, and scripts as well as greater uniformity of documentation for these systems.

Chapter 1. Linux Filesystem Hierarchy

1.1. Foreward

When migrating from another operating system such as Microsoft Windows to another; one thing that will profoundly affect the end user greatly will be the differences between the filesystems.

What are filesystems?

A *filesystem* is the methods and data structures that an operating system uses to keep track of files on a disk or partition; that is, the way the files are organized on the disk. The word is also used to refer to a partition or disk that is used to store the files or the type of the filesystem. Thus, one might say I have two filesystems meaning one has two partitions on which one stores files, or that one is using the extended filesystem, meaning the type of the filesystem.

The difference between a disk or partition and the filesystem it contains is important. A few programs (including, reasonably enough, programs that create filesystems) operate directly on the raw sectors of a disk or partition; if there is an existing file system there it will be destroyed or seriously corrupted. Most programs operate on a filesystem, and therefore won't work on a partition that doesn't contain one (or that contains one of the wrong type).

Before a partition or disk can be used as a filesystem, it needs to be initialized, and the bookkeeping data structures need to be written to the disk. This process is called *making a filesystem*.

Most UNIX filesystem types have a similar general structure, although the exact details vary quite a bit. The central concepts are *superblock*, *inode*, *data block*, *directory block*, and *indirection block*. The superblock contains information about the filesystem as a whole, such as its size (the exact information here depends on the filesystem). An inode contains all information about a file, except its name. The name is stored in the directory, together with the number of the inode. A directory entry consists of a filename and the number of the inode which represents the file. The inode contains the numbers of several data blocks, which are used to store the data in the file. There is space only for a few data block numbers in the inode, however, and if more are needed, more space for pointers to the data blocks is allocated dynamically. These dynamically allocated blocks are indirect blocks; the name indicates that in order to find the data block, one has to find its number in the indirect block first.

Like UNIX, Linux chooses to have a single hierarchical directory structure. Everything starts from the root directory, represented by /, and then expands into sub-directories instead of having so-called 'drives'. In the Windows environment, one may put one's files almost anywhere: on C drive, D drive, E drive etc. Such a file system is called a hierarchical structure and is managed by the programs themselves (program directories), not by the operating system. On the other hand, Linux sorts directories descending from the root directory / according to their importance to the boot process.

If you're wondering why Linux uses the frontslash / instead of the backslash \ as in Windows it's because it's simply following the UNIX tradition. Linux, like Unix also chooses to be case sensitive. What this means is that the case, whether in capitals or not, of the characters becomes very important. So this is not the same as THIS. This feature accounts for a fairly large proportion of problems for new users especially during file transfer operations whether it may be via removable disk media such as floppy disk or over the wire by way of FTP.

Linux Filesystem Hierarchy

The filesystem order is specific to the function of a file and not to its program context (the majority of Linux filesystems are 'Second Extended File Systems', short 'EXT2' (aka 'ext2fs' or 'extfs2') or are themselves subsets of this filesystem such as ext3 and Reiserfs). It is within this filesystem that the operating system determines into which directories programs store their files.

If you install a program in Windows, it usually stores most of its files in its own directory structure. A help file for instance may be in C:\Program Files\[program name]\ or in C:\Program Files\[program–name]\help or in C:\Program Files\[program –name]\humpty\dumpty\doo. In Linux, programs put their documentation into /usr/share/doc/[program–name], man(ual) pages into /usr/share/man/man[1–9] and info pages into /usr/share/info. They are merged into and with the system hierarchy.

As all Linux users know, unless you mount a partition or a device, the system does not know of the existence of that partition or device. This might not appear to be the easiest way to provide access to your partitions or devices, however it offers the advantage of far greater flexibility when compared to other operating systems. This kind of layout, known as the unified filesystem, does offer several advantages over the approach that Windows uses. Let's take the example of the /usr directory. This sub–directory of the root directory contains most of the system executables. With the Linux filesystem, you can choose to mount it off another partition or even off another machine over the network using an innumerable set of protocols such as NFS (Sun), Coda (CMU) or AFS (IBM). The underlying system will not and need not know the difference. The presence of the /usr directory is completely transparent. It appears to be a local directory that is part of the local directory structure.

Compliance requires that:

	shareable	unshareable
static	/usr	/etc
	/opt	/boot
variable	/var/mail	/var/run
	/var/spool/news	/var/lock

"Shareable" files are defined as those that can be stored on one host and used on others. "Unshareable" files are those that are not shareable. For example, the files in user home directories are shareable whereas device lock files are not. "Static" files include binaries, libraries, documentation files and other files that do not change without system administrator intervention. "Variable" files are defined as files that are not static.

Another reason for this unified filesystem is that Linux caches a lot of disk accesses using system memory while it is running to accelerate these processes. It is therefore vitally important that these buffers are flushed (get their content written to disk), before the system closes down. Otherwise files are left in an undetermined state which is of course a very bad thing. Flushing is achieved by 'unmounting' the partitions during proper system shutdown. In other words, don't switch your system off while it's running! You may get away with it quite often, since the Linux file system is very robust, but you may also wreak havoc upon important files. Just hit ctrl–alt–del or use the proper commands (e.g. shutdown, poweroff, init 0). This will shut down the system in a decent way which will thus, guarantee the integrity of your files.

Many of us in the Linux community have come to take for granted the existence of excellent books and documents about Linux, an example being those produced by the Linux Documentation Project. We are used to having various packages taken from different sources such as Linux FTP sites and distribution CD–ROMs

Linux Filesystem Hierarchy

integrate together smoothly. We have come to accept that we all know where critical files like mount can be found on any machine running Linux. We also take for granted CD-ROM based distributions that can be run directly from the CD and which consume only a small amount of physical hard disk or a RAM disk for some variable files like /etc/passwd, etc. This has not always been the case.

During the adolescent years of Linux during the early to mid-90s each distributor had his own favorite scheme for locating files in the directory hierarchy. Unfortunately, this caused many problems. The *Linux File System Structure* is a document, which was created to help end this anarchy. Often the group, which creates this document or the document itself, is referred to as the FSSTND. This is short for file system standard". This document has helped to standardize the layout of file systems on Linux systems everywhere. Since the original release of the standard, most distributors have adopted it in whole or in part, much to the benefit of all Linux users.

Since the first draft of the standard, the FSSTND project has been coordinated by Daniel Quinlan and development of this standard has been through consensus by a group of developers and Linux enthusiasts. The FSSTND group set out to accomplish a number of specific goals. The first goal was to solve a number of problems that existed with the current distributions at the time. Back then, it was not possible to have a shareable /usr partition, there was no clear distinction between /bin and /usr/bin, it was not possible to set up a diskless workstation, and there was just general confusion about what files went where. The second goal was to ensure the continuation of some reasonable compatibility with the de-facto standards already in use in Linux and other UNIX-like operating systems. Finally, the standard had to gain widespread approval by the developers, distributors, and users within the Linux community. Without such support, the standard would be pointless, becoming just another way of laying out the file system.

Fortunately, the FSSTND has succeeded though there are also some goals that the FSSTND project did not set out to achieve. The FSSTND does not try to emulate the scheme of any specific commercial UNIX operating system (e.g. SunOS, AIX, etc.) Furthermore, for many of the files covered by the FSSTND, the standard does not dictate whether the files should be present, merely where the files should be if they are present. Finally, for most files, the FSSTND does not attempt to dictate the format of the contents of the files. (There are some specific exceptions when several different packages may need to know the file formats to work together properly. For example, lock files that contain the process ID of the process holding the lock.) The overall objective was to establish the location where common files could be found, if they existed on a particular machine. The FSSTND project began in early August 1993. Since then, there have been a number of public revisions of this document. The latest, v2.3 was released on January 29, 2004.

If you're asking "What's the purpose of all this? Well, the answer depends on who you are. If you are a Linux user, and you don't administrate your own system then the FSSTND ensures that you will be able to find programs where you'd expect them to be if you've already had experience on another Linux machine. It also ensures that any documentation you may have makes sense. Furthermore, if you've already had some experience with Unix before, then the FSSTND shouldn't be too different from what you're currently using, with a few exceptions. Perhaps the most important thing is that the development of a standard brings Linux to a level of maturity authors and commercial application developers feel they can support.

If you administer your own machine then you gain all the benefits of the FSSTND mentioned above. You may also feel more secure in the ability of others to provide support for you, should you have a problem. Furthermore, periodic upgrades to your system are theoretically easier. Since there is an agreed-upon standard for the locations of files, package maintainers can provide instructions for upgrading that will not leave extra, older files lying around your system inhabiting valuable disk space. The FSSTND also means that there is more support from those providing source code packages for you to compile and install yourself. The provider knows, for example, where the executable for sed is to be found on a Linux machine and can use that in his installation scripts or Makefiles.

Linux Filesystem Hierarchy

If you run a large network, the FSSTND may ease many of your NFS headaches, since it specifically addresses the problems which formerly made shared implementations of /usr impractical. If you are a distributor, then you will be affected most by the Linux FSSTND. You may have to do a little extra work to make sure that your distribution is FSSTND-compliant, but your users (and hence your business) will gain by it. If your system is compliant, third party add-on packages (and possibly your own) will integrate smoothly with your system. Your users will, of course, gain all the benefits listed above, and many of your support headaches will be eased. You will benefit from all the discussion and thought that has been put into the FSSTND and avoid many of the pitfalls involved in designing a filesystem structure yourself. If you adhere to the FSSTND, you will also be able to take advantage of various features that the FSSTND was designed around. For example, the FSSTND makes "live" CD-ROMs containing everything except some of the files in the / and /var directories possible. If you write documentation for Linux, the FSSTND makes it much easier to do so, which makes sense to the Linux community. You no longer need to worry about the specific location of lock files on one distribution versus another, nor are you forced to write documentation that is only useful to the users of a specific distribution. The FSSTND is at least partly responsible for the recent explosion of Linux books being published.

If you are a developer, the existence of the FSSTND greatly eases the possibility for potential problems. You can know where important system binaries are found, so you can use them from inside your programs or your shell scripts. Supporting users is also greatly eased, since you don't have to worry about things like the location of these binaries when resolving support issues. If you are the developer of a program that needs to integrate with the rest of the system, the FSSTND ensures that you can be certain of the steps to meet this end. For example, applications such as kermit, which access the serial ports, need to know they can achieve exclusive access to the TTY device. The FSSTND specifies a common method of doing this so that all compliant applications can work together. That way you can concentrate on making more great software for Linux instead of worrying about how to detect and deal with the differences in flavors of Linux. The widespread acceptance of the FSSTND by the Linux community has been crucial to the success of both the standard and operating system. Nearly every modern distribution conforms to the Linux FSSTND. If your implementation isn't at least partially FSSTND compliant, then it is probably either very old or you built it yourself. The FSSTND itself contains a list of some of the distributions that aim to conform to the FSSTND. However, there are some distributions that are known to cut some corners in their implementation of FSSTND.

By no means does this mean that the standard itself is complete. There are still unresolved issues such as the organization of architecture-independent scripts and data files /usr/share. Up until now, the i386 has been the primary platform for Linux, so the need for standardization of such files was non-existent.

The rapid progress in porting Linux to other architectures (MC680x0, Alpha, MIPS, PowerPC) suggests that this issue will soon need to be dealt with. Another issue that is under some discussion is the creation of an /opt directory as in SVR4. The goal for such a directory would be to provide a location for large commercial or third party packages to install themselves without worrying about the requirements made by FSSTND for the other directory hierarchies. The FSSTND provides the Linux community with an excellent reference document and has proven to be an important factor in the maturation of Linux. As Linux continues to evolve, so will the FSSTND.

Now, that we have seen how things should be, let's take a look at the real world. As you will see, the implementation of this concept on Linux isn't perfect and since Linux has always attracted individualists who tend to be fairly opinionated, it has been a bone of contention among users for instance which directories certain files should be put into. With the arrival of different distributions, anarchy has once again descended upon us. Some distributions put mount directories for external media into the / directory, others into /mnt. Red Hat based distributions feature the /etc/sysconfig sub-hierarchy for configuration files concerning input and network devices. Other distributions do not have this directory at all and put the appropriate files elsewhere or

Linux Filesystem Hierarchy

even use completely different mechanisms to do the same thing. Some distributions put KDE into /opt/, others into /usr.

But even within a given file system hierarchy, there are inconsistencies. For example, even though this was never the intention of the XFree86 group, XFree86 does indeed have its own directory hierarchy.

These problems don't manifest themselves as long as you compile programs yourself. You can adapt configure scripts or Makefiles to your system's configuration or to your preference. It's a different story if you install pre-compiled packages like RPMs though. Often these are not adaptable from one file system hierarchy to another. What's worse: some RPMs might even create their own hierarchy. If you, say, install a KDE RPM from the SuSE Linux distribution on your Mandrake system, the binary will be put into /opt/kde2/bin. And thus it won't work, because Mandrake expects it to be in /usr/bin. There are of course ways to circumvent this problem but the current situation is clearly untenable. Thus, all the leading Linux distributors have joined the Linux Standard Base project, which is attempting to create a common standard for Linux distributions. This isn't easy, since changing the file system hierarchy means a lot of work for distributors so every distributor tries to push a standard which will allow them to keep as much of their own hierarchy as possible. The LSB will also encompass the proposals made by the Filesystem Hierarchy Standard project (FHS, former FSSTND).

1.2. The Root Directory

To comply with the FSSTND the following directories, or symbolic links to directories, are required in /.

/bin	Essential command binaries
/boot	Static files of the boot loader
/dev	Device files
/etc	Host-specific system configuration
/lib	Essential shared libraries and kernel modules
/media	Mount point for removable media
/mnt	Mount point for mounting a filesystem temporarily
/opt	Add-on application software packages
/sbin	Essential system binaries
/srv	Data for services provided by this system
/tmp	Temporary files
/usr	Secondary hierarchy
/var	Variable data

The following directories, or symbolic links to directories, must be in /, if the corresponding subsystem is installed:

```
/ -- the root directory
/home User home directories (optional)
/lib<qual> Alternate format essential shared libraries
          (optional)
/root Home directory for the root user (optional)
```

Each directory listed above is described in detail in separate subsections further on in this document.

The reference system will be based upon Debian 3.0r0 (Woody), 2.4.18 kernel configured to a Redhat kernel-2.4.18-i686.config file.

Hardware

Linux Filesystem Hierarchy

- ◊ Intel Celeron 766 Processor
- ◊ MSI MS-6309 V.2.0 Mainboard
- ◊ 512MB PQI PC133 SDRAM
- ◊ 16x Lite-On LTD-165H DVD-ROM
- ◊ 40x24x10 Sony CRX175A1 CD-RW
- ◊ NVIDIA RIVA 32MB TNT2 M64
- ◊ D-Link DFE-530TX 10/100 NIC
- ◊ Realtek RTL8029(AS) 10 NIC
- ◊ Lucent Mars2 Linmodem
- ◊ C-Media CMI8738 PCI Audio Device
- ◊ Miro DC-30 VIVO
- ◊ Aopen KF-45A Miditower Case
- ◊ Acer Accufeel Keyboard
- ◊ Genius Netscroll+ Mouse
- ◊ Compaq MV500 Presario Monitor

Software

- ◊ Windows XP on /dev/hda1
- ◊ FreeBSD 4.2 on /dev/hda2
- ◊ Redhat 8.0 on /dev/hda5
- ◊ Debian 3.0r0 on /dev/hda6
- ◊ Mandrake 9.1 on /dev/hda7
- ◊ Swap partition on /dev/hda8

As we all know Linux file system starts with `/`, the root directory. All other directories are 'children' of this directory. The partition which the root file system resides on is mounted first during boot and the system will not boot if it doesn't find it. On our reference system, the root directory contains the following sub-directories:

bin/ dev/ home/ lost+found/ proc/ sbin/ usr/ cdrom/ opt/ vmlinuz boot/ etc/ lib/ mnt/ root/ tmp/ var/ dvd/ floppy/ initrd/ /ftpboot

In days past it was also the home directory of 'root' but now he has been given his own directory for reasons that will be explained further on in this document.

1.3. /bin

Unlike `/sbin`, the `/bin` directory contains several useful commands that are of use to both the system administrator as well as non-privileged users. It usually contains the shells like `bash`, `csh`, etc.... and commonly used commands like `cp`, `mv`, `rm`, `cat`, `ls`. For this reason and in contrast to `/usr/bin`, the binaries in this directory are considered to be essential. The reason for this is that it contains essential system programs that must be available even if only the partition containing `/` is mounted. This situation may arise should you need to repair other partitions but have no access to shared directories (ie. you are in single user mode and hence have no network access). It also contains programs which boot scripts may depend on.

Compliance to the FSSTND means that there are no subdirectories in `/bin` and that the following commands, or symbolic links to commands, are located there.

<code>cat</code>	Utility to concatenate files to standard output
<code>chgrp</code>	Utility to change file group ownership

Linux Filesystem Hierarchy

chmod	Utility to change file access permissions
chown	Utility to change file owner and group
cp	Utility to copy files and directories
date	Utility to print or set the system date and time
dd	Utility to convert and copy a file
df	Utility to report filesystem disk space usage
dmesg	Utility to print or control the kernel message buffer
echo	Utility to display a line of text
false	Utility to do nothing, unsuccessfully
hostname	Utility to show or set the system's host name
kill	Utility to send signals to processes
ln	Utility to make links between files
login	Utility to begin a session on the system
ls	Utility to list directory contents
mkdir	Utility to make directories
mknod	Utility to make block or character special files
more	Utility to page through text
mount	Utility to mount a filesystem
mv	Utility to move/rename files
ps	Utility to report process status
pwd	Utility to print name of current working directory
rm	Utility to remove files or directories
rmdir	Utility to remove empty directories
sed	The 'sed' stream editor
sh	The Bourne command shell
stty	Utility to change and print terminal line settings
su	Utility to change user ID
sync	Utility to flush filesystem buffers
true	Utility to do nothing, successfully
umount	Utility to unmount file systems
uname	Utility to print system information

If /bin/sh is not a true Bourne shell, it must be a hard or symbolic link to the real shell command.

The rationale behind this is because sh and bash mightn't necessarily behave in the same manner. The use of a symbolic link also allows users to easily see that /bin/sh is not a true Bourne shell.

The [and test commands must be placed together in either /bin or /usr/bin.

The requirement for the [and test commands to be included as binaries (even if implemented internally by the shell) is shared with the POSIX.2 standard.

The following programs, or symbolic links to programs, must be in /bin if the corresponding subsystem is installed:

csh	The C shell (optional)
ed	The 'ed' editor (optional)
tar	The tar archiving utility (optional)
cpio	The cpio archiving utility (optional)
gzip	The GNU compression utility (optional)
gunzip	The GNU uncompression utility (optional)
zcat	The GNU uncompression utility (optional)
netstat	The network statistics utility (optional)
ping	The ICMP network test utility (optional)

If the gunzip and zcat programs exist, they must be symbolic or hard links to gzip. /bin/csh may be a symbolic link to /bin/tcsh or /usr/bin/tcsh.

The tar, gzip and cpio commands have been added to make restoration of a

Linux Filesystem Hierarchy

```
system possible (provided that / is intact).
```

Conversely, if no restoration from the root partition is ever expected, then these binaries might be omitted (e.g., a ROM chip root, mounting /usr through NFS). If restoration of a system is planned through the network, then ftp or tftp (along with everything necessary to get an ftp connection) must be available on the root partition.

1.4. /boot

This directory contains everything required for the boot process except for configuration files not needed at boot time (the most notable of those being those that belong to the GRUB boot-loader) and the map installer. Thus, the /boot directory stores data that is used before the kernel begins executing user-mode programs. This may include redundant (back-up) master boot records, sector/system map files, the kernel and other important boot files and data that is not directly edited by hand. Programs necessary to arrange for the boot loader to be able to boot a file are placed in /sbin. Configuration files for boot loaders are placed in /etc. The system kernel is located in either / or /boot (or as under Debian in /boot but is actually a symbolically linked at / in accordance with the FSSTND).

/boot/boot.0300

Backup master boot record.

/boot/boot.b

This is installed as the basic boot sector. In the case of most modern distributions it is actually a symbolic link to one of four files /boot/boot-bmp.b, /boot/boot-menu.b, /boot/boot-text.b, /boot/boot-compat.b which allow a user to change the boot-up schema so that it utilises a splash screen, a simple menu, a text based interface or a minimal boot loader to ensure compatibility respectively. In each case re-installation of lilo is necessary in order to complete the changes. To change the actual 'boot-logo' you can either use utilities such as fblogo or the more refined bootsplash.

/boot/chain.b

Used to boot non-Linux operating systems.

/boot/config-kernel-version

Installed kernel configuration. This file is most useful when compiling kernels on other systems or device modules. Below is a small sample of what the contents of the file looks like.

```
CONFIG_X86=y
CONFIG_MICROCODE=m
CONFIG_X86_MSR=m
CONFIG_MATH_EMULATION=y
CONFIG_MTRR=y
CONFIG_MODULES=y
CONFIG_MODVERSIONS=y
CONFIG_SCSI_DEBUG=m
CONFIG_I2O=m
CONFIG_ARCNET_ETH=y
CONFIG_FMV18X=m
CONFIG_HPLAN_PLUS=m
CONFIG_ETH16I=m
CONFIG_NE2000=m
CONFIG_HISAX_HFC_PCI=y
CONFIG_ISDN_DRV_AVMB1_C4=m
CONFIG_USB_RIO500=m
CONFIG_QUOTA=y
CONFIG_AUTOFS_FS=m
CONFIG_ADFS_FS=m
```

Linux Filesystem Hierarchy

```
CONFIG_AFFS_FS=m
CONFIG_HFS_FS=m
CONFIG_FAT_FS=y
CONFIG_MS DOS_FS=y
CONFIG_UMSDOS_FS=m
CONFIG_FBCON_VGA=m
CONFIG_FONT_8x8=y
CONFIG_FONT_8x16=y
CONFIG_SOUND=m
CONFIG_SOUND_CMPCI=m
CONFIG_AEDSP16=m
```

As you can see, it's rather simplistic. The line begins with the configuration option and whether it's configured as part of the kernel, as a module or not at all. Lines beginning with a # symbol are comments and are not interpreted during processing.

/boot/os2_d.b

Used to boot to the OS/2 operating system.

/boot/map

Contains the location of the kernel.

/boot/vmlinuz, /boot/vmlinuz-kernel-version

Normally the kernel or symbolic link to the kernel.

/boot/grub

This subdirectory contains the GRUB configuration files including boot-up images and sounds. GRUB is the GNU GRand Unified Bootloader, a project which intends to solve all bootup problems once and for all. One of the most interesting features, is that you don't have to install a new partition or kernel, you can change all parameters at boot time via the GRUB Console, since it knows about the filesystems.

/boot/grub/device.map

Maps devices in /dev to those used by grub. For example, (/dev/fd0) is represented by /dev/fd0 and (hd0, 4) is referenced by /dev/hda5.

/boot/grub/grub.conf, /boot/grub/menu.lst

Grub configuration file.

/boot/grub/messages

Grub boot-up welcome message.

/boot/grub/splash.xpm.gz

Grub boot-up background image.

1.5. /dev

/dev is the location of special or device files. It is a very interesting directory that highlights one important aspect of the Linux filesystem – everything is a file or a directory. Look through this directory and you should hopefully see hda1, hda2 etc.... which represent the various partitions on the first master drive of the system. /dev/cdrom and /dev/fd0 represent your CD-ROM drive and your floppy drive. This may seem strange but it will make sense if you compare the characteristics of files to that of your hardware. Both can be read from and written to. Take /dev/dsp, for instance. This file represents your speaker device. Any data written to this file will be re-directed to your speaker. If you try 'cat /boot/vmlinuz > /dev/dsp' (on a properly configured system) you should hear some sound on the speaker. That's the sound of your kernel! A file sent to /dev/lp0 gets printed. Sending data to and reading from /dev/ttys0 will allow you to communicate with a device attached there – for instance, your modem.

The majority of devices are either block or character devices; however other types of devices exist and can be created. In general, 'block devices' are devices that store or hold data, 'character devices' can be thought of as

Linux Filesystem Hierarchy

devices that transmit or transfer data. For example, diskette drives, hard drives and CD-ROM drives are all block devices while serial ports, mice and parallel printer ports are all character devices. There is a naming scheme of sorts but in the vast majority of cases these are completely illogical.

Some common device files as well as their equivalent counterparts under Windows that you may wish to remember are:

/dev/ttyS0 (First communications port, COM1)

First serial port (mice, modems).

/dev/psaux (PS/2)

Linux Filesystem Hierarchy

PS/2 mouse connection (mice, keyboards).

/dev/lp0 (First printer port, LPT1)

First parallel port (printers, scanners, etc).

/dev/dsp (First audio device)

The name DSP comes from the term digital signal processor, a specialized processor chip optimized for digital signal analysis. Sound cards may use a dedicated DSP chip, or may implement the functions with a number of discrete devices. Other terms that may be used for this device are digitized voice and PCM.

/dev/usb (USB Devices)

This subdirectory contains most of the USB device nodes. Device name allocations are fairly simplistic so no elaboration is necessary.

/dev/sda (C:\, SCSI device)

First SCSI device (HDD, Memory Sticks, external mass storage devices such as CD-ROM drives on laptops, etc).

/dev/scd (D:\, SCSI CD-ROM device)

First SCSI CD-ROM device.

/dev/js0 (Standard gameport joystick)

First joystick device.

Devices are defined by type, such as 'block' or 'character', and 'major' and 'minor' number. The major number is used to categorize a device and the minor number is used to identify a specific device type. For example, all IDE device connected to the primary controller have a major number of 3. Master and slave devices, as well as individual partitions are further defined by the use of minor numbers. These are the two numbers precede the date in the following display:

```
# ls -l /dev/hd*
```

brw-rw----	1	root	disk	3,	0 Mar 15 2002	/dev/hda

brw-rw----	1	root	disk	22,	64	Mar 15	2002	/dev/hdd

The major number for both hda and hdb devices is 3. Of course, the minor number changes for each specific partition. The definition of each major number category can be examined by looking at the contents of the /usr/src/linux/include/linux/major.h file. The devices.txt also documents major and minor numbers. It is located in the /usr/src/linux/Documentation directory. This file defines the major numbers. Almost all files devices are created by default at the install time. However, you can always create a device using the mknod command or the MAKEDEV script which is located in the /dev directory itself. Devices can be created with this utility by supplying the device to be created, the device type (block or character) and the major and minor numbers. For example, let's say you have accidentally deleted /dev/ttyS0 (COM1 under Windows), it can be recreated using the following command

```
# mknod ttyS0 c 4 64
```

For those of us who are rather lazy you can simply run the MAKEDEV script as such

```
# MAKEDEV *
```

which will create all devices known.

If is possible that /dev may also contain a MAKEDEV.local for the creation of any local device files.

In general and as required by the FSSTND, MAKEDEV will have provisions for creating any device that may be found on the system, not just those that a particular implementation installs.

For those of you who are wondering why Linux is using such a primitive system to reference devices its because we haven't been able to devise a sufficiently sophisticated mechanism which provides enough advantages over the current system in order to achieve widespread adoption.

To date (as of kernel version 2.4), the best attempt has been made by Richard Gooch of the CSIRO. It's called devfsd and has been a part of the kernel for a number of years now. It has been sanctioned by the kernel developers and Linus himself and details of its implementation can be found at /usr/src/linux/Documentation/filesystems/devfs/README. Below is an excerpt from this document.

Devfs is an alternative to "real" character and block special devices on your root filesystem. Kernel device drivers can register devices by name rather than major and minor numbers. These devices will appear in devfs automatically, with whatever default ownership and protection the driver specified. A daemon (devfsd) can be used to override these defaults. Devfs has been in the kernel since 2.3.46.

Linux Filesystem Hierarchy

NOTE that devfs is entirely optional. If you prefer the old disc-based device nodes, then simply leave CONFIG_DEVFS_FS=n (the default). In this case, nothing will change. ALSO NOTE that if you do enable devfs, the defaults are such that full compatibility is maintained with the old devices names.

There are two aspects to devfs: one is the underlying device namespace, which is a namespace just like any mounted filesystem. The other aspect is the filesystem code which provides a view of the device namespace. The reason I make a distinction is because devfs can be mounted many times, with each mount showing the same device namespace. Changes made are global to all mounted devfs filesystems. Also, because the devfs namespace exists without any devfs mounts, you can easily mount the root filesystem by referring to an entry in the devfs namespace.

The cost of devfs is a small increase in kernel code size and memory usage. About 7 pages of code (some of that in __init sections) and 72 bytes for each entry in the namespace. A modest system has only a couple of hundred device entries, so this costs a few more pages. Compare this with the suggestion to put /dev on a ramdisc.

On a typical machine, the cost is under 0.2 percent. On a modest system with 64 MBytes of RAM, the cost is under 0.1 percent. The accusations of "bloatware" levelled at devfs are not justified.

As of kernel version 2.6, devfs has been marked obsolete and has now been replaced by udev. A system very similar (at least from the end user's point of view) to devfs but which works entirely in userspace. An overview of udev can be found at

http://www.kroah.com/linux/talks/ols_2003_udev_paper/Reprint-Kroah-Hartman-OLS2003.pdf

1.6. /etc

This is the nerve center of your system, it contains all system related configuration files in here or in its sub-directories. A "configuration file" is defined as a local file used to control the operation of a program; it must be static and cannot be an executable binary. For this reason, it's a good idea to backup this directory regularly. It will definitely save you a lot of re-configuration later if you re-install or lose your current installation. Normally, no binaries should be or are located here.

/etc/X11/

This directory tree contains all the configuration files for the X Window System. Users should note that many of the files located in this directory are actually symbolic links to the /usr/X11R6 directory tree. Thus, the presence of these files in these locations can not be certain.

/etc/X11/XF86Config, /etc/X11/XF86Config-4

The 'X' configuration file. Most modern distributions possess hardware autodetection systems that enable automatic creation of a valid file. Should autodetection fail a configuration file can also be created manually provided that you have sufficient knowledge about your system. It would be considered prudent not to attempt to type out a file from beginning to end. Rather, use common configuration utilities such as xf86config, XF86Setup and xf86cfg to create a workable template. Then, using suitable documentation commence optimization through intuition and/or trial and error. Options that can be configured via this file include X modules to be loaded on startup, keyboard, mouse, monitor and graphic chipset type. Often, commercial distributions will include their own X configuration utilities such as XDrake on Mandrake and also Xconfiguration on Redhat. Below is a sample X configuration file from the reference system

```
### BEGIN DEBCONF SECTION
# XF86Config-4 (XFree86 server configuration file) generated by dexconf, the
```

Linux Filesystem Hierarchy

```
# Debian X Configuration tool, using values from the debconf database.
#
# Edit this file with caution, and see the XF86Config-4 manual page.
# (Type "man XF86Config-4" at the shell prompt.)
#
# If you want your changes to this file preserved by dexconf, only
# make changes
# before the "### BEGIN DEBCONF SECTION" line above, and/or after the
# "### END DEBCONF SECTION" line below.
#
# To change things within the debconf section, run the command:
#   dpkg-reconfigure xserver-xfree86
# as root. Also see "How do I add custom sections to a dexconf-
# generated
# XF86Config or XF86Config-4 file?" in /usr/share/doc/xfree86-
# common/FAQ.gz.

```

As you can see, the layout of the file is quite simple and tends to be quite standard across most distributions. At the top are the locations of the various font files for X (note – X will not start if you do not specify a valid font), next is the "Modules" section. It details what modules are to be loaded upon startup. The most well known extensions are probably GLX (required for 3D rendering of graphics and games) and Xinerama which allows users to expand their desktop over several monitors. Next are the various "Device" sections which describe the type of hardware you have. Improper configuration of these subsections can lead to heartache and trauma with seemingly misplaced keys, bewitched mice and also constant flashing as X attempts to restart in a sometimes never ending loop. In most cases when all else fails the vesa driver seems to be able to initialise most modern video cards. In the "Screen" section it is possible to alter the default startup resolution and depth. Quite often it is possible to alter these attributes on the fly by using the alt–ctrl–+ or alt–ctrl– set of keystrokes. Lastly are the "ServerLayout" and "DRI" sections. Users will almost never touch the "DRI" section and only those who wish to utilise the Xinerama extensions of X will require having to change any of the ServerLayout options.

/etc/X11/Xmodmap

In general your default keyboard mapping comes from your X server setup. If this setup is insufficient and you are unwilling to go through the process of reconfiguration and/or you are not the superuser you'll need to use the xmodmap program. This is the utility's global configuration file.

/etc/X11/xkb/

The various symbols, types, geometries of keymaps that the X server supports can be found in this directory tree.

/etc/X11/lbxproxy/

Low Bandwidth X (LBX) proxy server configuration files. Applications that would like to take advantage of the Low Bandwidth extension to X (LBX) must make their connections to an lbxproxy. These applications need know nothing about LBX, they simply connect to the lbxproxy as if it were a regular X server. The lbxproxy accepts client connections, multiplexes them over a single connection to the X server, and performs various optimizations on the X protocol to make it faster over low bandwidth and/or high latency connections. It should be noted that such compression will not increase the pace of rendering all that much. Its primary purpose is to reduce network load and thus increase overall network latency. A competing project called DXPC (Differential X Protocol Compression) has been found to be more efficient at this task. Studies have shown though that in almost all cases ssh tunneling of X will produce far better results than through any of these specialised pieces of software.

/etc/X11/proxymngr/

X proxy services manager initialisation files. proxymngr is responsible for resolving requests from xfindproxy (in the xbase-clients package) and other similar clients, starting new proxies when appropriate, and keeping track of all the available proxy services.

/etc/X11/xdm/

X display manager configuration files. xdm manages a collection of X servers, which may be on the local host or remote machines. It provides services similar to those provided by init, getty, and login on character-based terminals: prompting for login name and password, authenticating the user, and

Linux Filesystem Hierarchy

running a session. xdm supports XDMCP (X Display Manager Control Protocol) and can also be used to run a chooser process which presents the user with a menu of possible hosts that offer XDMCP display management. If the xutils package is installed, xdm can use the sessreg utility to register login sessions to the system utmp file; this, however, is not necessary for xdm to function.

/etc/X11/xdm/xdm--config

This is the master 'xdm' configuration file. It determines where all other 'xdm' configuration files will be located. It is almost certain to be left undisturbed.

/etc/X11/gdm/

GNOME Display Manager configuration files. gdm provides the equivalent of a "login:" prompt for X displays– it pops up a login window and starts an X session. It provides all the functionality of xdm, including XDMCP support for managing remote displays. The greeting window is written using the GNOME libraries and hence looks like a GNOME application– even to the extent of supporting themes! By default, the greeter is run as an unprivileged user for security.

/etc/X11/gdm/gdm.conf

This is the primary configuration file for GDM. Through it, users can specify whether they would like their system to automatically login as a certain user, background startup image and also if they would like to run their machine as somewhat of a terminal server by using the XDMCP protocol.

/etc/X11/fonts

Home of xfs fonts.

/etc/X11/fs/

X font server configuration files. xfs is a daemon that listens on a network port and serves X fonts to X servers (and thus to X clients). All X servers have the ability to serve locally installed fonts for themselves, but xfs makes it possible to offload that job from the X server, and/or have a central repository of fonts on a networked machine running xfs so that all the machines running X servers on a network do not require their own set of fonts. xfs may also be invoked by users to, for instance, make available X fonts in user accounts that are not available to the X server or to an already running system xfs.

/etc/X11/fs/config

This is the 'xfs' initialisation file. It specifies the number of clients that are allowed to connect to the 'xfs' server at any one time, the location of log files, default resolution, the location of the fonts, etc.

```
# font server configuration file
# $Xorg: config.cpp,v 1.3 2000/08/17 19:54:19 cpqbld Exp $

# allow a maximum of 10 clients to connect to this font server
client-limit = 10
# when a font server reaches its limit, start up a new one
clone-self = on
# log messages to /var/log/xfs.log (if syslog is not used)
error-file = /var/log/xfs.log
# log errors using syslog
use-syslog = on
# turn off TCP port listening (Unix domain connections are still permitted)
no-listen = tcp
# paths to search for fonts
catalogue = /usr/lib/X11/fonts/misc/,/usr/lib/X11/fonts/cyrillic/,
/usr/lib/X11/fonts/100dpi/:unscaled,/usr/lib/X11/fonts/75dpi/:unscaled,
/usr/lib/X11/fonts/Type1/,/usr/lib/X11/fonts/CID,
/usr/lib/X11/fonts/Speedo/,/usr/lib/X11/fonts/100dpi/,
/usr/lib/X11/fonts/75dpi/
# in decipoints
default-point-size = 120
# x1,y1,x2,y2,...
default-resolutions = 100,100,75,75
```

Linux Filesystem Hierarchy

```
# font cache control, specified in kB
cache-hi-mark = 2048
cache-low-mark = 1433
cache-balance = 70
```

/etc/X11/twm

Home of configuration files for twm. The original Tabbed Window Manager.

/etc/X11/xinit/

xinit configuration files. 'xinit' is a configuration method of starting up an X session that is designed to be used as part of a script. Normally, this is used at larger sites as part of a tailored login process.

/etc/X11/xinit/xinitrc

Global xinitrc file, used by all X sessions started by xinit (startx). Its usage is of course overridden by a .xinitrc file located in the home directory of a user.

/etc/adduser.conf

'adduser' configuration. The adduser command can create new users, groups and add existing users to existing groups. Adding users with adduser is much easier than adding them by hand. Adduser will choose appropriate UID and GID values, create a home directory, copy skeletal user configuration from /etc/skel, allow you to set an initial password and the GECOS field. Optionally a custom script can be executed after this command. See adduser(8) and adduser.conf(5) for full documentation.

/etc/adjtime

Has parameters to help adjust the software (kernel) time so that it matches the RTC.

/etc/aliases

This is the aliases file – it says who gets mail for whom. It was originally generated by `eximconfig', part of the exim package distributed with Debian, but it may be edited by the mail system administrator. See exim info section for details of the things that can be configured here. An aliases database file (aliases.db) is built from the entries in the aliases files by the newaliases utility.

/etc/alternatives

It is possible for several programs fulfilling the same or similar functions to be installed on a single system at the same time. For example, many systems have several text editors installed at once. This gives choice to the users of a system, allowing each to use a different editor, if desired, but makes it difficult for a program to make a good choice of editor to invoke if the user has not specified a particular preference.

The alternatives system aims to solve this problem. A generic name in the filesystem is shared by all files providing interchangeable functionality. The alternatives system and the system administrator together determine which actual file is referenced by this generic name. For example, if the text editors ed(1) and nvi(1) are both installed on the system, the alternatives system will cause the generic name /usr/bin/editor to refer to /usr/bin/nvi by default. The system administrator can override this and cause it to refer to /usr/bin/ed instead, and the alternatives system will not alter this setting until explicitly requested to do so.

The generic name is not a direct symbolic link to the selected alternative. Instead, it is a symbolic link to a name in the alternatives directory, which in turn is a symbolic link to the actual file referenced.

This is done so that the system administrator's changes can be confined within the /etc directory.

/etc/apt

This is Debian's next generation front-end for the dpkg package manager. It provides the apt-get utility and APT dselect method that provides a simpler, safer way to install and upgrade packages. APT features complete installation ordering, multiple source capability and several other unique features, see the Users Guide in /usr/share/doc/apt/guide.text.gz

/etc/apt/sources.list

```
deb cdrom:[Debian GNU/Linux 3.0 r0 _Woody_ - Official i386 Binary-7 (20020718)]/
      unstable contrib main non-US/contrib non-US/main
```

Linux Filesystem Hierarchy

      unstable contrib main non-US/contrib non-US/main  
  
# deb http://security.debian.org/ stable/updates main
```

Contains a list of apt-sources from which packages may be installed via APT.

/etc/asound.conf

ALSA (Advanced Linux Sound Architecture) configuration file. It is normally created via alsactl or other third-party sound configuration utilities that may be specific to a distribution such as sndconfig from Redhat.

/etc/at.deny

Users denied access to the at daemon. The 'at' command allows user to execute programs at an arbitrary time.

/etc/autoconf

Configuration files for autoconf. 'autoconf' creates scripts to configure source code packages using templates. To create configure from configure.in, run the autoconf program with no arguments. autoconf processes configure.ac with the m4 macro processor, using the Autoconf macros. If you give autoconf an argument, it reads that file instead of configure.ac and writes the configuration script to the standard output instead of to configure. If you give autoconf the argument -, it reads the standard input instead of configure.ac and writes the configuration script on the standard output.

The Autoconf macros are defined in several files. Some of the files are distributed with Autoconf; autoconf reads them first. Then it looks for the optional file acsite.m4 in the directory that contains the distributed Autoconf macro files, and for the optional file aclocal.m4 in the current directory. Those files can contain your site's or the package's own Autoconf macro definitions. If a macro is defined in more than one of the files that autoconf reads, the last definition it reads overrides the earlier ones.

/etc/bash.bashrc

System wide functions and aliases' file for interactive bash shells.

/etc/bash_completion

Programmable completion functions for bash 2.05a.

/etc/chatscripts/provider

This is the chat script used to dial out to your default service provider.

/etc/cron.d, /etc/cron.daily, /etc/cron.weekly, /etc/cron.monthly

These directories contain scripts to be executed on a regular basis by the cron daemon.

/etc/crontab

'cron' configuration file. This file is for the cron table to setup the automatic running of system routines. A cron table can also be established for individual users. The location of these user cron table files will be explained later on.

```
# /etc/crontab: system-wide crontab  
# Unlike any other crontab you don't have to run the `crontab'  
# command to install the new version when you edit this file.  
# This file also has a username field, that none of the other crontabs do.  
  
SHELL=/bin/sh
```

Linux Filesystem Hierarchy

```
PATH=/usr/local/sbin:/usr/local/bin:/sbin:/bin:/usr/sbin:/usr/bin

# m h dom mon dow user  command
25 6 * * * root test -e /usr/sbin/anacron || run-parts --report /etc/cron.daily
47 6 * * 7 root test -e /usr/sbin/anacron || run-parts --report /etc/cron.weekly
52 6 1 * * root test -e /usr/sbin/anacron || run-parts --report /etc/cron.monthly
#
```

/etc/csh.login

System-wide .login file for csh(1). This file is sourced on all invocations of the shell. It contains commands that are to be executed upon login and sometimes aliases also.

/etc/csh.logout

System-wide .logout file for csh(1). This file is sourced on all invocations of the shell. It contains commands that are to be executed upon logout.

/etc/csh.cshrc

System-wide .cshrc file for csh(1). This file is sourced on all invocations of the shell. This file should contain commands to set the command search path, plus other important environment variables. This file should not contain commands that produce output or assume the shell is attached to a tty.

/etc/cups

Configuration files for the Common UNIX Printing System (CUPS). Files here are used to define client-specific parameters, such as the default server or default encryption settings.

/etc/deluser.conf

'deluser' configuration files. The deluser command can remove users and groups and remove users from a given group. Deluser can optionally remove and backup the user's home directory and mail spool or all files on the system owned by him. Optionally a custom script can also be executed after each of the commands.

/etc/devfs

This daemon sets up the /dev filesystem for use. It creates required symbolic links in /dev and also creates (if so configured, as is the default) symbolic links to the "old" names for devices.

/etc/devfs/conf.d/

'devfsd' configuration files. This daemon sets up the /dev filesystem for use. It creates required symbolic links in /dev and also creates (if so configured, as is the default) symbolic links to the "old" names for devices.

/etc/dhclient.conf, /etc/dhclient-script

'dhclient' configuration file and 'dhclient' script files respectively. It configures your system so that it may act as a client on a DHCP based network. It is essential to connect to the Internet nowadays.

/etc/dict.conf

```
#  /etc/dict.conf Written by Bob Hilliard <hilliard@debian.org>
#  1998/03/20.  Last revised Sun, 22 Nov 1998 18:10:04 -0500 This is
#  the configuration file for /usr/bin/dict.  In most cases only the
#  server keyword need be specified.

#  This default configuration will try to access a dictd server on
#  the local host, failing that, it will try the public server.  In
#  many cases this will be slow, so you should comment out the line
#  for the server that you don't want to use. To use any other
#  server, enter its IP address in place of "dict.org".

#  Refer to the dict manpage (man dict) for other options that could
#  be inserted in here.

server localhost
server dict.org
```

dict is a client for the Dictionary Server Protocol (DICT), a TCP transaction based query/response

Linux Filesystem Hierarchy

protocol that provides access to dictionary definitions from a set of natural language dictionary databases.

/etc/dosemu.conf

Configuration file for the Linux DOS Emulator. DOSEMU is a PC Emulator application that allows Linux to run a DOS operating system in a virtual x86 machine. This allows you to run many DOS applications. It includes the FreeDOS kernel, color text and full keyboard emulation (via hotkeys) via terminal, built-in X support, IBM character set font, graphics capability at the console with most compatible video cards, DPMI support so you can run DOOM, CDROM support, builtin IPX and pktdrvr support. Note – 'dosemu' is simply a ported version of Corel's own PC-DOS.

/etc/email-addresses

Part of the exim package. This file contains email addresses to use for outgoing mail. Any local part not in here will be qualified by the system domain as normal. It should contain lines of the form:

```
user: someone@isp.com
otheruser: someoneelse@anotherisp.com
```

Exim is an MTA that is considered to be rather easier to configure than smail or sendmail. It is a drop-in replacement for sendmail, mailq and rsmtip. Advanced features include the ability to reject connections from known spam sites, and an extremely efficient queue processing algorithm.

/etc/esound.conf

ESD configuration files. The Enlightened sound daemon is designed to mix together several digitized audio streams for playback by a single device. Like nasd, artsd and rplay it also has the capability to play sounds remotely.

/etc/exports

The control list of systems who want to access the system via NFS, a the list of directories that you would like to share and the permissions allocated on each share.

```
# /etc/exports: the access control list for filesystems which may be
# exported to NFS clients. See exports(5).
## LTS-begin ##

#
# The lines between the 'LTS-begin' and the 'LTS-end' were added
# on: Sun Feb 23 05:54:17 EST 2003 by the ltsp installation script.
# For more information, visit the ltsp homepage
# at http://www.ltsp.org
#

/opt/ltsp/i386           192.168.0.0/255.255.255.0(ro,no_root_squash)

# Local App support in ltsp
#
#/home                   192.168.0.0/255.255.255.0(rw,no_root_squash)

## LTS-end ##
```

/etc/fdprm

Floppy disk parameter table. Describes what different floppy disk formats look like. Used by setfdprm.

/etc/fstab

The configuration file for 'mount' and now 'supermount'. It lists the filesystems mounted automatically at startup by the mount -a command (in /etc/rc or equivalent startup file). Under Linux, also contains information about swap areas used automatically by swapon -a.

Linux Filesystem Hierarchy

```
# /etc/fstab: static file system information.
#
# The following is an example. Please see fstab(5) for further details.
# Please refer to mount(1) for a complete description of mount options.
#
# Format:
# <file system> <mount point> <type> <options> <dump> <pass>
#
# dump(8) uses the <dump> field to determine which file systems need
# to be dumped. fsck(8) uses the <pass> column to determine which file
# systems need to be checked--the root file system should have a 1 in
# this field, other file systems a 2, and any file systems that should
# not be checked (such as MS-DOS or NFS file systems) a 0.
#
# The `sw' option indicates that the swap partition is to be activated
# with `swapon -a'.
/dev/hda2 none swap sw 0 0
# The `bsdgroups' option indicates that the file system is to be mounted
# with BSD semantics (files inherit the group ownership of the directory
# in which they live). `ro' can be used to mount a file system read-only.
/dev/hda3 / ext2 defaults 0 1
/dev/hda5 /home ext2 defaults 0 2
/dev/hda6 /var ext2 defaults 0 2
/dev/hda7 /usr ext2 defaults,ro 0 2
/dev/hda8 /usr/local ext2 defaults,bsdgroups 0 2
# The `noauto' option indicates that the file system should not be mounted
# with `mount -a'. `user' indicates that normal users are allowed to mount
# the file system.
/dev/cdrom /cdrom iso9660 defaults,noauto,ro,user 0 0
/dev/fd0 /floppy minix defaults,noauto,user 0 0
/dev/fd1 /floppy minix defaults,noauto,user 0 0
# NFS file systems: server:
/export/usr /usr nfs defaults 0 0
# proc file system:
proc /proc proc defaults 0 0
```

/etc/ftpaccess

Determines who might get ftp-access to your machine.

/etc/ftpchroot

List of ftp users that need to be chrooted.

/etc/ftpuser

List of disallowed ftp users.

/etc/gateways

Lists gateways for 'routed'.

/etc/gettydefs

Configures console-logins.

/etc/gnome-vfs-mime-magic

MIME magic patterns as used by the Gnome VFS library.

/etc/group

Similar to /etc/passwd. It lists the configured user groups and who belongs to them.

/etc/group-

Old /etc/group file.

/etc/gshadow

Contains encrypted forms of group passwords.

/etc/gshadow-

Old /etc/gshadow file.

/etc/hostname

Linux Filesystem Hierarchy

Contains the hostname of your machine (can be fully qualified or not).

/etc/host.conf

Determines the search order for look-ups (usually hosts bind, i.e. "check /etc/hosts first and then look for a DNS").

/etc/hosts

This file is used to define a system name and domain combination with a specific IP address. This file needs to always contain an entry for an IP address, if the machine is connected to the network.

```
## etherconf DEBCONF AREA. DO NOT EDIT THIS AREA OR INSERT TEXT BEFORE IT.
127.0.0.1 localhost ::1 localhost
ip6-localhost ip6-loopback
fe00::0 ip6-localnet
ff00::0 ip6-mcastprefix
ff02::1 ip6-allnodes
ff02::2 ip6-allrouters
ff02::3 ip6-allhosts
192.168.0.99 debian.localdomain.com debian
## END OF DEBCONF AREA. PLACE YOUR EDITS BELOW; THEY WILL BE PRESERVED.
192.168.0.1 ws001
```

/etc/hosts.allow

Part of the tcp-wrappers system to control access to your machine's services. It lists hosts that are allowed to access the system and specific daemons.

```
# /etc/hosts.allow: list of hosts that are allowed to access the
# system.
# See the manual pages hosts_access(5), hosts_options(5)
# and /usr/doc/netbase/portmapper.txt.gz
#
# Example: ALL: LOCAL @some_netgroup
# ALL: .foobar.edu EXCEPT terminalserver.foobar.edu
#
# If you're going to protect the portmapper use the name "portmap"
# for the daemon name. Remember that you can only use the keyword
# "ALL" and IP addresses (NOT host or domain names) for the
# portmapper. See portmap(8) and /usr/doc/portmap/portmapper.txt.gz
# for further information.
bootpd: 0.0.0.0 in.tftpd: 192.168.0.
portmap: 192.168.0.
rpc.mountd: 192.168.0.
rpc.nfsd: 192.168.0.
gdm: 192.168.0.
nasd: 192.168.0.
```

/etc/hosts.deny

part of the tcp-wrappers system to control access to your machine's services. It lists hosts that are not allowed to access the system.

```
# Example: ALL: some.host.name, .some.domain
# ALL EXCEPT in.fingerd: other.host.name, .other.domain
#
# If you're going to protect the portmapper use the name "portmap"
# for the daemon name. Remember that you can only use the keyword
# "ALL" and IP addresses (NOT host or domain names) for the
# portmapper. See portmap(8) and /usr/doc/portmap/portmapper.txt.gz
# for further information.
#
# The PARANOID wildcard matches any host whose name does not match
```

Linux Filesystem Hierarchy

```
# its address. You may wish to enable this to ensure any programs
# that don't validate looked up hostnames still leave understandable
# logs. In past versions of Debian this has been the default.
# ALL: PARANOID
```

/etc/httpd

Apache configuration files. Apache is a versatile, high-performance HTTP server. The most popular server in the world, Apache features a modular design and supports dynamic selection of extension modules at runtime. Its strong points are its range of possible customization, dynamic adjustment of the number of server processes, and a whole range of available modules including many authentication mechanisms, server-parsed HTML, server-side includes, access control, CERN httpd metafiles emulation, proxy caching, etc. Apache also supports multiple virtual homing.

/etc/identd.conf

TCP/IP IDENT protocol server. It implements the TCP/IP proposed standard IDENT user identification protocol (RFC 1413). identd operates by looking up specific TCP/IP connections and returning the username of the process owning the connection. It can also return other information besides the username.

```
# /etc/identd.conf - an example configuration file

#-- The syslog facility for error messages
# syslog:facility = daemon

#-- User and group (from passwd database) to run as
server:user = nobody

#-- Override the group id
# server:group = kmem

#-- What port to listen on when started as a daemon or from /etc/inittab
# server:port = 113

#-- The socket backlog limit
# server:backlog = 256

#-- Where to write the file containing our process id
# server:pid-file = "/var/run/identd/identd.pid"

#-- Maximum number of concurrent requests allowed (0 = unlimited)
# server:max-requests = 0

#-- Enable some protocol extensions like "VERSION" or "QUIT"
protocol:extensions = enabled

#-- Allow multiple queries per connection
protocol:multiquery = enabled

#-- Timeout in seconds since connection or last query. Zero = disable
# protocol:timeout = 120

#-- Maximum number of threads doing kernel lookups
# kernel:threads = 8

#-- Maximum number of queued kernel lookup requests
# kernel:buffers = 32

#-- Maximum number of time to retry a kernel lookup in case of failure
```

Linux Filesystem Hierarchy

```
# kernel:attempts = 5

--- Disable username lookups (only return uid numbers)
# result:uid-only = no

--- Enable the ".noident" file
# result:noident = enabled

--- Charset token to return in replies
# result:charset = "US-ASCII"

--- Opsys token to return in replies
# result:opsys = "UNIX"

--- Log all request replies to syslog (none == don't)
# result:syslog-level = none

--- Enable encryption (only available if linked with a DES library)
# result:encrypt = no

--- Path to the DES key file (only available if linked with a DES library)
# encrypt:key-file = "/usr/local/etc/identd.key"

--- Include a machine local configuration file
# include = /etc/identd.conf
```

/etc/inetd.conf

Configuration of services that are started by the INETD TCP/IP super server. 'inetd' is now deprecated. 'xinetd' has taken its place. See [/etc/xinetd.conf](#) for further details.

```
# /etc/inetd.conf: see inetd(8) for further information.
#
# Internet server configuration database
#
#
# Lines starting with "#:LABEL:" or "#<off>#" should not
# be changed unless you know what you are doing!
#
# If you want to disable an entry so it isn't touched during
# package updates just comment it out with a single '#' character.
#
# Packages should modify this file by using update-inetd(8)
#
# <service_name> <sock_type> <proto>
# <flags> <user> <server_path>
# <args>
#

```

/etc/init.d

```
Order of scripts run in /etc/rc?.d
=====
=====
```

0. Overview.

All scripts executed by the init system are located in /etc/init.d. The directories /etc/rc?.d (? = S, 0 .. 6) contain relative links to those scripts. These links are named S<2-digit-number><original-name> or K<2-digit-number><original-name>.

If a script has the ".sh" suffix it is a bourne shell script and MAY be handled in an optimized manner. The behaviour of executing the script in an optimized way will not differ in any way from it being forked and executed in the regular way.

The following runlevels are defined:

N	System bootup (NONE).
S	Single user mode (not to be switched to directly)
0	halt
1	single user mode
2 .. 5	multi user mode
6	reboot

1. Boot.

When the system boots, the /etc/init.d/rcS script is executed. It in turn executes all the S* scripts in /etc/rcS.d in alphabetical (and thus numerical) order. The first argument passed to the executed scripts is "start". The runlevel at this point is "N" (none).

Only things that need to be run once to get the system in a consistent state are to be run. The rcS.d directory is NOT meant to replace rc.local. One should not start daemons in this runlevel unless absolutely necessary. Eg, NFS might need the portmapper, so it is OK to start it early in the boot process. But this is not the time to start the

Linux Filesystem Hierarchy

squid proxy server.

2. Going multiuser.

After the rcS.d scripts have been executed, init switches to the default runlevel as specified in /etc/inittab, usually "2".

Init then executes the /etc/init.d/rc script which takes care of starting the services in /etc/rc2.d.

Because the previous runlevel is "N" (none) the /etc/rc2.d/KXXXXXX scripts will NOT be executed - there is nothing to stop yet, the system is busy coming up.

If for example there is a service that wants to run in runlevel 4 and ONLY in that level, it will place a KXXXXXX script in /etc/rc{2,3,5}.d to stop the service when switching out of runlevel 4. We do not need to run that script at this point.

The /etc.rc2.d/SXXXXXXX scripts will be executed in alphabetical order, with the first argument set to "start".

3. Switching runlevels.

When one switches from (for example) runlevel 2 to runlevel 3, /etc/init.d/rc will first execute in alphabetical order all K scripts for runlevel 3 (/etc/rc3.d/KXXXXXX) with as first argument "stop" and then all S scripts for runlevel 3 (/etc/rc3.d/SXXXXXXX) with as first argument "start".

As an optimization, a check is made for each "service" to see if it was already running in the previous runlevel. If it was, and there is no K (stop) script present for it in the new runlevel, there is no need to start it a second time so that will not be done.

On the other hand, if there was a K script present, it is assumed the service was stopped on purpose first and so needs to be restarted.

We MIGHT make the same optimization for stop scripts as well - if no S script was present in the previous runlevel, we can assume that service was not running and we don't need to stop it either. In that case we can remove the "coming from level N" special case mentioned above in 2). But right now that has not been implemented.

4. Single user mode.

Switching to single user mode is done by switching to runlevel 1. That will cause all services to be stopped (assuming they all have a K script in /etc/rc1.d). The runlevel 1 scripts will then switch to runlevel "S" which has no scripts - all it does is spawn a shell directly on /dev/console for maintenance.

5. Halt/reboot

Going to runlevel 0 or 6 will cause the system to be halted or rebooted, respectively. For example, if we go to runlevel 6 (reboot) first all /etc/rc6.d/KXXXXXX scripts will be executed alphabetically with "stop" as the first argument.

Then the /etc/rc6.d/SXXXXXXX scripts will be executed alphabetically with "stop" as the first argument as well. The reason is that there is nothing to start any more at this point - all scripts that are

Linux Filesystem Hierarchy

run are meant to bring the system down.

In the future, the /etc/rc6.d/SXXXXXX scripts MIGHT be moved to /etc/rc6.d/K1XXXXXX for clarity.

/etc/inittab

Boot-time system configuration/initialization script. Tells init how to handle runlevels. It sets the default runlevel. This is run first except when booting in emergency (-b) mode. It also enables a user to startup a getty session on an external device such as the serial ports. To add terminals or dial-in modem lines to a system, just add more lines to /etc/inittab, one for each terminal or dial-in line. For more details, see the manual pages init, inittab, and getty. If a command fails when it starts, and init is configured to restart it, it will use a lot of system resources: init starts it, it fails, init starts it, it fails, and so on. To prevent this, init will keep track of how often it restarts a command, and if the frequency grows to high, it will delay for five minutes before restarting again. /etc/inittab also has some special features that allow init to react to special circumstances. powerwait Allows init to shut the system down, when the power fails. This assumes the use of a UPS, and software that watches the UPS and informs init that the power is off. ctrlaltdel Allows init to reboot the system, when the user presses ctrl-alt-del on the console keyboard. Note that the system administrator can configure the reaction to ctrl-alt-del to be something else instead, e.g., to be ignored, if the system is in a public location. sysinit Command to be run when the system is booted. This command usually cleans up /tmp, for example. The list above is not exhaustive. See your inittab manual page for all possibilities, and for details on how to use the ones above. To set (or reset) initial terminal colours. The following shell script should work for VGA consoles: for n in 1 2 4 5 6 7 8; do setterm -fore yellow -bold on -back blue -store > /dev/tty\$ done Substitute your favorite colors, and use /dev/ttyn for serial terminals. To make sure they are reset when people log out (if they've been changed) replace the references to getty (or mingetty or uugetty or whatever) in /etc/inittab with references to /sbin/mygetty. #!/bin/sh setterm -fore yellow -bold on -back blue -store > \$1 exec /sbin/mingetty \$@ An example /etc/inittab is provided below.

```
# /etc/inittab: init(8) configuration.
# $Id: etc.xml,v 1.10 2004/02/03 21:42:57 binh Exp $

# Example how to put a getty on a modem line.
#
#T3:23:respawn:/sbin/mgetty -x0 -s 57600 ttyS3
```

Undocumented features

The letters A-C can be used to spawn a daemon listed in /etc/inittab. For example, assuming you want to start getty on a port to receive a call, but only after receiving a voice call first (and not all the time). Furthermore, you want to be able to receive a data or a fax call and that when you get the voice message you'll know which you want. You insert two new lines in /etc/inittab, each with its own ID, and each with a runlevel such as A for data and B for fax. When you know which you need, you simply spawn the appropriate daemon by calling 'telinit A' or 'telinit B'.

The appropriate getty is put on the line until the first call is received. When the caller terminates the connection, the getty drops because, by definition, on demand will not respawn. The other two letters, S and Q, are special. S brings your system to maintenance mode and is the same as changing state to runlevel 1. The Q is used to tell init to reread inittab. The /etc/inittab file can be changed as often as required, but will only be read under certain circumstances: -One of its processes dies (do you need to respawn another?) -On a powerful signal from a power daemon (or a command line) -When told to change state by telinit The Q argument tells init to reread the /etc/inittab file. Even though it is called the System V runlevel system runlevels 7-9 are legitimate runlevels that can be used if necessary. The administrator must remember to alter the inittab file though and also to create the required rc?.d files.

/etc/inputrc

Global inputrc for libreadline. Readline is a function that gets a line from a user and automatically edits it.

/etc/isapnp.conf

Configuration file for ISA based cards. This standard is virtually redundant in new systems. The 'isapnptools' suite of ISA Plug-And-Play configuration utilities is used to configure such devices. These programs are suitable for all systems, whether or not they include a PnP BIOS. In fact, PnP BIOS adds some complications because it may already activate some cards so that the drivers can find them, and these tools can unconfigure them, or change their settings causing all sorts of nasty effects.

/etc/isdn

ISDN configuration files.

/etc/issue

Linux Filesystem Hierarchy

Output by getty before the login prompt. Usually contains a short description or welcoming message to the system. The contents are up to the system administrator. Debian GNU\ls 3.0 \n \l

/etc/issue.net

Presents the welcome screen to users who login remotely to your machine (whereas /etc/issue determines what a local user sees on login). Debian GNU/\%s 3.0 \%h

/etc/kde

KDE initialization scripts and KDM configuration.

/etc/kde/kdm

Location for the K Desktop Manager files. kdm manages a collection of X servers, which may be on the local host or remote machines. It provides services similar to those provided by init, getty, and login on character-based terminals: prompting for login name and password, authenticating the user, and running a session. kdm supports XDMCP (X Display Manager Control Protocol) and can also be used to run a chooser process which presents the user with a menu of possible hosts that offer XDMCP display management.

/etc/kderc

System wide KDE initialization script. Commands here executed every time the KDE environment is loaded. It's a link to /etc/kde2/system.kdeglobals

```
[Directories]
dir_config=/etc/kde2
dir_html=/usr/share/doc/kde/HTML
dir_cgi=/usr/lib/cgi-bin
dir_apps=/usr/share/applnk
dir_mime=/usr/share/mimelnk
dir_services=/usr/share/services
dir_servicetypes=/usr/share/servicetypes
[General]
TerminalApplication=x-terminal-emulator
```

/etc/ld.so.conf, /etc/ld.so.cache

/etc/ld.so.conf is a file containing a list of colon, space, tab, newline, or comma separated directories in which to search for libraries. /etc/ld.so.cache containing an ordered list of libraries found in the directories specified in /etc/ld.so.conf. This file is not in human readable format, and is not intended to be edited.

'ldconfig' creates the necessary links and cache (for use by the run-time linker, ld.so) to the most recent shared libraries found in the directories specified on the command line, in the file /etc/ld.so.conf, and in the trusted directories (/usr/lib and /lib). 'ldconfig' checks the header and file names of the libraries it encounters when determining which versions should have their links updated. ldconfig ignores symbolic links when scanning for libraries.

'ldconfig' will attempt to deduce the type of ELF libs (ie. libc5 or libc6/glibc) based on what C libs if any the library was linked against, therefore when making dynamic libraries, it is wise to explicitly link against libc (use -lc).

Some existing libs do not contain enough information to allow the deduction of their type, therefore the /etc/ld.so.conf file format allows the specification of an expected type. This is only used for those ELF libs which we can not work out. The format is like this "dirname=TYPE", where type can be libc4, libc5 or libc6. (This syntax also works on the command line). Spaces are not allowed. Also see the -p option.

Directory names containing an = are no longer legal unless they also have an expected type specifier.

'ldconfig' should normally be run by the super-user as it may require write permission on some root owned directories and files. It is normally run automatically at bootup or manually whenever new shared libraries are installed.

Linux Filesystem Hierarchy

/usr/X11R6/lib

X libraries.

/usr/local/lib

Local libraries.

/etc/lilo.conf

Configuration file for the Linux boot loader 'lilo'. 'lilo' is the original OS loader and can load Linux and others. The 'lilo' package normally contains lilo (the installer) and boot-record-images to install Linux, OS/2, DOS and generic Boot Sectors of other Oses. You can use Lilo to manage your Master Boot Record (with a simple text screen, text menu or colorful splash graphics) or call 'lilo' from other boot-loaders to jump-start the Linux kernel.

```

```

/etc/local.gen

This file lists locales that you wish to have built. You can find a list of valid supported locales at `/usr/share/i18n/SUPPORTED`. Other combinations are possible, but may not be well tested. If you change this file, you need to re-run `locale-gen`.

/etc/locale.alias

Locale name alias data base.

/etc/login.defs

Configuration control definitions for the login package. An inordinate number of attributes can be altered via this single file such as the location of mail, delay in seconds after a failed login, enabling display of fail log information, display of unknown username login failures, shell environment variables, etc....

/etc/logrotate.conf

The logrotate utility is designed to simplify the administration of log files on a system which generates a lot of log files. Logrotate allows for the automatic rotation compression, removal and mailing of log files. Logrotate can be set to handle a log file daily, weekly, monthly or when the log file gets to a certain size. Normally, logrotate runs as a daily cron job.

```
# see "man logrotate" for details
# rotate log files weekly
weekly

# keep 4 weeks worth of backlogs
rotate 4

# create new (empty) log files after rotating old ones
create

# uncomment this if you want your log files compressed
#compress

# packages drop log rotation information into this directory
include /etc/logrotate.d

# no packages own wtmp, or btmp -- we'll rotate them here
/var/log/wtmp {
    monthly
    create 0664 root utmp
    rotate 1
}

/var/log/btmp {
    missingok
    monthly
    create 0664 root utmp
    rotate 1
}

# system-specific logs may be configured here
```

/etc/ltrace.conf

Configuration file for ltrace (Library Call Tracer). It tracks runtime library calls in dynamically linked programs. 'ltrace' is a debugging program which runs a specified command until it exits. While the command is executing, ltrace intercepts and records the dynamic library calls which are called by the executed process and the signals received by that process. It can also intercept and print the system calls executed by the program. The program to be traced need not be recompiled for this, so you can

Linux Filesystem Hierarchy

use it on binaries for which you don't have the source handy. You should install ltrace if you need a sysadmin tool for tracking the execution of processes.

/etc/magic

Magic local data and configuration file for the file(1) command. Contains the descriptions of various file formats based on which file guesses the type of the file. Insert here your local magic data. Format is described in magic(5).

/etc/mail.rc

Initialization file for 'mail'. 'mail' is an intelligent mail processing system which has a command syntax reminiscent of ed with lines replaced by messages. It's basically a command line version of Microsoft Outlook.

/etc/mailcap

'metamail' capabilities file. The mailcap file is read by the metamail program to determine how to display non-text at the local site. The syntax of a mailcap file is quite simple, at least compared to termcap files. Any line that starts with "#" is a comment. Blank lines are ignored. Otherwise, each line defines a single mailcap entry for a single content type. Long lines may be continued by ending them with a backslash character, \. Each individual mailcap entry consists of a content-type specification, a command to execute, and (possibly) a set of optional "flag" values.

/etc/mailcap.order

The mailcap ordering specifications. The order of entries in the /etc/mailcap file can be altered by editing the /etc/mailcap.order file. Each line of that file specifies a package and an optional mime type. Mailcap entries that match will be placed in the order of this file. Entries that don't match will be placed later.

/etc/mailname

Mail server hostname. Normally the same as the hostname.

/etc/menu, /etc/menu-methods

The menu package was inspired by the install-fvwm2-menu program from the old fvwm2 package. However, menu tries to provide a more general interface for menu building. With the update-menus command from this package, no package needs to be modified for every X window manager again, and it provides a unified interface for both text-and X-oriented programs.

When a package that wants to add something to the menu tree gets installed, it will run update-menus in its postinstall script. Update-menus then reads in all menu files in /etc/menu/ /usr/lib/menu and /usr/lib/menu/default, and stores the menu entries of all installed packages in memory. Once that has been done, it will run the menu-methods in /etc/menu-methods/*, and pipe the information about the menu entries to the menu-methods on stdout, so that the menu-methods can read this. Each Window Manager or other program that wants to have the debian menu tree, will supply a menu-method script in /etc/menu-methods/. This menu-method then knows how to generate the startup-file for that window manager. To facilitate this task for the window-manager maintainers, menu provides a install-menu program. This program can generate the startup files for just about every window manager.

/etc/mgetty+sendfax

Configuration files for use of mgetty as the interface on the serial port. The mgetty routine special routine has special features for handling things such as dial up connections and fax connections.

/etc/mime.types

MIME-TYPES and the extensions that represent them. This file is part of the "mime-support" package. Note: Compression schemes like "gzip", "bzip", and "compress" are not actually "mime-types". They are "encodings" and hence must not have entries in this file to map their extensions. The "mime-type" of an encoded file refers to the type of data that has been encoded, not the type of the encoding.

/etc/minicom

Linux Filesystem Hierarchy

'minicom' configuration files. 'minicom' is a communication program which somewhat resembles the shareware program TELIX but is free with source code and runs under most unices. Features include dialling directory with auto-redial, support for UUCP-style lock files on serial devices, a separate script language interpreter, capture to file, multiple users with individual configurations, and more.

/etc/modules

List of modules to be loaded at startup.

```
# /etc/modules: kernel modules to load at boot time.
#
# This file should contain the names of kernel modules that are
# to be loaded at boot time, one per line. Comments begin with
# a "#", and everything on the line after them are ignored.
unix
af_packet
via-rhine
cmpci
ne2k-pci
nvidia
```

/etc/modules.conf

```
### This file is automatically generated by update-modules"
#
# Please do not edit this file directly. If you want to change or add
# anything please take a look at the files in /etc/modutils and read
# the manpage for update-modules.
#
### update-modules: start processing /etc/modutils/0keep
# DO NOT MODIFY THIS FILE!
# This file is not marked as conffile to make sure if you upgrade modutils
# it will be restored in case some modifications have been made.
#
# The keep command is necessary to prevent insmod and friends from ignoring
# the builtin defaults of a path-statement is encountered. Until all other
# packages use the new `add path'-statement this keep-statement is essential
# to keep your system working
keep

### update-modules: end processing /etc/modutils/0keep

/etc/modutils

These utilities are intended to make a Linux modular kernel manageable for all users, administrators and distribution maintainers.

/etc/mtools

Debian default mtools configuration file. The mtools series of commands work with MS-DOS files and directories on floppy disks. This allows you to use Linux with MS-DOS formatted diskettes on DOS and Windows systems.

/etc/manpath.conf

This file is used by the man_db package to configure the man and cat paths. It is also used to provide a manpath for those without one by examining their PATH environment variable. For details see the manpath(5) man page.

/etc/mediaprm

Was formally named /etc/fdprm. See /etc/fdprm for further details.

/etc/motd

The message of the day, automatically output after a successful login. Contents are up to the system administrator. Often used for getting information to every user, such as warnings about planned downtimes. Linux debian.localdomain.com 2.4.18 #1 Sat Mar 15 00:17:39 EST 2003 i686 unknown
Most of the programs included with the Debian GNU/Linux system are freely redistributable; the exact distribution terms for each program are described in the individual files in /usr/share/doc/*/copyright
Debian GNU/Linux comes with ABSOLUTELY NO WARRANTY, to the extent permitted by applicable law.

/etc/mtab

List of currently mounted filesystems. Initially set up by the bootup scripts, and updated automatically by the mount command. Used when a list of mounted filesystems is needed, e.g., by the df command.

This file is sometimes a symbolic link to /proc/mounts.

/etc/networks

Linux Filesystem Hierarchy

List of networks that the system is currently located on. For example, 192.168.0.0.

/etc/nsswitch.conf

System Database/Name Service Switch configuration file.

/etc/oss.conf

OSS (Open Sound System) configuration file.

/etc/pam.d/

This directory is the home of the configuration files for PAMs, Pluggable Authentication Modules.

/etc/postfix/

Holds your postfix configuration files. Postfix is now the MTA of choice among Linux distributions.

It is sendmail-compatible, offers improved speed over sendmail, ease of administration and security.

It was originally developed by IBM and was called the IBM Secure Mailer and is used in many large commercial networks. It is now the de-facto standard.

/etc/ppp/

The place where your dial-up configuration files are placed. More than likely to be created by the text menu based pppconfig or other GUI based ppp configuration utilities such as kppp or gnome-ppp.

/etc/pam.conf

Most programs use a file under the /etc/pam.d/ directory to setup their PAM service modules. This file is and can be used, but is not recommended.

/etc/paper.config

Paper size configuration file.

/etc/papersize

Default papersize.

/etc/passwd

This is the 'old' password file, It is kept for compatibility and contains the user database, with fields giving the username, real name, home directory, encrypted password, and other information about each user. The format is documented in the passwd man(ual) page.

```
root:x:0:0:root:/root:/bin/bash daemon:x:1:1:daemon:/usr/sbin:/bin/sh

```

/etc/passwd--

Old /etc/passwd file.

/etc/printcap

Printer configuration (capabilities) file. The definition of all system printers, whether local or remote, is stored in this file. Its layout is similar to that of /etc/termcap but it uses a different syntax.

/etc/profile

Files and commands to be executed at login or startup time by the Bourne or C shells. These allow the system administrator to set global defaults for all users.

Linux Filesystem Hierarchy

/etc/profile.d

Shells scripts to be executed upon login to the Bourne or C shells. These scripts are normally called from the /etc/profile file.

/etc/protocols

Protocols definitions file. It describes the various DARPA Internet protocols that are available from the TCP/IP subsystem. It should be consulted instead of using the numbers in the ARPA include files or resorting to guesstimation. This file should be left untouched since changes could result in incorrect IP packages.

/etc/pcmcia

Configuration files for PCMCIA devices. Generally only useful to laptop users.

/etc/reportbug.conf

Configuration file for reportbug. Reportbug is primarily designed to report bugs in the Debian distribution. By default it creates an e-mail to the Debian bug tracking system at mit@bugs.debian.org with information about the bug. Using the –bts option you can report bugs to other servers also using ddebbugs such as KDE.org. It is similar to bug but has far greater capabilities while still maintaining simplicity.

/etc/rc.boot or /etc/rc?.d

These directories contain all the files necessary to control system services and configure runlevels. A skeleton file is provided in /etc/init.d/skeleton

/etc/rcS.d

The scripts in this directory are executed once when booting the system, even when booting directly into single user mode. The files are all symbolic links, the real files are located in /etc/init.d/. For a more general discussion of this technique, see /etc/init.d/README.

/etc/resolv.conf

Configuration of how DNS is to occur is defined in this file. It tells the name resolver libraries where they need to go to find information not found in the /etc/hosts file. This always has at least one nameserver line, but preferably three. The resolver uses each in turn. More than the first three can be included but anything beyond the first three will be ignored. Two lines that appear in the /etc/resolv.conf file are domain and search. Both of these are mutually exclusive options, and where both show up, the last one wins. Other entries beyond the three discussed here are listed in the man pages but aren't often used.

/etc/rmt

This is not a mistake. This shell script (/etc/rmt) has been provided for compatibility with other Unix-like systems, some of which have utilities that expect to find (and execute) rmt in the /etc directory on remote systems.

/etc/rpc

The rpc file contains user readable names that can be used in place of rpc program numbers. Each line has the following information: –name of server for the rpc program –rpc program number –aliases Items are separated by any number of blanks and/or tab characters. A `#` indicates the beginning of a comment; characters up to the end of the line are not interpreted by routines which search the file.

```
# /etc/rpc:
# $Id: etc.xml,v 1.10 2004/02/03 21:42:57 binh Exp $
#
# rpc 88/08/01 4.0 RPCSRC; from 1.12    88/02/07 SMI

```

/etc/samba

Samba configuration files. A 'LanManager' like file and printer server for Unix. The Samba software suite is a collection of programs that implements the SMB protocol for unix systems, allowing you to serve files and printers to Windows, NT, OS/2 and DOS clients. This protocol is sometimes also referred to as the LanManager or NetBIOS protocol.

/etc/sane.d

Sane configuration files. SANE stands for "Scanner Access Now Easy" and is an application programming interface (API) that provides standardized access to any raster image scanner hardware (flatbed scanner, hand-held scanner, video- and still-cameras, frame-grabbers, etc.). The SANE API is public domain and its discussion and development is open to everybody. The current source code is written for UNIX (including GNU/Linux) and is available under the GNU General Public License (the SANE API is available to proprietary applications and backends as well, however).

SANE is a universal scanner interface. The value of such a universal interface is that it allows writing just one driver per image acquisition device rather than one driver for each device and application. So, if you have three applications and four devices, traditionally you'd have had to write 12 different programs. With SANE, this number is reduced to seven: the three applications plus the four drivers. Of course, the savings get even bigger as more and more drivers and/or applications are added.

Not only does SANE reduce development time and code duplication, it also raises the level at which applications can work. As such, it will enable applications that were previously unheard of in the UNIX world. While SANE is primarily targeted at a UNIX environment, the standard has been carefully designed to make it possible to implement the API on virtually any hardware or operating system.

While SANE is an acronym for ``Scanner Access Now Easy'' the hope is of course that SANE is indeed sane in the sense that it will allow easy implementation of the API while accommodating all

Linux Filesystem Hierarchy

features required by today's scanner hardware and applications. Specifically, SANE should be broad enough to accommodate devices such as scanners, digital still and video cameras, as well as virtual devices like image file filters.

If you're familiar with TWAIN, you may wonder why there is a need for SANE. Simply put, TWAIN does not separate the user-interface from the driver of a device. This, unfortunately, makes it difficult, if not impossible, to provide network transparent access to image acquisition devices (which is useful if you have a LAN full of machines, but scanners connected to only one or two machines; it's obviously also useful for remote-controlled cameras and such). It also means that any particular TWAIN driver is pretty much married to a particular GUI API (be it Win32 or the Mac API). In contrast, SANE cleanly separates device controls from their representation in a user-interface. As a result, SANE has no difficulty supporting command-line driven interfaces or network-transparent scanning. For these reasons, it is unlikely that there will ever be a SANE backend that can talk to a TWAIN driver. The converse is no problem though: it would be pretty straight forward to access SANE devices through a TWAIN source. In summary, if TWAIN had been just a little better designed, there would have been no reason for SANE to exist, but things being the way they are, TWAIN simply isn't SANE.

/etc/securetty

Identifies secure terminals, i.e., the terminals from which root is allowed to log in. Typically only the virtual consoles are listed, so that it becomes impossible (or at least harder) to gain superuser privileges by breaking into a system over a modem or a network.

```
# /etc/securetty: list of terminals on which root is allowed to login.
# See securetty(5) and login(1).
console

# Standard consoles
tty1
tty2
tty3
tty4
tty5
tty6
tty7
tty8
tty9
tty10
tty11
tty12

# Same as above, but these only occur with devfs devices
vc/1
vc/2
vc/3
vc/4
vc/5
vc/6
vc/7
vc/8
vc/9
vc/10
vc/11
vc/12
```

/etc/sensors.conf

Linux Filesystem Hierarchy

Configuration file for libsensors. A set of libraries designed to ascertain current hardware states via motherboard sensor chips. Useful statistics such as core voltages, CPU temperature can be determined through third party utilities that make use of these libraries such as 'gkrellm'. If you do not wish to install these packages you may also utilise the /proc filesystem real-time nature.

/etc/sudoers

Sudoers file. This file must be edited with the 'visudo' command as root. The sudo command allows an authenticated user to execute an authorized command as root. Both the effective UID and GID are set to 0 (you are basically root). It determines which users are authorized and which commands they are authorized to use. Configuration of this command is via this file.

/etc/shadow

Shadow password file on systems with shadow password software installed (PAMs). Shadow passwords move the encrypted password from /etc/passwd into /etc/shadow; the latter is not readable by anyone except root. This makes it more difficult to crack passwords.

/etc/shadow--

Old /etc/shadow file.

/etc/sysctl.conf

Configuration file for setting system variables, most notably kernel parameters. 'sysctl' is a means of configuring certain aspects of the kernel at run-time, and the /proc/sys/ directory is there so that you don't even need special tools to do it!

/etc/security

Essential to security. This subdirectory allows administrators to impose quota limits, access limits and also to configure PAM environments.

/etc/serial.conf

Serial port configuration. Changeable parameters include speed, baud rate, port, irq and type.

/etc/services

A definition of the networks, services and the associated port for each protocol that are available on this system. For example, web services (http) are assigned to port 80 by default. # /etc/services: # \$Id: etc.xml,v 1.10 2004/02/03 21:42:57 binh Exp \$ # # Network services, Internet style # # Note that it is presently the policy of IANA to assign a single # well-known port number for both TCP and UDP; hence, most entries # here have two entries even if the protocol doesn't support UDP # operations.

Updated from RFC 1700, ``Assigned Numbers'' (October # 1994). Not all ports are included, only the more common ones. echo 7/tcp echo 7/udp discard 9/tcp sink null discard 9/udp sink null systat 11/tcp users daytime 13/tcp daytime 13/udp netstat 15/tcp qotd 17/tcp quote msp 18/tcp # message send protocol msp 18/udp # message send protocol chargen 19/tcp ttyst source chargen 19/udp ttyst source ftp-data 20/tcp ftp 21/tcp fsp 21/udp fspd ssh 22/tcp # SSH Remote Login Protocol ssh 22/udp # SSH Remote Login Protocol telnet 23/tcp # 24 – private smtp 25/tcp mail # 26 – unassigned time 37/tcp timserver time 37/udp timserver rlp 39/udp resource # resource location nameserver 42/tcp name # IEN 116 whois 43/tcp nickname re-mail-ck 50/tcp # Remote Mail Checking Protocol re-mail-ck 50/udp # Remote Mail Checking Protocol domain 53/tcp nameserver # name-domain server domain 53/udp nameserver netbios-ns 137/tcp # NETBIOS Name Service netbios-ns 137/udp netbios-dgm 138/tcp # NETBIOS Datagram Service netbios-dgm 138/udp netbios-ssn 139/tcp # NETBIOS session service netbios-ssn 139/udp x11 6000/tcp x11-0 # X windows system x11 6000/udp x11-0 # X windows system

/etc/shells

Lists trusted shells. The chsh command allows users to change their login shell only to shells listed in this file. ftpd, the server process that provides FTP services for a machine, will check that the user's shell is listed in /etc/shells and will not let people log in unless the shell is listed there. There are also some display managers that will passively or actively (dependent upon on distribution and display manager being used) refuse a user access to the system unless their shell is one of those listed here.

Linux Filesystem Hierarchy

```
# /etc/shells: valid login shells
/bin/ash
/bin/bash
/bin/csh
/bin/sh
/usr/bin/es
/usr/bin/ksh
/bin/ksh
/usr/bin/rc
/usr/bin/tcsh
/bin/tcsh
/usr/bin/zsh
/bin/sash
/bin/zsh
/usr/bin/esh
```

/etc/skel/

The default files for each new user are stored in this directory. Each time a new user is added, these skeleton files are copied into their home directory. An average system would have: .alias, .bash_profile, .bashrc and .cshrc files. Other files are left up to the system administrator.

/etc/sysconfig/

This directory contains configuration files and subdirectories for the setup of system configuration specifics and for the boot process, like 'clock', which sets the timezone, or 'keyboard' which controls the keyboard map. The contents may vary drastically depending on which distribution and what utilities you have installed. For example, on a Redhat or Mandrake based system it is possible to alter an endless array of attributes from the default desktop to whether DMA should be enabled for your IDE devices. On our Debian reference system though this folder is almost expedient containing only two files hwconf and soundcard which are both configured by the Redhat utilities hwconf and sndconfig respectively.

/etc/slip

Configuration files for the setup and operation of SLIP (serial line IP) interface. Generally unused nowadays. This protocol has been superceded by the faster and more efficient PPP protocol.

/etc/screenrc

This is the system wide screenrc. You can use this file to change the default behavior of screen system wide or copy it to ~/.screenrc and use it as a starting point for your own settings. Commands in this file are used to set options, bind screen functions to keys, redefine terminal capabilities, and to automatically establish one or more windows at the beginning of your screen session. This is not a comprehensive list of options, look at the screen manual for details on everything that you can put in this file.

/etc/scrollkeeper.conf

A free electronic cataloging system for documentation. It stores metadata specified by the <http://www.ibiblio.org/osrt/omf/> (Open Source Metadata Framework) as well as certain metadata extracted directly from documents (such as the table of contents). It provides various functionality pertaining to this metadata to help browsers, such as sorting the registered documents or searching the metadata for documents which satisfy a set of criteria.

/etc/ssh

'ssh' configuration files. 'ssh' is a secure rlogin/rsh/rpc replacement (OpenSSH). This is the portable version of OpenSSH, a free implementation of the Secure Shell protocol as specified by the IETF secsh working group. 'ssh' (Secure Shell) is a program for logging into a remote machine and for executing commands on a remote machine. It provides secure encrypted communications between two untrusted hosts over an insecure network. X11 connections and arbitrary TCP/IP ports can also be forwarded over the secure channel. It is intended as a replacement for rlogin, rsh and rcp, and can be used to provide applications with a secure communication channel. It should be noted that in some

Linux Filesystem Hierarchy

countries, particularly Iraq, and Pakistan, it may be illegal to use any encryption at all without a special permit.

/etc/syslog.conf

Lists where log files should go, what messages are written to them and the level of verbosity. It is also now possible to filter based on message content, message integrity, message encryption (near future), portability and better network forwarding.

/etc/termcap

The terminal capability database. Describes the "escape sequences" by which various terminals can be controlled. Programs are written so that instead of directly outputting an escape sequence that only works on a particular brand of terminal, they look up the correct sequence to do whatever it is they want to do in /etc/termcap. As a result most programs work with most kinds of terminals.

/etc/timezone

local timezone.

/etc/updatedb.conf

Sets environment variables that are used by updatedb which therefore configures the database for 'locate', a utility that locates a pattern in a database of filenames and returns the filenames that match.

```
# This file sets environment variables which are used by updatedb

# filesystems which are pruned from updatedb database
PRUNEFS="NFS nfs afs proc smbfs autoiso9660 ncpfs coda devpts ftpfs"
export PRUNEFS
# paths which are pruned from updatedb database
PRUNEPATHS="/tmp /usr/tmp /var/tmp /afs /amd /alex /var/spool"
export PRUNEPATHS
# netpaths which are added
NETPATHS=""
export NETPATHS
```

/etc/vga

The configuration file for the svgalib is stored in this directory. svgalib provides graphics capabilities to programs running on the system console, without going through the X Window System. It uses direct access to the video hardware to provide low-level access to the standard VGA and SVGA graphics modes. It only works with some video hardware; so use with caution.

/etc/vim

Contains configuration files for both vim and its X based counterpart gvim. A wide range of options can be accessed through these two files such as automatic indentation, syntax highlighting, etc....

/etc/xinetd.d/

The original 'inetd' daemon has now been superceded by the much improved 'xinetd'. 'inetd' should be run at boot time by /etc/init.d/inetd (or /etc/rc.local on some systems). It then listens for connections on certain Internet sockets. When a connection is found on one of its sockets, it decides what service the socket corresponds to, and invokes a program to service the request. After the program is finished, it continues to listen on the socket (except in some cases). Essentially, inetd allows running one daemon to invoke several others, reducing load on the system. Services controlled via xinetd put their configuration files here.

/etc/zlogin

System-wide .zlogin file for zsh(1). This file is sourced only for login shells. It should contain commands that should be executed only in login shells. It should be used to set the terminal type and run a series of external commands (fortune, msgs, from, etc.)

/etc/zlogout

Commands to be executed upon user exit from the zsh. Its control is system-wide but the .zlogout file for zsh(1) does override it in terms of importance.

/etc/zprofile

Linux Filesystem Hierarchy

System-wide .zprofile file for zsh(1). This file is sourced only for login shells (i.e. Shells invoked with “–” as the first character of argv[0], and shells invoked with the -l flag.)

/etc/zshenv

System-wide .zshenv file for zsh(1). This file is sourced on all invocations of the shell. If the -f flag is present or if the NO_RCS option is set within this file, all other initialization files are skipped. This file should contain commands to set the command search path, plus other important environment variables. This file should not contain commands that produce output or assume the shell is attached to a tty.

/etc/zshrc

System-wide .zshrc file for zsh(1). This file is sourced only for interactive shells. It should contain commands to set up aliases, functions, options, key bindings, etc.

Compliance with the FSSTND requires that the following directories, or symbolic links to directories are required in /etc:

```
opt      Configuration for /opt
X11     Configuration for the X Window system (optional)
sgml    Configuration for SGML (optional)
xml     Configuration for XML (optional)
```

The following directories, or symbolic links to directories must be in /etc, if the corresponding subsystem is installed:

```
opt      Configuration for /opt
```

The following files, or symbolic links to files, must be in /etc if the corresponding subsystem is installed (it is recommended that files be stored in subdirectories of /etc/ rather than directly in /etc):

```
csh.login  Systemwide initialization file for C shell logins (optional)
exports    NFS filesystem access control list (optional)
fstab      Static information about filesystems (optional)
ftpusers   FTP daemon user access control list (optional)
gateways   File which lists gateways for routed (optional)
gettydefs  Speed and terminal settings used by getty (optional)
group      User group file (optional)
host.conf   Resolver configuration file (optional)
hosts      Static information about host names (optional)
hosts.allow Host access file for TCP wrappers (optional)
hosts.deny  Host access file for TCP wrappers (optional)
hosts.equiv List of trusted hosts for rlogin, rsh, rcp (optional)
hosts.lpd   List of trusted hosts for lpd (optional)
inetd.conf  Configuration file for inetd (optional)
inittab    Configuration file for init (optional)
issue      Pre-login message and identification file (optional)
ld.so.conf  List of extra directories to search for shared libraries
            (optional)
motd       Post-login message of the day file (optional)
mtab       Dynamic information about filesystems (optional)
mtools.conf Configuration file for mtools (optional)
networks   Static information about network names (optional)
passwd     The password file (optional)
printcap   The lpd printer capability database (optional)
profile    Systemwide initialization file for sh shell logins (optional)
protocols  IP protocol listing (optional)
resolv.conf Resolver configuration file (optional)
rpc        RPC protocol listing (optional)
securetty  TTY access control for root login (optional)
services   Port names for network services (optional)
```

Linux Filesystem Hierarchy

shells Pathnames of valid login shells (optional)
syslog.conf Configuration file for syslogd (optional)

mtab does not fit the static nature of /etc: it is excepted for historical reasons. On some Linux systems, this may be a symbolic link to /proc/mounts, in which case this exception is not required.

/etc/opt : Configuration files for /opt
Host-specific configuration files for add-on application software packages must be installed within the directory /etc/opt/&60;subdir&62;, where &60;subdir&62; is the name of the subtree in /opt where the static data from that package is stored.

No structure is imposed on the internal arrangement of /etc/opt/&60;subdir&62;. If a configuration file must reside in a different location in order for the package or system to function properly, it may be placed in a location other than /etc/opt/&60;subdir&62;.

The rationale behind this subtree is best explained by referring to the rationale for /opt.

/etc/X11 : Configuration for the X Window System (optional)
/etc/X11 is the location for all X11 host-specific configuration. This directory is necessary to allow local control if /usr is mounted read only.

The following files, or symbolic links to files, must be in /etc/X11 if the corresponding subsystem is installed:

Xconfig The configuration file for early versions of XFree86 (optional)
XF86Config The configuration file for XFree86 versions 3 and 4 (optional)
Xmodmap Global X11 keyboard modification file (optional)

Subdirectories of /etc/X11 may include those for xdm and for any other programs (some window managers, for example) that need them.

/etc/X11/xdm holds the configuration files for xdm. These are most of the files previously found in /usr/lib/X11/xdm. Some local variable data for xdm is stored in /var/lib/xdm.

It is recommended that window managers with only one configuration file which is a default .*wmrc file must name it system.*wmrc (unless there is a widely-accepted alternative name) and not use a subdirectory. Any window manager subdirectories must be identically named to the actual window manager binary.

/etc/sgml : Configuration files for SGML (optional)
Generic configuration files defining high-level parameters of the SGML systems are installed here. Files with names *.conf indicate generic configuration files. File with names *.cat are the DTD-specific centralized catalogs, containing references to all other catalogs needed to use the given DTD. The super catalog file catalog references all the centralized catalogs.

/etc/xml : Configuration files for XML (optional)
Generic configuration files defining high-level parameters of the XML systems are installed here. Files with names *.conf indicate generic configuration files. The super catalog file catalog references all the centralized catalogs.

1.7. /home

Linux is a multi-user environment so each user is also assigned a specific directory that is accessible only to them and the system administrator. These are the user home directories, which can be found under '/home/\$USER' (~). It is your playground: everything is at your command, you can write files, delete them, install programs, etc.... Your home directory contains your personal configuration files, the so-called dot files (their name is preceded by a dot). Personal configuration files are usually 'hidden', if you want to see them, you either have to turn on the appropriate option in your file manager or run ls with the -a switch. If there is a conflict between personal and system wide configuration files, the settings in the personal file will prevail.

Dotfiles most likely to be altered by the end user are probably your .xsession and .bashrc files. The configuration files for X and Bash respectively. They allow you to be able to change the window manager to be startup upon login and also aliases, user-specified commands and environment variables respectively. Almost always when a user is created their dotfiles will be taken from the /etc/skel directory where system administrators place a sample file that user's can modify to their hearts content.

/home can get quite large and can be used for storing downloads, compiling, installing and running programs, your mail, your collection of image or sound files etc.

The FSSTND states that:

/home is a fairly standard concept, but it is clearly a site-specific filesystem.

Different people prefer to place user accounts in a variety of places. This section describes only a suggested placement for user home directories; nevertheless we recommend that all FHS-compliant distributions use this as the default location for home directories. On small systems, each user's directory is typically one of the many subdirectories of /home such as /home smith, /home/torvalds, /home/operator, etc. On large systems (especially when the /home directories are shared amongst many hosts using NFS) it is useful to subdivide user home directories. Subdivision may be accomplished by using subdirectories such as /home/staff, /home/guests, /home/students, etc.

The setup will differ from host to host. Therefore, no program should rely on this location.

If you want to find out a user's home directory, you should use the getpwent(3) library function rather than relying on /etc/passwd because user information may be stored remotely using systems such as NIS.

User specific configuration files for applications are stored in the user's home directory in a file that starts with the '.' character (a "dot file"). If an application needs to create more than one dot file then they should be placed in a subdirectory with a name starting with a '.' character, (a "dot directory"). In this case the configuration files should not start with the '.' character.

It is recommended that apart from autosave and lock files programs should refrain from creating non dot files or directories in a home directory without user intervention.

1.8. /initrd

initrd provides the capability to load a RAM disk by the boot loader. This RAM disk can then be mounted as the root file system and programs can be run from it. Afterwards, a new root file system can be mounted from a different device. The previous root (from initrd) is then moved to a directory and can be subsequently unmounted.

initrd is mainly designed to allow system startup to occur in two phases, where the kernel comes up with a minimum set of compiled-in drivers, and where additional modules are loaded from initrd.

Operation

When using initrd, the system typically boots as follows:

- 1) the boot loader loads the kernel and the initial RAM disk
- 2) the kernel converts initrd into a "normal" RAM disk and frees the memory used by initrd
- 3) initrd is mounted read-write as root
- 4) /linuxrc is executed (this can be any valid executable, including shell scripts; it is run with uid 0 and can do basically everything init can do)
- 5) linuxrc mounts the "real" root file system
- 6) linuxrc places the root file system at the root directory using the pivot_root system call
- 7) the usual boot sequence (e.g. invocation of /sbin/init) is performed on the root file system
- 8) the initrd file system is removed

Note that changing the root directory does not involve unmounting it. It is therefore possible to leave processes running on initrd during that procedure. Also note that file systems mounted under initrd continue to be accessible.

Usage scenarios

The main motivation for implementing initrd was to allow for modular kernel configuration at system installation.

The procedure would work as follows:

- 1) system boots from floppy or other media with a minimal kernel (e.g. support for RAM disks, initrd, a.out, and the Ext2 FS) and loads initrd
- 2) /linuxrc determines what is needed to (1) mount the "real" root FS (i.e. device type, device drivers, file system) and (2) the distribution media (e.g. CD-ROM, network, tape, ...). This can be done by asking the user, by auto-probing, or by using a hybrid approach.
- 3) /linuxrc loads the necessary kernel modules
- 4) /linuxrc creates and populates the root file system (this doesn't have to be a very usable system yet)
- 5) /linuxrc invokes pivot_root to change the root file system and execs - via chroot - a program that continues the installation
- 6) the boot loader is installed
- 7) the boot loader is configured to load an initrd with the set of modules that was used to bring up the system (e.g. /initrd can

Linux Filesystem Hierarchy

```
be modified, then unmounted, and finally, the image is written
from /dev/ram0 or /dev/rd/0 to a file)
8) now the system is bootable and additional installation tasks
can be performed
```

The key role of initrd here is to re-use the configuration data during normal system operation without requiring the use of a bloated "generic" kernel or re-compiling or re-linking the kernel.

A second scenario is for installations where Linux runs on systems with different hardware configurations in a single administrative domain. In such cases, it is desirable to generate only a small set of kernels (ideally only one) and to keep the system-specific part of configuration information as small as possible. In this case, a common initrd could be generated with all the necessary modules. Then, only /linuxrc or a file read by it would have to be different.

A third scenario are more convenient recovery disks, because information like the location of the root FS partition doesn't have to be provided at boot time, but the system loaded from initrd can invoke a user-friendly dialog and it can also perform some sanity checks (or even some form of auto-detection).

Last not least, CD-ROM distributors may use it for better installation from CD, e.g. by using a boot floppy and bootstrapping a bigger RAM disk via initrd from CD; or by booting via a loader like LOADLIN or directly from the CD-ROM, and loading the RAM disk from CD without need of floppies.

1.9. /lib

The /lib directory contains kernel modules and those shared library images (the C programming code library) needed to boot the system and run the commands in the root filesystem, ie. by binaries in /bin and /sbin. Libraries are readily identifiable through their filename extension of *.so. Windows equivalent to a shared library would be a DLL (dynamically linked library) file. They are essential for basic system functionality. Kernel modules (drivers) are in the subdirectory /lib/modules/'kernel-version'. To ensure proper module compilation you should ensure that /lib/modules/'kernel-version'/kernel/build points to /usr/src/'kernel-version' or ensure that the Makefile knows where the kernel source itself are located.

/lib/'machine-architecture'

Contains platform/architecture dependent libraries.

/lib/iptables

iptables shared library files.

/lib/kbd

Contains various keymaps.

/lib/modules/'kernel-version'

The home of all the kernel modules. The organisation of files here is reasonably clear so no requires no elaboration.

/lib/modules/'kernel-version'/isapnppmap.dep

has details on ISA based cards, the modules that they require and various other attributes.

/lib/modules/'kernel-version'/modules.dep

lists all modules dependencies. This file can be updated using the depmod command.

/lib/modules/'kernel-version'/pcimap

is the PCI equivalent of the /lib/modules/'kernel-version'/isapnppmap.dep file.

/lib/modules/'kernel-version'/usbmap

is the USB equivalent of the /lib/modules/'kernel-version'/isapnppmap.dep file.

Linux Filesystem Hierarchy

/lib/oss

All OSS (Open Sound System) files are installed here by default.

/lib/security

PAM library files.

The FSSTND states that the /lib directory contains those shared library images needed to boot the system and run the commands in the root filesystem, ie. by binaries in /bin and /sbin.

Shared libraries that are only necessary for binaries in /usr (such as any X Window binaries) must not be in /lib. Only the shared libraries required to run binaries in /bin and /sbin may be here. In particular, the library libm.so.* may also be placed in /usr/lib if it is not required by anything in /bin or /sbin.

At least one of each of the following filename patterns are required (they may be files, or symbolic links):

```
libc.so.* The dynamically-linked C library (optional)
ld*       The execution time linker/loader (optional)
```

If a C preprocessor is installed, /lib/cpp must be a reference to it, for historical reasons. The usual placement of this binary is /usr/bin/cpp.

The following directories, or symbolic links to directories, must be in /lib, if the corresponding subsystem is installed:

```
modules Loadable kernel modules (optional)

/lib<qual> : Alternate format essential shared libraries (optional)
```

There may be one or more variants of the /lib directory on systems which support more than one binary format requiring separate libraries.

This is commonly used for 64-bit or 32-bit support on systems which support multiple binary formats, but require libraries of the same name. In this case, /lib32 and /lib64 might be the library directories, and /lib a symlink to one of them.

If one or more of these directories exist, the requirements for their contents are the same as the normal /lib directory, except that /lib<qual>/cpp is not required.

/lib<qual>/cpp is still permitted: this allows the case where /lib and /lib<qual> are the same (one is a symbolic link to the other).

1.10. /lost+found

As was explained earlier during the overview of the FSSTND, Linux should always go through a proper shutdown. Sometimes your system might crash or a power failure might take the machine down. Either way, at the next boot, a lengthy filesystem check (the speed of this check is dependent on the type of filesystem that you actually use. ie. ext3 is faster than ext2 because it is a journalled filesystem) using fsck will be done. Fsck will go through the system and try to recover any corrupt files that it finds. The result of this recovery operation will be placed in this directory. The files recovered are not likely to be complete or make much sense but there always is a chance that something worthwhile is recovered. Each partition has its own lost+found directory. If you find files in there, try to move them back to their original location. If you find something like a broken symbolic link to 'file', you have to reinstall the file/s from the corresponding RPM,

Linux Filesystem Hierarchy

since your file system got damaged so badly that the files were mutilated beyond recognition. Below is an example of a /lost+found directory. As you can see, the vast majority of files contained here are in actual fact sockets. As for the rest of the other files they were found to be damaged system files and personal files. These files were not able to be recovered.

```
total 368
-rw-r--r-- 1 root root 110891 Oct 5 14:14 #388200
-rw-r--r-- 1 root root 215 Oct 5 14:14 #388201

srwx----- 1 root root 0 Oct 6 23:09 #51448
```

1.11. /media

Amid much controversy and consternation on the part of system and network administrators a directory containing mount points for removable media has now been created. Funnily enough, it has been named /media.

This directory contains subdirectories which are used as mount points for removable media such as floppy disks, cdroms and zip disks.

The motivation for the creation of this directory has been that historically there have been a number of other different places used to mount removable media such as /cdrom, /mnt or /mnt/cdrom. Placing the mount points for all removable media directly in the root directory would potentially result in a large number of extra directories in /. Although the use of subdirectories in /mnt as a mount point has recently been common, it conflicts with a much older tradition of using /mnt directly as a temporary mount point.

The following directories, or symbolic links to directories, must be in /media, if the corresponding subsystem is installed:

```
floppy      Floppy drive (optional)
cdrom       CD-ROM drive (optional)
cdrecorder  CD writer (optional)
zip         Zip drive (optional)
```

On systems where more than one device exists for mounting a certain type of media, mount directories can be created by appending a digit to the name of those available above starting with '0', but the unqualified name must also exist.

A compliant implementation with two CDROM drives might have /media/cdrom0

and /media/cdrom1 with /media/cdrom a symlink to either of these.

Please see the section on the /mnt directory to achieve a better understanding of the process on mounting and unmounting filesystems.

1.12. /mnt

This is a generic mount point under which you mount your filesystems or devices. Mounting is the process by which you make a filesystem available to the system. After mounting your files will be accessible under the mount-point. This directory usually contains mount points or sub-directories where you mount your floppy and your CD. You can also create additional mount-points here if you wish. Standard mount points would include /mnt/cdrom and /mnt/floppy. There is no limitation to creating a mount-point anywhere on your system but by convention and for sheer practicality do not litter your file system with mount-points. It should be noted that some distributions like Debian allocate /floppy and /cdrom as mount points while Redhat and Mandrake puts them in /mnt/floppy and /mnt/cdrom respectively.

However, it should be noted that as of FSSTND version 2.3 the purpose of this directory has changed.

This directory is provided so that the system administrator may temporarily mount a filesystem as needed. The content of this directory is a local issue and should not affect the manner in which any program is run.

This directory must not be used by installation programs: a suitable temporary directory not in use by the system must be used instead.

1.12.1. Mounting and unmounting

Before one can use a filesystem, it has to be *mounted*. The operating system then does various bookkeeping things to make sure that everything works. Since all files in UNIX are in a single directory tree, the mount operation will make it look like the contents of the new filesystem are the contents of an existing subdirectory in some already mounted filesystem.

The mounts could be done as in the following example:

```
$ mount /dev/hda2 /home  
$ mount /dev/hda3 /usr  
$
```

The **mount** command takes two arguments. The first one is the device file corresponding to the disk or partition containing the filesystem. The second one is the directory below which it will be mounted. After these commands the contents of the two filesystems look just like the contents of the /home and /usr directories, respectively. One would then say that `/dev/hda2 is mounted on /home`, and similarly for /usr. To look at either filesystem, one would look at the contents of the directory on which it has been mounted, just as if it were any other directory. Note the difference between the device file, /dev/hda2, and the mounted-on directory, /home. The device file gives access to the raw contents of the disk, the mounted-on directory gives access to the files on the disk. The mounted-on directory is called the *mount point*.

Linux supports many filesystem types. **mount** tries to guess the type of the filesystem. You can also use the -t fstype option to specify the type directly; this is sometimes necessary, since the heuristics **mount** uses do not always work. For example, to mount an MS-DOS floppy, you could use the following command:

Linux Filesystem Hierarchy

```
$ mount -t msdos /dev/fd0 /floppy  
$
```

The mounted-on directory need not be empty, although it must exist. Any files in it, however, will be inaccessible by name while the filesystem is mounted. (Any files that have already been opened will still be accessible. Files that have hard links from other directories can be accessed using those names.) There is no harm done with this, and it can even be useful. For instance, some people like to have `/tmp` and `/var/tmp` synonymous, and make `/tmp` be a symbolic link to `/var/tmp`. When the system is booted, before the `/var` filesystem is mounted, a `/var/tmp` directory residing on the root filesystem is used instead. When `/var` is mounted, it will make the `/var/tmp` directory on the root filesystem inaccessible. If `/var/tmp` didn't exist on the root filesystem, it would be impossible to use temporary files before mounting `/var`.

If you don't intend to write anything to the filesystem, use the `-r` switch for **mount** to do a *read-only mount*. This will make the kernel stop any attempts at writing to the filesystem, and will also stop the kernel from updating file access times in the inodes. Read-only mounts are necessary for unwritable media, e.g., CD-ROMs.

The alert reader has already noticed a slight logistical problem. How is the first filesystem (called the *root filesystem*, because it contains the root directory) mounted, since it obviously can't be mounted on another filesystem? Well, the answer is that it is done by magic.

For more information, see the kernel source or the Kernel Hackers' Guide.

The root filesystem is magically mounted at boot time, and one can rely on it to always be mounted. If the root filesystem can't be mounted, the system does not boot. The name of the filesystem that is magically mounted as root is either compiled into the kernel, or set using LILO or **rdev**.

The root filesystem is usually first mounted read-only. The startup scripts will then run **fsck** to verify its validity, and if there are no problems, they will *re-mount* it so that writes will also be allowed. **fsck** must not be run on a mounted filesystem, since any changes to the filesystem while **fsck** is running *will* cause trouble. Since the root filesystem is mounted read-only while it is being checked, **fsck** can fix any problems without worry, since the remount operation will flush any metadata that the filesystem keeps in memory.

On many systems there are other filesystems that should also be mounted automatically at boot time. These are specified in the `/etc/fstab` file; see the `fstab` man page for details on the format. The details of exactly when the extra filesystems are mounted depend on many factors, and can be configured by each administrator if need be.

When a filesystem no longer needs to be mounted, it can be unmounted with **umount**.

It should of course be **umount**, but the `n` mysteriously disappeared in the 70s, and hasn't been seen since. Please return it to Bell Labs, NJ, if you find it.

umount takes one argument: either the device file or the mount point. For example, to unmount the directories of the previous example, one could use the commands

```
$ umount /dev/hda2  
$ umount /usr  
$
```

See the man page for further instructions on how to use the command. It is imperative that you always unmount a mounted floppy. *Don't just pop the floppy out of the drive!* Because of disk caching, the data is not

Linux Filesystem Hierarchy

necessarily written to the floppy until you unmount it, so removing the floppy from the drive too early might cause the contents to become garbled. If you only read from the floppy, this is not very likely, but if you write, even accidentally, the result may be catastrophic.

Mounting and unmounting requires super user privileges, i.e., only root can do it. The reason for this is that if any user can mount a floppy on any directory, then it is rather easy to create a floppy with, say, a Trojan horse disguised as `/bin/sh`, or any other often used program. However, it is often necessary to allow users to use floppies, and there are several ways to do this:

- Give the users the root password. This is obviously bad security, but is the easiest solution. It works well if there is no need for security anyway, which is the case on many non-networked, personal systems.
- Use a program such as **sudo** to allow users to use `mount`. This is still bad security, but doesn't directly give super user privileges to everyone. [1]
- Make the users use **mtools**, a package for manipulating MS-DOS filesystems, without mounting them. This works well if MS-DOS floppies are all that is needed, but is rather awkward otherwise.
- List the floppy devices and their allowable mount points together with the suitable options in `/etc/fstab`.

The last alternative can be implemented by adding a line like the following to the `/etc/fstab` file:

```
/dev/fd0 /floppy  
msdos user,noauto 0 0
```

The columns are: device file to mount, directory to mount on, filesystem type, options, backup frequency (used by **dump**), and **fsck** pass number (to specify the order in which filesystems should be checked upon boot; 0 means no check).

The `noauto` option stops this mount to be done automatically when the system is started (i.e., it stops **mount -a** from mounting it). The `user` option allows any user to mount the filesystem, and, because of security reasons, disallows execution of programs (normal or setuid) and interpretation of device files from the mounted filesystem. After this, any user can mount a floppy with an msdos filesystem with the following command:

```
$ mount /floppy  
$
```

The floppy can (and needs to, of course) be unmounted with the corresponding **umount** command.

If you want to provide access to several types of floppies, you need to give several mount points. The settings can be different for each mount point. For example, to give access to both MS-DOS and ext2 floppies, you could have the following two lines in `/etc/fstab`:

```
/dev/fd0 /dosfloppy msdos user,noauto 0 0 /dev/fd0  
/ext2floppy ext2 user,noauto 0 0
```

For MS-DOS filesystems (not just floppies), you probably want to restrict access to it by using the `uid`, `gid`, and `umask` filesystem options, described in detail on the **mount** manual page. If you aren't careful, mounting an MS-DOS filesystem gives everyone at least read access to the files in it, which is not a good idea.

1.13. /opt

This directory is reserved for all the software and add-on packages that are not part of the default installation. For example, StarOffice, Kylix, Netscape Communicator and WordPerfect packages are normally found here. To comply with the FSSTND, all third party applications should be installed in this directory. Any package to be installed here must locate its static files (ie. extra fonts, clipart, database files) must locate its static files in a separate /opt/'package' or /opt/'provider' directory tree (similar to the way in which Windows will install new software to its own directory tree C:\Windows\Program Files\"Program Name"), where 'package' is a name that describes the software package and 'provider' is the provider's LANANA registered name.

Although most distributions neglect to create the directories /opt/bin, /opt/doc, /opt/include, /opt/info, /opt/lib, and /opt/man they are reserved for local system administrator use. Packages may provide "front-end" files intended to be placed in (by linking or copying) these reserved directories by the system administrator, but must function normally in the absence of these reserved directories. Programs to be invoked by users are located in the directory /opt/'package'/bin. If the package includes UNIX manual pages, they are located in /opt/'package'/man and the same substructure as /usr/share/man must be used. Package files that are variable must be installed in /var/opt. Host-specific configuration files are installed in /etc/opt.

Under no circumstances are other package files to exist outside the /opt, /var/opt, and /etc/opt hierarchies except for those package files that must reside in specific locations within the filesystem tree in order to function properly. For example, device lock files in /var/lock and devices in /dev. Distributions may install software in /opt, but must not modify or delete software installed by the local system administrator without the assent of the local system administrator.

The use of /opt for add-on software is a well-established practice in the UNIX community. The System V Application Binary Interface [AT&T 1990], based on the System V Interface Definition (Third Edition) and the Intel Binary Compatibility Standard v. 2 (iBCS2) provides for an /opt structure very similar to the one defined here.

Generally, all data required to support a package on a system must be present within /opt/'package', including files intended to be copied into /etc/opt/'package' and /var/opt/'package' as well as reserved directories in /opt. The minor restrictions on distributions using /opt are necessary because conflicts are possible between distribution installed and locally installed software, especially in the case of fixed pathnames found in some binary software.

The structure of the directories below /opt/'provider' is left up to the packager of the software, though it is recommended that packages are installed in /opt/'provider'/'package' and follow a similar structure to the guidelines for /opt/package. A valid reason for diverging from this structure is for support packages which may have files installed in /opt/ 'provider'/lib or /opt/'provider'/bin.

1.14. /proc

/proc is very special in that it is also a virtual filesystem. It's sometimes referred to as a process information pseudo-file system. It doesn't contain 'real' files but runtime system information (e.g. system memory, devices mounted, hardware configuration, etc). For this reason it can be regarded as a control and information centre for the kernel. In fact, quite a lot of system utilities are simply calls to files in this directory. For example, 'lsmod' is the same as 'cat /proc/modules' while 'lspci' is a synonym for 'cat /proc/pci'. By altering files located in this directory you can even read/change kernel parameters (sysctl) while the system is running.

Linux Filesystem Hierarchy

The most distinctive thing about files in this directory is the fact that all of them have a file size of 0, with the exception of kcore, mtrr and self. A directory listing looks similar to the following:

```
total 525256
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 1
dr-xr-xr-x  3 daemon    root          0 Jan 19 15:00 109
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 170
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 173
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 178
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 2
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 3
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 4
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 421
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 425
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 433
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 439
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 444
dr-xr-xr-x  3 daemon    daemon        0 Jan 19 15:00 446
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 449
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 453
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 456
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 458
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 462
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 463
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 464
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 465
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 466
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 467
dr-xr-xr-x  3 gdm       gdm          0 Jan 19 15:00 472
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 483
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 5
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 6
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 7
dr-xr-xr-x  3 root      root          0 Jan 19 15:00 8
-r--r--r--   1 root      root          0 Jan 19 15:00 apm

```

Linux Filesystem Hierarchy

```
dr-xr-xr-x    3 root    root      0 Jan 19 15:00 net
dr-xr-xr-x    2 root    root      0 Jan 19 15:00 nv
-r--r--r--    1 root    root      0 Jan 19 15:00 partitions
-r--r--r--    1 root    root      0 Jan 19 15:00 pci
dr-xr-xr-x    4 root    root      0 Jan 19 15:00 scsi
lrwxrwxrwx    1 root    root      64 Jan 19 14:58 self -> 483
-rw-r--r--    1 root    root      0 Jan 19 15:00 slabinfo
-r--r--r--    1 root    root      0 Jan 19 15:00 stat
-r--r--r--    1 root    root      0 Jan 19 15:00 swaps
dr-xr-xr-x   10 root    root      0 Jan 19 15:00 sys
dr-xr-xr-x    2 root    root      0 Jan 19 15:00 sysvipc
dr-xr-xr-x    4 root    root      0 Jan 19 15:00 tty
-r--r--r--    1 root    root      0 Jan 19 15:00 uptime
-r--r--r--    1 root    root      0 Jan 19 15:00 version
```

Each of the numbered directories corresponds to an actual process ID. Looking at the process table, you can match processes with the associated process ID. For example, the process table might indicate the following for the secure shell server:

```
# ps ax | grep sshd
439 ? S 0:00 /usr/sbin/sshd
```

Details of this process can be obtained by looking at the associated files in the directory for this process, /proc/460. You might wonder how you can see details of a process that has a file size of 0. It makes more sense if you think of it as a window into the kernel. The file doesn't actually contain any data; it just acts as a pointer to where the actual process information resides. For example, a listing of the files in the /proc/460 directory looks similar to the following:

```
total 0
-r--r--r--    1 root    root      0 Jan 19 15:02 cmdline
lrwxrwxrwx    1 root    root      0 Jan 19 15:02 cwd -> /
-r-----    1 root    root      0 Jan 19 15:02 environ
lrwxrwxrwx    1 root    root      0 Jan 19 15:02 exe -> /usr/sbin/sshd
dr-x-----    2 root    root      0 Jan 19 15:02 fd
-r--r--r--    1 root    root      0 Jan 19 15:02 maps
-rw-----    1 root    root      0 Jan 19 15:02 mem
lrwxrwxrwx    1 root    root      0 Jan 19 15:02 root -> /
-r--r--r--    1 root    root      0 Jan 19 15:02 stat
-r--r--r--    1 root    root      0 Jan 19 15:02 statm
-r--r--r--    1 root    root      0 Jan 19 15:02 status
```

The purpose and contents of each of these files is explained below:

/proc/PID/cmdline

Command line arguments.

/proc/PID/cpu

Current and last cpu in which it was executed.

/proc/PID/cwd

Link to the current working directory.

/proc/PID/environ

Values of environment variables.

/proc/PID/exe

Link to the executable of this process.

/proc/PID/fd

Directory, which contains all file descriptors.

/proc/PID/maps

Memory maps to executables and library files.

/proc/PID/mem

Linux Filesystem Hierarchy

Memory held by this process.

/proc/PID/root

Link to the root directory of this process.

/proc/PID/stat

Process status.

/proc/PID/statm

Process memory status information.

/proc/PID/status

Process status in human readable form.

Should you wish to know more, the man page for proc describes each of the files associated with a running process ID in far greater detail.

Even though files appear to be of size 0, examining their contents reveals otherwise:

```
# cat status
```

```
Name: sshd
State: S (sleeping)
Tgid: 439
Pid: 439
PPid: 1
TracerPid: 0
Uid: 0 0 0 0
Gid: 0 0 0 0
FDSize: 32
Groups:
VmSize:      2788 kB
VmLck:        0 kB
VmRSS:       1280 kB
VmData:       252 kB
VmStk:        16 kB
VmExe:        268 kB
VmLib:       2132 kB
SigPnd: 0000000000000000
SigBlk: 0000000000000000
SigIgn: 8000000000001000
SigCgt: 00000000000014005
CapInh: 0000000000000000
CapPrm: 00000000fffffeff
CapEff: 00000000fffffeff
```

The files in the /proc directory act very similar to the process ID subdirectory files. For example, examining the contents of the /proc/interrupts file displays something like the following:

```
# cat interrupts
```

```
          CPU0
0:    32657      XT-PIC  timer
1:    1063       XT-PIC  keyboard
2:      0        XT-PIC  cascade
8:      3        XT-PIC  rtc
9:      0        XT-PIC  cmpci
11:   332       XT-PIC  nvidia
14:   5289      XT-PIC  ide0
15:   13        XT-PIC  ide1
NMI:    0
ERR:    0
```

Linux Filesystem Hierarchy

Each of the numbers down the left-hand column represents the interrupt that is in use. Examining the contents of the file dynamically gathers the associated data and displays it to the screen. Most of the /proc file system is read-only; however, some files allow kernel variable to be changed. This provides a mechanism to actually tune the kernel without recompiling and rebooting.

The procinfo utility summarizes /proc file system information into a display similar to the following:

```
# /usr/bin/procinfo

Linux 2.4.18 (root@DEB) (gcc 2.95.4 20011002 ) #2 1CPU [DEB. (none) ]

Memory:      Total        Used        Free        Shared       Buffers       Cached
Mem:        513908     107404    406504          0        2832     82180
Swap:       265032          0    265032

```

/proc/apm

Advanced power management info.

/proc/bus

Directory containing bus specific information.

/proc/cmdline

Kernel command line.

/proc/cpuinfo

Information about the processor, such as its type, make, model, and performance.

/proc/devices

List of device drivers configured into the currently running kernel (block and character).

/proc/dma

Shows which DMA channels are being used at the moment.

/proc/driver

Various drivers grouped here, currently rtc

/proc/execdomains

Execdomains, related to security.

/proc/fb

Frame Buffer devices.

/proc/filesystems

Filesystems configured/supported into/by the kernel.

/proc/fs

File system parameters, currently nfs/exports.

/proc/ide

This subdirectory contains information about all IDE devices of which the kernel is aware. There is one subdirectory for each IDE controller, the file drivers and a link for each IDE device, pointing to

Linux Filesystem Hierarchy

the device directory in the controller-specific subtree. The file drivers contains general information about the drivers used for the IDE devices. More detailed information can be found in the controller-specific subdirectories. These are named ide0, ide1 and so on. Each of these directories contains the files shown here:

```
/proc/ide/ide?/channel
    IDE channel (0 or 1)
/proc/ide/ide?/config
    Configuration (only for PCI/IDE bridge)
/proc/ide/ide?/mate
    Mate name (onchip partnered controller)
/proc/ide/ide?/model
    Type/Chipset of IDE controller
    Each device connected to a controller has a separate subdirectory in the controllers directory.
    The following files listed are contained in these directories:
/proc/ide/ide?/model/cache
    The cache.
/proc/ide/ide?/model/capacity
    Capacity of the medium (in 512Byte blocks)
/proc/ide/ide?/model/driver
    driver and version
/proc/ide/ide?/model/geometry
    physical and logical geometry
/proc/ide/ide?/model/identify
    device identify block
/proc/ide/ide?/model/media
    media type
/proc/ide/ide?/model/model
    device identifier
/proc/ide/ide?/model/settings
    device setup
/proc/ide/ide?/model/smart_thresholds
    IDE disk management thresholds
/proc/ide/ide?/model/smart_values
    IDE disk management values
```

/proc/interrupts

Shows which interrupts are in use, and how many of each there have been.

You can, for example, check which interrupts are currently in use and what they are used for by looking in the file /proc/interrupts:

```
# cat /proc/interrupts

CPU0 0: 8728810
XT-PIC timer 1: 895
XT-PIC keyboard 2:
0 XT-PIC cascade 3: 531695
XT-PIC aha152x 4: 2014133
XT-PIC serial 5: 44401
XT-PIC pcnet_cs 8: 2
XT-PIC rtc 11: 8
XT-PIC i82365 12: 182918
XT-PIC PS/2 Mouse 13: 1
XT-PIC fpu 14: 1232265
```

Linux Filesystem Hierarchy

```
XT-PIC ide0 15: 7  
XT-PIC ide1 NMI: 0
```

In 2.4 based kernels a couple of lines were added to this file LOC & ERR (this is the output of an SMP machine):

```
# cat /proc/interrupts
```

```
CPU0 CPU1  
0: 1243498 1214548 IO-APIC-edge timer  
1: 8949 8958 IO-APIC-edge keyboard  
2: 0 0 XT-PIC cascade  
5: 11286 10161 IO-APIC-edge soundblaster  
8: 1 0 IO-APIC-edge rtc  
9: 27422 27407 IO-APIC-edge 3c503  
12: 113645 113873 IO-APIC-edge PS/2 Mouse  
13: 0 0 XT-PIC fpu 14: 22491 24012 IO-APIC-edge ide0  
15: 2183 2415 IO-APIC-edge ide1  
17: 30564 30414 IO-APIC-level eth0  
18: 177 164 IO-APIC-level bttv NMI: 2457961 2457959  
LOC: 2457882 2457881 ERR: 2155
```

NMI is incremented in this case because every timer interrupt generates a NMI (Non Maskable Interrupt) which is used by the NMI Watchdog to detect lookups.

LOC is the local interrupt counter of the internal APIC of every CPU.

ERR is incremented in the case of errors in the IO-APIC bus (the bus that connects the CPUs in an SMP system). This means that an error has been detected, the IO-APIC automatically retries the transmission, so it should not be a big problem, but you should read the SMP-FAQ.

In this context it could be interesting to note the new irq directory in 2.4. It could be used to set IRQ to CPU affinity, this means that you can "hook" an IRQ to only one CPU, or to exclude a CPU from handling IRQs. The contents of the irq subdir is one subdir for each IRQ, and one file; prof_cpu_mask. For example,

```
# ls /proc/irq/ 0 10 12 14 16 18 2 4 6 8 prof_cpu_mask  
1 11 13 15 17 19 3 5 7 9
```

```
# ls /proc/irq/0/ smp_affinity
```

The contents of the prof_cpu_mask file and each smp_affinity file for each IRQ is the same by default:

```
# cat /proc/irq/0/smp_affinity  
ffffffffff
```

It's a bitmask, in which you can specify which CPUs can handle the IRQ, you can set it by doing:

```
# echo 1 > /proc/irq/prof_cpu_mask
```

This means that only the first CPU will handle the IRQ, but you can also echo 5 which means that only the first and fourth CPU can handle the IRQ. The way IRQs are routed is handled by the IO-APIC, and its Round Robin between all the CPUs which are allowed to handle it. As usual the kernel has more info than you and does a better job than you, so the defaults are the

Linux Filesystem Hierarchy

best choice for almost everyone.

/proc/iomem

Memory map.

/proc/ioports

Which I/O ports are in use at the moment.

/proc/irq

Masks for irq to cpu affinity.

/proc/isapnp

ISA PnP (Plug&Play) Info.

/proc/kcore

An image of the physical memory of the system (can be ELF or A.OUT (deprecated in 2.4)). This is exactly the same size as your physical memory, but does not really take up that much memory; it is generated on the fly as programs access it. (Remember: unless you copy it elsewhere, nothing under /proc takes up any disk space at all.)

/proc/kmsg

Messages output by the kernel. These are also routed to syslog.

/proc/ksyms

Kernel symbol table.

/proc/loadavg

The 'load average' of the system; three indicators of how much work the system has done during the last 1, 5 & 15 minutes.

/proc/locks

Kernel locks.

/proc/meminfo

Information about memory usage, both physical and swap. Concatenating this file produces similar results to using 'free' or the first few lines of 'top'.

/proc/misc

Miscellaneous pieces of information. This is for information that has no real place within the rest of the proc filesystem.

/proc/modules

Kernel modules currently loaded. Typically its output is the same as that given by the 'lsmod' command.

/proc/mounts

Mounted filesystems

/proc/mtrr

Information regarding mtrrs. (On Intel P6 family processors (Pentium Pro, Pentium II and later) the Memory Type Range Registers (MTRRs) may be used to control processor access to memory ranges. This is most useful when you have a video (VGA) card on a PCI or AGP bus. Enabling write-combining allows bus write transfers to be combined into a larger transfer before bursting over the PCI/AGP bus. This can increase performance of image write operations 2.5 times or more. The Cyrix 6x86, 6x86MX and M II processors have Address Range Registers (ARRs) which provide a similar functionality to MTRRs. For these, the ARRs are used to emulate the MTRRs. The AMD K6-2 (stepping 8 and above) and K6-3 processors have two MTRRs. These are supported. The AMD Athlon family provide 8 Intel style MTRRs. The Centaur C6 (WinChip) has 8 MCRs, allowing write-combining. These are also supported. The VIA Cyrix III and VIA C3 CPUs offer 8 Intel style MTRRs.) For more details regarding mtrr technology see /usr/src/linux/Documentation/mtrr.txt.

/proc/net

Status information about network protocols.

IPv6 information

/proc/net/udp6

Linux Filesystem Hierarchy

- UDP sockets (IPv6).
- /proc/net/tcp6
 - TCP sockets (IPv6).
- /proc/net/raw6
 - Raw device statistics (IPv6).
- /proc/net/igmp6
 - IP multicast addresses, which this host joined (IPv6).
- /proc/net/if_inet6
 - List of IPv6 interface addresses.
- /proc/net/ipv6_route
 - Kernel routing table for IPv6.
- /proc/net/rt6_stats
 - Global IPv6 routing tables statistics.
- /proc/net/sockstat6
 - Socket statistics (IPv6).
- /proc/net/snmp6
 - Snmp data (IPv6).

General Network information

- /proc/net/arp
 - Kernel ARP table.
- /proc/net/dev
 - network devices with statistics.
- /proc/net/dev_mcast
 - the Layer2 multicast groups which a device is listening to (interface index, label, number of references, number of bound addresses).
- /proc/net/dev_stat
 - network device status.
- /proc/net/ip_fwchains
 - Firewall chain linkage.
- /proc/net/ip_fwnames
 - Firewall chain names.
- /proc/net/ip_masq
 - Directory containing the masquerading tables.
- /proc/net/ip_masquerade
 - Major masquerading table.
- /proc/net/netstat
 - Network statistics.
- /proc/net/raw
 - raw device statistics.
- /proc/net/route
 - Kernel routing table.
- /proc/net/rpc
 - Directory containing rpc info.
- /proc/net/rt_cache
 - Routing cache.
- /proc/net/snmp
 - SNMP data.
- /proc/net/sockstat
 - Socket statistics.
- /proc/net/tcp

Linux Filesystem Hierarchy

TCP sockets.

/proc/net/tr_rif
Token ring RIF routing table.

/proc/net/udp
UDP sockets.

/proc/net/unix
UNIX domain sockets.

/proc/net/wireless
Wireless interface data (Wavelan etc).

/proc/net/igmp
IP multicast addresses, which this host joined.

/proc/net/psched
Global packet scheduler parameters.

/proc/net/netlink
List of PF_NETLINK sockets.

/proc/net/ip_mr_vifs
List of multicast virtual interfaces.

/proc/net/ip_mr_cache
List of multicast routing cache.

You can use this information to see which network devices are available in your system and how much traffic was routed over those devices. In addition, each Channel Bond interface has its own directory. For example, the bond0 device will have a directory called /proc/net/bond0/. It will contain information that is specific to that bond, such as the current slaves of the bond, the link status of the slaves, and how many times the slaves link has failed.

/proc/parport
The directory /proc/parport contains information about the parallel ports of your system. It has one subdirectory for each port, named after the port number (0,1,2,...).

/proc/parport/autoprobe
Any IEEE-1284 device ID information that has been acquired.

/proc/parport/devices
list of the device drivers using that port. A + will appear by the name of the device currently using the port (it might not appear against any).

/proc/parport/hardware
Parallel port's base address, IRQ line and DMA channel.

/proc/parport/irq
IRQ that parport is using for that port. This is in a separate file to allow you to alter it by writing a new value in (IRQ number or none).

/proc/partitions
Table of partitions known to the system

/proc/pci, /proc/bus/pci
Deprecated info of PCI bus.

/proc/rtc
Real time clock

/proc/scsi
If you have a SCSI host adapter in your system, you'll find a subdirectory named after the driver for this adapter in /proc/scsi. You'll also see a list of all recognized SCSI devices in /proc/scsi. The directory named after the driver has one file for each adapter found in the system. These files contain information about the controller, including the used IRQ and the IO address range. The amount of information shown is dependent on the adapter you use.

Linux Filesystem Hierarchy

/proc/self

A symbolic link to the process directory of the program that is looking at /proc. When two processes look at /proc, they get different links. This is mainly a convenience to make it easier for programs to get at their process directory.

/proc/slabinfo

The slabinfo file gives information about memory usage at the slab level. Linux uses slab pools for memory management above page level in version 2.2. Commonly used objects have their own slab pool (such as network buffers, directory cache, and so on).

/proc/stat

Overall/various statistics about the system, such as the number of page faults since the system was booted.

/proc/swaps

Swap space utilization

/proc/sys

This is not only a source of information, it also allows you to change parameters within the kernel without the need for recompilation or even a system reboot. Take care when attempting this as it can both optimize your system and also crash it. It is advisable to read both documentation and source before actually making adjustments. The entries in /proc may change slightly between kernel versions, so if there is any doubt review the kernel documentation in the directory

/usr/src/linux/Documentation. Under some circumstances, you may have no alternative but to reboot the machine once an error occurs. To change a value, simply echo the new value into the file. An example is given below in the section on the file system data. Of course, you need to be 'root' to do any of this. You can create your own boot script to perform this every time your system boots.

/proc/sys/fs

Contains file system data. This subdirectory contains specific file system, file handle, inode, dentry and quota information.

dentry-state

Status of the directory cache. Since directory entries are dynamically allocated and deallocated, this file indicates the current status. It holds six values, in which the last two are not used and are always zero. The others are listed below:

File	Content
nr_dentry	Almost always zero
nr_unused	Number of unused cache entries
age_limit	in seconds after the entry may be reclaimed, when memory is short want_pages internally

dquot-max

The file dquot-max shows the maximum number of cached disk quota entries.

dquot-nr

shows the number of allocated disk quota entries and the number of free disk quota entries. If the number of available cached disk quotas is very low and you have a large number of simultaneous system users, you might want to raise the limit.

file-nr and file-max

The kernel allocates file handles dynamically, but doesn't free them again at this time. The value in file-max denotes the maximum number of file handles that the Linux kernel will allocate. When you get a lot of error messages about running out of file handles, you might want to raise this limit. The default value is 4096. To change it, just write the new number into the file:

Linux Filesystem Hierarchy

```
# cat /proc/sys/fs/file-max
4096
# echo 8192 > /proc/sys/fs/file-max
# cat /proc/sys/fs/file-max
8192
```

This method of revision is useful for all customizable parameters of the kernel – simply echo the new value to the corresponding file.

The three values in file-nr denote the number of allocated file handles, the number of used file handles, and the maximum number of file handles. When the allocated file handles come close to the maximum, but the number of actually used handles is far behind, you've encountered a peak in your usage of file handles and you don't need to increase the maximum. inode-state, inode-nr and inode-max

As with file handles, the kernel allocates the inode structures dynamically, but can't free them yet.

The value in inode-max denotes the maximum number of inode handlers. This value should be 3 to 4 times larger than the value in file-max, since stdin, stdout, and network sockets also need an inode struct to handle them. If you regularly run out of inodes, you should increase this value.

The file inode-nr contains the first two items from inode-state, so we'll skip to that file... inode-state contains three actual numbers and four dummy values. The numbers are nr_inodes, nr_free_inodes, and preshrink (in order of appearance).

nr_inodes

Denotes the number of inodes the system has allocated. This can be slightly more than inode-max because Linux allocates them one pageful at a time.

nr_free_inodes

Represents the number of free inodes and preshrink is nonzero when nr_inodes is greater than inode-max and the system needs to prune the inode list instead of allocating more.

super-nr and super-max

Again, super block structures are allocated by the kernel, but not freed. The file super-max contains the maximum number of super block handlers, where super-nr shows the number of currently allocated ones. Every mounted file system needs a super block, so if you plan to mount lots of file systems, you may want to increase these numbers.

binfmt_misc

This handles the kernel support for miscellaneous binary formats. binfmt_misc provides the ability to register additional binary formats to the kernel without compiling an additional module/kernel. Therefore, binfmt_misc needs to know magic numbers at the beginning or the filename extension of the binary. It works by maintaining a linked list of structs that contain a description of a binary format, including a magic with size (or the filename extension), offset and mask, and the interpreter name. On request it invokes the given interpreter with the original program as argument, as binfmt_java and binfmt_em86 and binfmt_mz do. Since binfmt_misc does not define any default binary-formats, you have to register an additional binary-format. There are two general files in binfmt_misc and one file per registered format. The two general files are register and status. To register a new binary format you have to issue the command echo :name:type:offset:magic:mask:interpreter: > /proc/sys/fs/binfmt_misc/register with appropriate name (the name for the /proc-dir entry), offset (defaults to 0, if omitted), magic, mask (which can be omitted, defaults to all 0xff) and last but not least, the interpreter that is to be invoked (for example and testing /bin/echo).

Type can be M for usual magic matching or E for filename extension matching (give extension in place of magic). If you do a cat on the file /proc/sys/fs/binfmt_misc/status, you will get the current status (enabled/disabled) of binfmt_misc. Change the status by echoing 0 (disables) or 1 (enables) or -1 (caution: this clears all previously registered binary formats) to

Linux Filesystem Hierarchy

status. For example echo 0 > status to disable binfmt_misc (temporarily). Each registered handler has an entry in /proc/sys/fs/binfmt_misc. These files perform the same function as status, but their scope is limited to the actual binary format. By 'cating' this file, you also receive all related information about the interpreter/magic of the binfmt. An example of the usage of binfmt_misc (emulate binfmt_java) follows:

```
cd /proc/sys/fs/binfmt_misc
echo ':Java:M::\xca\xfe\xba\xbe:::/usr/local/java/bin/javawrapper:' > register
echo ':HTML:E::html:::/usr/local/java/bin/appletviewer:' > register
echo ':Applet:M::<!--applet:::/usr/local/java/bin/appletviewer:' > register
echo ':DExE:M::\x0eDEX:::/usr/bin/dosexec:' < register
```

These four lines add support for Java executables and Java applets (like binfmt_java, additionally recognizing the .html extension with no need to put <!--applet> to every applet file). You have to install the JDK and the shell-script /usr/local/java/bin/javawrapper too. It works around the brokenness of the Java filename handling. To add a Java binary, just create a link to the class-file somewhere in the path.

/proc/sys/kernel

This directory reflects general kernel behaviors and the contents will be dependent upon your configuration. Here you'll find the most important files, along with descriptions of what they mean and how to use them.

/proc/sys/kernel/acct

The file contains three values; highwater, lowwater, and frequency. It exists only when BSD-style process accounting is enabled. These values control its behavior. If the free space on the file system where the log lives goes below lowwater percentage, accounting suspends. If it goes above highwater percentage, accounting resumes. Frequency determines how often you check the amount of free space (value is in seconds). Default settings are: 4, 2, and 30. That is, suspend accounting if there is less than 2 percent free; resume it if we have a value of 3 or more percent; consider information about the amount of free space valid for 30 seconds

/proc/sys/kernel/ctrl-alt-del

When the value in this file is 0, ctrl-alt-del is trapped and sent to the init program to handle a graceful restart. However, when the value is greater than zero, Linux's reaction to this key combination will be an immediate reboot, without syncing its dirty buffers. It should be noted that when a program (like dosemu) has the keyboard in raw mode, the ctrl-alt-del is intercepted by the program before it ever reaches the kernel tty layer, and it is up to the program to decide what to do with it.

/proc/sys/kernel/domainname, /proc/sys/kernel/hostname

These files can be controlled to set the NIS domainname and hostname of your box. For the classic darkstar.frop.org a simple: # echo "darkstar" > /proc/sys/kernel/hostname # echo "frop.org" > /proc/sys/kernel/domainname would suffice to set your hostname and NIS domainname. /proc/sys/kernel/osrelease, /proc/sys/kernel/ostype, /proc/sys/kernel/version The names make it pretty obvious what these fields contain: # cat /proc/sys/kernel/osrelease 2.2.12 # cat /proc/sys/kernel/ostype Linux # cat /proc/sys/kernel/version #4 Fri Oct 1 12:41:14 PDT 1999 The files osrelease and ostype should be clear enough. Version needs a little more clarification. The #4 means that this is the 4th kernel built from this source base and the date after it indicates the time the kernel was built. The only way to tune these values is to rebuild the kernel.

/proc/sys/kernel/panic

Linux Filesystem Hierarchy

The value in this file represents the number of seconds the kernel waits before rebooting on a panic. When you use the software watchdog, the recommended setting is 60. If set to 0, the auto reboot after a kernel panic is disabled, which is the default setting.

/proc/sys/kernel/printk

The four values in printk denote * console_loglevel, * default_message_loglevel, * minimum_console_level and * default_console_loglevel respectively. These values influence printk() behavior when printing or logging error messages, which come from inside the kernel. See syslog(2) for more information on the different log levels.

/proc/sys/kernel/console_loglevel

Messages with a higher priority than this will be printed to the console.

/proc/sys/kernel/default_message_level

Messages without an explicit priority will be printed with this priority.

/proc/sys/kernel/minimum_console_loglevel

Minimum (highest) value to which the console_loglevel can be set.

/proc/sys/kernel/default_console_loglevel

Default value for console_loglevel.

/proc/sys/kernel/sg-big-buff

This file shows the size of the generic SCSI (sg) buffer. At this point, you can't tune it yet, but you can change it at compile time by editing include/scsi/sg.h and changing the value of SG_BIG_BUFF. If you use a scanner with SANE (Scanner Access Now Easy) you might want to set this to a higher value. Refer to the SANE documentation on this issue.

/proc/sys/kernel/modprobe

The location where the modprobe binary is located. The kernel uses this program to load modules on demand.

/proc/sys/vm

The files in this directory can be used to tune the operation of the virtual memory (VM) subsystem of the Linux kernel. In addition, one of the files (bdflush) has some influence on disk usage.

nfract

This parameter governs the maximum number of dirty buffers in the buffer cache. Dirty means that the contents of the buffer still have to be written to disk (as opposed to a clean buffer, which can just be forgotten about). Setting this to a higher value means that Linux can delay disk writes for a long time, but it also means that it will have to do a lot of I/O at once when memory becomes short. A lower value will spread out disk I/O more evenly.

ndirty

Ndirty gives the maximum number of dirty buffers that bdflush can write to the disk at one time. A high value will mean delayed, bursty I/O, while a small value can lead to memory shortage when bdflush isn't woken up often enough.

nrefill

This is the number of buffers that bdflush will add to the list of free buffers when refill_freelist() is called. It is necessary to allocate free buffers beforehand, since the buffers are often different sizes than the memory pages and some bookkeeping needs to be done beforehand. The higher the number, the more memory will be wasted and the less often refill_freelist() will need to run.

nref_dirt

When refill_freelist() comes across more than nref_dirt dirty buffers, it will wake up bdflush.

age_buffer, age_super

Finally, the age_buffer and age_super parameters govern the maximum time Linux waits before writing out a dirty buffer to disk. The value is expressed in jiffies (clockticks), the number of jiffies per second is 100. Age_buffer is the maximum age for data blocks, while age_super is for filesystems meta data.

buffermem

Linux Filesystem Hierarchy

The three values in this file control how much memory should be used for buffer memory. The percentage is calculated as a percentage of total system memory.

The values are:

`min_percent`

This is the minimum percentage of memory that should be spent on buffer memory.

`borrow_percent`

When Linux is short on memory, and the buffer cache uses more than it has been allotted, the memory management (MM) subsystem will prune the buffer cache more heavily than other memory to compensate.

`max_percent`

This is the maximum amount of memory that can be used for buffer memory.

`freepages`

This file contains three values: min, low and high:

`min`

When the number of free pages in the system reaches this number, only the kernel can allocate more memory.

`low`

If the number of free pages falls below this point, the kernel starts swapping aggressively.

`high`

The kernel tries to keep up to this amount of memory free; if memory falls below this point, the kernel starts gently swapping in the hopes that it never has to do really aggressive swapping.

`kswapd`

Kswapd is the kernel swap out daemon. That is, kswapd is that piece of the kernel that frees memory when it gets fragmented or full. Since every system is different, you'll probably want some control over this piece of the system.

The file contains three numbers:

`tries_base`

The maximum number of pages kswapd tries to free in one round is calculated from this number. Usually this number will be divided by 4 or 8 (see mm/vmscan.c), so it isn't as big as it looks. When you need to increase the bandwidth to/from swap, you'll want to increase this number.

`tries_min`

This is the minimum number of times kswapd tries to free a page each time it is called.

Basically it's just there to make sure that kswapd frees some pages even when it's being called with minimum priority.

`swap_cluster`

This is probably the greatest influence on system performance. `swap_cluster` is the number of pages kswapd writes in one turn. You'll want this value to be large so that kswapd does its I/O in large chunks and the disk doesn't have to seek as often, but you don't want it to be too large since that would flood the request queue.

`overcommit_memory`

This file contains one value. The following algorithm is used to decide if there's enough memory: if the value of `overcommit_memory` is positive, then there's always enough memory. This is a useful feature, since programs often malloc() huge amounts of memory 'just in case', while they only use a small part of it. Leaving this value at 0 will lead to the failure of such a huge malloc(), when in fact the system has enough memory for the program to run. On the other hand, enabling this feature can cause you to run out of memory and thrash the system to death, so large and/or important servers will want to set this value to 0.

`pagecache`

Linux Filesystem Hierarchy

This file does exactly the same job as buffermem, only this file controls the amount of memory allowed for memory mapping and generic caching of files. You don't want the minimum level to be too low, otherwise your system might thrash when memory is tight or fragmentation is high.

pagetable_cache

The kernel keeps a number of page tables in a per-processor cache (this helps a lot on SMP systems). The cache size for each processor will be between the low and the high value. On a low-memory, single CPU system, you can safely set these values to 0 so you don't waste memory. It is used on SMP systems so that the system can perform fast pagetable allocations without having to acquire the kernel memory lock. For large systems, the settings are probably fine. For normal systems they won't hurt a bit. For small systems (less than 16MB ram) it might be advantageous to set both values to 0.

swapctl

This file contains no less than 8 variables. All of these values are used by kswapd. The first four variables sc_max_page_age, sc_page_advance, sc_page_decline and sc_page_initial_age are used to keep track of Linux's page aging. Page ageing is a bookkeeping method to track which pages of memory are often used, and which pages can be swapped out without consequences.

When a page is swapped in, it starts at sc_page_initial_age (default 3) and when the page is scanned by kswapd, its age is adjusted according to the following scheme.

If the page was used since the last time we scanned, its age is increased by sc_page_advance (default 3). Where the maximum value is given by sc_max_page_age (default 20). Otherwise (meaning it wasn't used) its age is decreased by sc_page_decline (default 1).

When a page reaches age 0, it's ready to be swapped out.

The variables sc_age_cluster_fract, sc_age_cluster_min, sc_pageout_weight and sc_bufferout_weight, can be used to control kswapd's aggressiveness in swapping out pages. Sc_age_cluster_fract is used to calculate how many pages from a process are to be scanned by kswapd. The formula used is

(sc_age_cluster_fract divided by 1024) times resident set size

So if you want kswapd to scan the whole process, sc_age_cluster_fract needs to have a value of 1024. The minimum number of pages kswapd will scan is represented by sc_age_cluster_min, which is done so that kswapd will also scan small processes. The values of sc_pageout_weight and sc_bufferout_weight are used to control how many tries kswapd will make in order to swap out one page/buffer. These values can be used to fine-tune the ratio between user pages and buffer/cache memory. When you find that your Linux system is swapping out too many process pages in order to satisfy buffer memory demands, you may want to either increase sc_bufferout_weight, or decrease the value of sc_pageout_weight.

/proc/sys/dev

Device specific parameters. Currently there is only support for CDROM drives, and for those, there is only one read-only file containing information about the CD-ROM drives attached to the system:
>cat /proc/sys/dev/cdrom/info
CD-ROM information, Id: cdrom.c 2.55 1999/04/25 drive name: sr0
hdb drive speed: 32 40 drive # of slots: 1 0 Can close tray: 1 1 Can open tray: 1 1 Can lock tray: 1 1
Can change speed: 1 1 Can select disk: 0 1 Can read multisession: 1 1 Can read MCN: 1 1 Reports media changed: 1 1 Can play audio: 1 1 You see two drives, sr0 and hdb, along with a list of their features.

SUNRPC

/proc/sys/sunrpc

This directory contains four files, which enable or disable debugging for the RPC functions NFS, NFS-daemon, RPC and NLM. The default values are 0. They can be set to one to turn debugging on. (The default value is 0 for each)

/proc/sys/net

Linux Filesystem Hierarchy

The interface to the networking parts of the kernel is located in /proc/sys/net. The following table shows all possible subdirectories. You may see only some of them, depending on your kernel's configuration. Our main focus will be on IP networking since AX15, X.25, and DEC Net are only minor players in the Linux world. Should you wish review the online documentation and the kernel source to get a detailed view of the parameters for those protocols not covered here. In this section we'll discuss the subdirectories listed above. As default values are suitable for most needs, there is no need to change these values.

GENERAL PARAMETERS

/proc/sys/net/core	Network core options
rmem_default	The default setting of the socket receive buffer in bytes.
rmem_max	The maximum receive socket buffer size in bytes.
wmem_default	The default setting (in bytes) of the socket send buffer.
wmem_max	The maximum send socket buffer size in bytes.
message_burst and message_cost	These parameters are used to limit the warning messages written to the kernel log from the networking code. They enforce a rate limit to make a denial-of-service attack impossible. A higher message_cost factor, results in fewer messages that will be written. Message_burst controls when messages will be dropped. The default settings limit warning messages to one every five seconds.
netdev_max_backlog	Maximum number of packets, queued on the INPUT side, when the interface receives packets faster than kernel can process them.
optmem_max	Maximum ancillary buffer size allowed per socket. Ancillary data is a sequence of struct cmsghdr structures with appended data.

UNIX DOMAIN SOCKETS

/proc/sys/net/unix	Parameters for Unix domain sockets
	There are only two files in this subdirectory. They control the delays for deleting and destroying socket descriptors.

IPv4

/proc/sys/net/ipv4	IPV4 settings. IP version 4 is still the most used protocol in Unix networking. It will be replaced by IP version 6 in the next couple of years, but for the moment it's the de facto standard for the internet and is used in most networking environments around the world. Because of the importance of this protocol, we'll have a deeper look into the subtree controlling the behavior of the Ipv4 subsystem of the Linux kernel.
	Let's start with the entries in /proc/sys/net/ipv4.

ICMP settings

icmp_echo_ignore_all and icmp_echo_ignore_broadcasts	Turn on (1) or off (0), if the kernel should ignore all ICMP ECHO requests, or just those to broadcast and multicast addresses.
--	---

Linux Filesystem Hierarchy

Please note that if you accept ICMP echo requests with a broadcast/multi\–cast destination address your network may be used as an exploder for denial of service packet flooding attacks to other hosts.

icmp_destunreach_rate, icmp_echo_reply_rate, icmp_paramprob_rate and icmp_timeexceed_rate

Sets limits for sending ICMP packets to specific targets. A value of zero disables all limiting. Any positive value sets the maximum package rate in hundredth of a second (on Intel systems).

IP settings

ip_autoconfig

This file contains the number one if the host received its IP configuration by RARP, BOOTP, DHCP or a similar mechanism. Otherwise it is zero.

ip_default_ttl

TTL (Time To Live) for IPv4 interfaces. This is simply the maximum number of hops a packet may travel.

ip_dynaddr

Enable dynamic socket address rewriting on interface address change. This is useful for dialup interface with changing IP addresses.

ip_forward

Enable or disable forwarding of IP packages between interfaces. Changing this value resets all other parameters to their default values. They differ if the kernel is configured as host or router.

ip_local_port_range

Range of ports used by TCP and UDP to choose the local port. Contains two numbers, the first number is the lowest port, the second number the highest local port. Default is 1024–4999. Should be changed to 32768–61000 for high–usage systems.

ip_no_pmtu_disc

Global switch to turn path MTU discovery off. It can also be set on a per socket basis by the applications or on a per route basis.

ip_masq_debug

Enable/disable debugging of IP masquerading.

IP fragmentation settings

ipfrag_high_trash and ipfrag_low_trash

Maximum memory used to reassemble IP fragments. When ipfrag_high_trash bytes of memory is allocated for this purpose, the fragment handler will toss packets until ipfrag_low_trash is reached.

ipfrag_time

Time in seconds to keep an IP fragment in memory.

TCP settings

tcp_ecn

This file controls the use of the ECN bit in the IPv4 headers, this is a new feature about Explicit Congestion Notification, but some routers and firewalls block traffic that has this bit set, so it could be necessary to echo 0 to /proc/sys/net/ipv4/tcp_ecn, if you want to talk to this sites. For more info you could read RFC2481.

tcp_retrans_collapse

Bug-to-bug compatibility with some broken printers. On retransmit, try to send larger packets to work around bugs in certain TCP stacks. Can be turned off by setting it to zero.

tcp_keepalive_probes

Number of keep alive probes TCP sends out, until it decides that the connection is broken.

Linux Filesystem Hierarchy

tcp_keepalive_time

How often TCP sends out keep alive messages, when keep alive is enabled. The default is 2 hours.

tcp_syn_retries

Number of times initial SYNs for a TCP connection attempt will be retransmitted. Should not be higher than 255. This is only the timeout for outgoing connections, for incoming connections the number of retransmits is defined by tcp_retries1.

tcp_sack

Enable select acknowledgments after RFC2018.

tcp_timestamps

Enable timestamps as defined in RFC1323.

tcp_stdurg

Enable the strict RFC793 interpretation of the TCP urgent pointer field. The default is to use the BSD compatible interpretation of the urgent pointer pointing to the first byte after the urgent data. The RFC793 interpretation is to have it point to the last byte of urgent data.

Enabling this option may lead to interoperability problems. Disabled by default.

tcp_syncookies

Only valid when the kernel was compiled with CONFIG_SYNCOOKIES. Send out syncookies when the syn backlog queue of a socket overflows. This is to ward off the common 'syn flood attack'. Disabled by default. Note that the concept of a socket backlog is abandoned. This means the peer may not receive reliable error messages from an over loaded server with syncookies enabled.

tcp_window_scaling

Enable window scaling as defined in RFC1323.

tcp_fin_timeout

The length of time in seconds it takes to receive a final FIN before the socket is always closed. This is strictly a violation of the TCP specification, but required to prevent denial-of-service attacks.

tcp_max_ka_probes

Indicates how many keep alive probes are sent per slow timer run. Should not be set too high to prevent bursts.

tcp_max_syn_backlog

Length of the per socket backlog queue. Since Linux 2.2 the backlog specified in listen(2) only specifies the length of the backlog queue of already established sockets. When more connection requests arrive Linux starts to drop packets. When syncookies are enabled the packets are still answered and the maximum queue is effectively ignored.

tcp_retries1

Defines how often an answer to a TCP connection request is retransmitted before giving up.

tcp_retries2

Defines how often a TCP packet is retransmitted before giving up.

/proc/sys/net/ipv4/conf

Here you'll find one subdirectory for each interface the system knows about and one directory called all. Changes in the all subdirectory affect all interfaces, whereas changes in the other subdirectories affect only one interface. All directories have the same entries:

accept_redirects

This switch decides if the kernel accepts ICMP redirect messages or not. The default is 'yes' if the kernel is configured for a regular host and 'no' for a router configuration.

accept_source_route

Should source routed packages be accepted or declined. The default is dependent on the kernel configuration. It's 'yes' for routers and 'no' for hosts.

bootp_relay

Linux Filesystem Hierarchy

Accept packets with source address 0.b.c.d with destinations not to this host as local ones. It is supposed that a BOOTP relay daemon will catch and forward such packets. The default is 0.

forwarding

Enable or disable IP forwarding on this interface.

log_martians

Log packets with source addresses with no known route to kernel log.

mc_forwarding

Do multicast routing. The kernel needs to be compiled with CONFIG_MROUTE and a multicast routing daemon is required.

proxy_arp

Does (1) or does not (0) perform proxy ARP.

rp_filter

Integer value determines if a source validation should be made. 1 means yes, 0 means no.

Disabled by default, but local/broadcast address spoofing is always on. If you set this to 1 on a router that is the only connection for a network to the net, it will prevent spoofing attacks against your internal networks (external addresses can still be spoofed), without the need for additional firewall rules.

secure_redirects

Accept ICMP redirect messages only for gateways, listed in default gateway list. Enabled by default.

shared_media

If it is not set the kernel does not assume that different subnets on this device can communicate directly. Default setting is 'yes'.

send_redirects

Determines whether to send ICMP redirects to other hosts.

Routing settings

The directory /proc/sys/net/ipv4/route contains several file to control routing issues.

error_burst and error_cost

These parameters are used to limit the warning messages written to the kernel log from the routing code. The higher the error_cost factor is, the fewer messages will be written.

Error_burst controls when messages will be dropped. The default settings limit warning messages to one every five seconds.

flush

Writing to this file results in a flush of the routing cache.

gc_elastic, gc_interval, gc_min_interval, gc_tresh, gc_timeout

Values to control the frequency and behavior of the garbage collection algorithm for the routing cache.

max_size

Maximum size of the routing cache. Old entries will be purged once the cache reached has this size.

max_delay, min_delay

Delays for flushing the routing cache.

redirect_load, redirect_number

Factors which determine if more ICPM redirects should be sent to a specific host. No redirects will be sent once the load limit or the maximum number of redirects has been reached.

redirect_silence

Timeout for redirects. After this period redirects will be sent again, even if this has been stopped, because the load or number limit has been reached.

/proc/sys/net/ipv4/neigh

Linux Filesystem Hierarchy

Network Neighbor handling. It contains settings about how to handle connections with direct neighbors (nodes attached to the same link). As we saw it in the conf directory, there is a default subdirectory which holds the default values, and one directory for each interface. The contents of the directories are identical, with the single exception that the default settings contain additional options to set garbage collection parameters.

In the interface directories you'll find the following entries:

`base_reachable_time`

A base value used for computing the random reachable time value as specified in RFC2461.
`retrans_time`

The time, expressed in jiffies (1/100 sec), between retransmitted Neighbor Solicitation messages. Used for address resolution and to determine if a neighbor is unreachable.

`unres_qlen`

Maximum queue length for a pending arp request – the number of packets which are accepted from other layers while the ARP address is still resolved.

`anycast_delay`

Maximum for random delay of answers to neighbor solicitation messages in jiffies (1/100 sec). Not yet implemented (Linux does not have anycast support yet).

`ucast_solicit`

Maximum number of retries for unicast solicitation.

`mcast_solicit`

Maximum number of retries for multicast solicitation.

`delay_first_probe_time`

Delay for the first time probe if the neighbor is reachable. (see `gc_stale_time`)

`locktime`

An ARP/neighbor entry is only replaced with a new one if the old is at least locktime old.

This prevents ARP cache thrashing.

`proxy_delay`

Maximum time (real time is random [0..proxftime]) before answering to an ARP request for which we have an proxy ARP entry. In some cases, this is used to prevent network flooding.

`proxy_qlen`

Maximum queue length of the delayed proxy arp timer. (see `proxy_delay`).

`app_solicit`

Determines the number of requests to send to the user level ARP daemon. Use 0 to turn off.

`gc_stale_time`

Determines how often to check for stale ARP entries. After an ARP entry is stale it will be resolved again (which is useful when an IP address migrates to another machine). When `ucast_solicit` is greater than 0 it first tries to send an ARP packet directly to the known host. When that fails and `mcast_solicit` is greater than 0, an ARP request is broadcasted.

APPLETALK

`/proc/sys/net/appletalk`

Holds the Appletalk configuration data when Appletalk is loaded. The configurable parameters are:

`aarp-expiry-time`

The amount of time we keep an ARP entry before expiring it. Used to age out old hosts.

`aarp-resolve-time`

The amount of time we will spend trying to resolve an Appletalk address.

`aarp-retransmit-limit`

The number of times we will retransmit a query before giving up.

`aarp-tick-time`

Controls the rate at which expires are checked.

Linux Filesystem Hierarchy

/proc/net/appletalk

Holds the list of active Appletalk sockets on a machine. The fields indicate the DDP type, the local address (in network:node format) the remote address, the size of the transmit pending queue, the size of the received queue (bytes waiting for applications to read) the state and the uid owning the socket.

/proc/net/atalk_iface

lists all the interfaces configured for appletalk. It shows the name of the interface, its Appletalk address, the network range on that address (or network number for phase 1 networks), and the status of the interface.

/proc/net/atalk_route

lists each known network route. It lists the target (network) that the route leads to, the router (may be directly connected), the route flags, and the device the route is using.

IPX

The IPX protocol has no tunable values in proc/sys/net, it does, however, provide proc/net/ipx. This lists each IPX socket giving the local and remote addresses in Novell format (that is network:node:port). In accordance with the strange Novell tradition, everything but the port is in hex. Not_Connected is displayed for sockets that are not tied to a specific remote address. The Tx and Rx queue sizes indicate the number of bytes pending for transmission and reception. The state indicates the state the socket is in and the uid is the owning uid of the socket.

ipx_interface

Lists all IPX interfaces. For each interface it gives the network number, the node number, and indicates if the network is the primary network. It also indicates which device it is bound to (or Internal for internal networks) and the Frame Type if appropriate. Linux supports 802.3, 802.2, 802.2 SNAP and DIX (Blue Book) ethernet framing for IPX.

ipx_route

Table holding a list of IPX routes. For each route it gives the destination network, the router node (or Directly) and the network address of the router (or Connected) for internal networks.

/proc/sysvipc

Info of SysVIPC Resources (msg, sem, shm) (2.4)

/proc/tty

Information about the available and actually used tty's can be found in the directory /proc/tty. You'll find entries for drivers and line disciplines in this directory.

/proc/tty/drivers

list of drivers and their usage.

/proc/tty/ldiscs

registered line disciplines.

/proc/tty/serial

usage statistic and status of single tty lines.

To see which tty's are currently in use, you can simply look into the file /proc/tty/drivers:

```
# cat /proc/tty/drivers
serial          /dev/cua      5  64-127 serial:callout
serial          /dev/ttys     4  64-127 serial
pty_slave       /dev/pts     143 0-255 pty:slave
pty_master      /dev/ptm     135 0-255 pty:master
pty_slave       /dev/pts     142 0-255 pty:slave
pty_master      /dev/ptm     134 0-255 pty:master
pty_slave       /dev/pts     141 0-255 pty:slave
pty_master      /dev/ptm     133 0-255 pty:master
pty_slave       /dev/pts     140 0-255 pty:slave
pty_master      /dev/ptm     132 0-255 pty:master
pty_slave       /dev/pts     139 0-255 pty:slave
```

Linux Filesystem Hierarchy

pty_master	/dev/ptm	131	0-255	pty:master
pty_slave	/dev/pts	138	0-255	pty:slave
pty_master	/dev/ptm	130	0-255	pty:master
pty_slave	/dev/pts	137	0-255	pty:slave
pty_master	/dev/ptm	129	0-255	pty:master
pty_slave	/dev/pts	136	0-255	pty:slave
pty_master	/dev/ptm	128	0-255	pty:master
pty_slave	/dev/ttyp	3	0-255	pty:slave
pty_master	/dev/pty	2	0-255	pty:master
/dev/vc/0	/dev/vc/0	4	0	system:vtmaster
/dev/ptmx	/dev/ptmx	5	2	system
/dev/console	/dev/console	5	1	system:console
/dev/tty	/dev/tty	5	0	system:/dev/tty
unknown	/dev/vc/%d	4	1-63	console

Note that while the above files tend to be easily readable text files, they can sometimes be formatted in a way that is not easily digestible. There are many commands that do little more than read the above files and format them for easier understanding. For example, the free program reads /proc/meminfo and converts the amounts given in bytes to kilobytes (and adds a little more information, as well).

/proc/uptime

The time the system has been up.

/proc/version

The kernel version.

/proc/video

BTTV info of video resources.

1.15. /root

This is the home directory of the System Administrator, 'root'. This may be somewhat confusing ('root on root') but in former days, '/' was root's home directory (hence the name of the Administrator account). To keep things tidier, 'root' got his own home directory. Why not in '/home'? Because '/home' is often located on a different partition or even on another system and would thus be inaccessible to 'root' when – for some reason – only '/' is mounted.

The FSSTND merely states that this is the recommended location for the home directory of 'root'. It is left up to the end user to determine the home directory of 'root'. However, the FSSTND also says that:

If the home directory of the root account is not stored on the root partition it will be necessary to make certain it will default to / if it can not be located.

We recommend against using the root account for tasks that can be performed as an unprivileged user, and that it be used solely for system administration. For this reason, we recommend that subdirectories for mail and other applications not appear in the root account's home directory, and that mail for administration roles such as root, postmaster, and webmaster be forwarded to an appropriate user.

1.16. /sbin

Linux discriminates between 'normal' executables and those used for system maintenance and/or administrative tasks. The latter reside either here or – the less important ones – in /usr/sbin. Locally installed system administration programs should be placed into /usr/local/sbin.

Programs executed after /usr is known to be mounted (when there are no problems) are generally placed into /usr/sbin. This directory contains binaries that are essential to the working of the system. These include system administration as well as maintenance and hardware configuration programs. You may find lilo, fdisk, init, ifconfig, etc.... here.

Another directory that contains system binaries is /usr/sbin. This directory contains other binaries of use to the system administrator. This is where you will find the network daemons for your system along with other binaries that (generally) only the system administrator has access to, but which are not required for system maintenance and repair. Normally, these directories are never part of normal user's \$PATHs, only of roots (PATH is an environment variable that controls the sequence of locations that the system will attempt to look in for commands).

The FSSTND states that:

```
/sbin should contain only binaries essential for booting, restoring,
recovering, and/or repairing the system in addition to the binaries
in /bin.
```

A particular eccentricity of the Linux filesystem hierarchy is that originally /sbin binaries were kept in /etc.

```
Deciding what things go into "sbin" directories is simple: if a normal
(not a system administrator) user will ever run it directly, then it
must be placed in one of the "bin" directories. Ordinary users should
not have to place any of the sbin directories in their path.
```

```
For example, files such as chfn which users only occasionally use must
still be placed in /usr/bin. ping, although it is absolutely necessary
for root (network recovery and diagnosis) is often used by users and
must live in /bin for that reason.
```

```
We recommend that users have read and execute permission for everything
in /sbin except, perhaps, certain setuid and setgid programs. The
division between /bin and /sbin was not created for security reasons or
to prevent users from seeing the operating system, but to provide a
good partition between binaries that everyone uses and ones that are
primarily used for administration tasks. There is no inherent security
advantage in making /sbin off-limits for users.
```

FSSTND compliance requires that the following commands, or symbolic links to commands, are required in /sbin.

```
shutdown Command to bring the system down.
```

The following files, or symbolic links to files, must be in /sbin if the corresponding subsystem is installed:

fastboot	Reboot the system without checking the disks (optional)
fasthalt	Stop the system without checking the disks (optional)
fdisk	Partition table manipulator (optional)
fsck	File system check and repair utility (optional)

Linux Filesystem Hierarchy

fsck.*	File system check and repair utility for a specific filesystem (optional)
getty	The getty program (optional)
halt	Command to stop the system (optional)
ifconfig	Configure a network interface (optional)
init	Initial process (optional)
mkfs	Command to build a filesystem (optional)
mkfs.*	Command to build a specific filesystem (optional)
mkswap	Command to set up a swap area (optional)
reboot	Command to reboot the system (optional)
route	IP routing table utility (optional)
swapon	Enable paging and swapping (optional)
swapoff	Disable paging and swapping (optional)
update	Daemon to periodically flush filesystem buffers (optional)

1.17. /usr

/usr usually contains by far the largest share of data on a system. Hence, this is one of the most important directories in the system as it contains all the user binaries, their documentation, libraries, header files, etc.... X and its supporting libraries can be found here. User programs like telnet, ftp, etc.... are also placed here. In the original Unix implementations, /usr was where the home directories of the users were placed (that is to say, /usr/someone was then the directory now known as /home/someone). In current Unices, /usr is where user-land programs and data (as opposed to 'system land' programs and data) are. The name hasn't changed, but it's meaning has narrowed and lengthened from "everything user related" to "user usable programs and data". As such, some people may now refer to this directory as meaning 'User System Resources' and not 'user' as was originally intended.

/usr is shareable, read-only data. That means that /usr should be shareable between various FHS-compliant hosts and must not be written to. Any information that is host-specific or varies with time is stored elsewhere.

Large software packages must not use a direct subdirectory under the /usr hierarchy.

/usr/X11R6

Another large subdirectory structure begins here, containing libraries, executables, docs, fonts and much more concerning the X Window System. Its inclusion here is somewhat inconsistent and so is the difference between '/usr' and '/usr/X11R6' directories. One would assume that programs that run on X only have their files in the '/usr/X11R6' hierarchy, while the others use '/usr'. Regrettably, it isn't so. KDE and GNOME put their files in the '/usr' hierarchy, whereas the window manager Window Maker uses '/usr/X11R6'. Documentation files for X11R6 are not in '/usr/X11R6/doc', but primarily in '/usr/X11R6/lib/X11/doc'. This mess is due to the fact that in contrast to other operating systems, the graphical desktop isn't an integral part of the system. Linux is still primarily used on servers, where graphical systems don't make sense.

This hierarchy is reserved for the X Window System, version 11 release 6, and related files. To simplify matters and make XFree86 more compatible with the X Window System on other systems, the following symbolic links must be present if /usr/X11R6 exists:

```
/usr/bin/X11 -> /usr/X11R6/bin  
/usr/lib/X11 -> /usr/X11R6/lib/X11  
/usr/include/X11 -> /usr/X11R6/include/X11
```

In general, software must not be installed or managed via the above symbolic links. They are intended for utilization by users only. The difficulty is related to the release version of the X

Linux Filesystem Hierarchy

Window System – in transitional periods, it is impossible to know what release of X11 is in use.

/usr/X11R6/bin

XFree86 system binaries. These are necessary for the initialisation, configuration and running of the X windowing system. X, xf86config, xauth, xmodmap and even xpenguin are located here.

/usr/X11R6/include

XFree86 system header files. There are required for the compilation of some applications that utilise the X toolkit.

/usr/X11R6/lib

XFree86 system libraries.

/usr/X11R6/lib/modules

XFree86 system modules. These are the modules that X loads upon startup. Without these modules video4linux, DRI and GLX extensions and drivers for certain input devices would cease to function.

/usr/X11R6/lib/X11/fonts

XFree86 system fonts. Fonts that are utilised by 'xfs' (the X Font Server) and programs of that ilk.

/usr/bin

This directory contains the vast majority of binaries on your system. Executables in this directory vary widely. For instance vi, gcc, gnome-session and mozilla and are all found here.

/usr/doc

The central documentation directory. Documentation is actually located in /usr/share/doc and linked from here.

/usr/etc

Theoretically, that's another directory for configuration files. Virtually unused now.

/usr/games

Once upon a time, this directory contained network games files. Rarely used now.

/usr/include

The directory for 'header files', needed for compiling user space source code.

/usr/include/'package-name'

Application specific header files.

/usr/info

This directory used to contain the files for the info documentation system. Now they are in '/usr/share/info'.

/usr/lib

This directory contains program libraries. Libraries are collections of frequently used program routines.

/usr/local

The original idea behind '/usr/local' was to have a separate ('local') '/usr' directory on every machine besides '/usr', which might be just mounted read-only from somewhere else. It copies the structure of '/usr'. These days, '/usr/local' is widely regarded as a good place in which to keep self-compiled or third-party programs. The /usr/local hierarchy is for use by the system administrator when installing software locally. It needs to be safe from being overwritten when the system software is updated. It may be used for programs and data that are shareable amongst a group of hosts, but not found in /usr. Locally installed software must be placed within /usr/local rather than /usr unless it is being installed to replace or upgrade software in /usr.

/usr/man

It once held the man pages. It has been moved to /usr/share/man.

/usr/sbin

This directory contains programs for administering a system, meant to be run by 'root'. Like '/sbin', it's not part of a user's \$PATH. Examples of included binaries here are chroot, useradd, in.tftpd and pppconfig.

/usr/share

Linux Filesystem Hierarchy

This directory contains 'shareable', architecture-independent files (docs, icons, fonts etc). Note, however, that '/usr/share' is generally not intended to be shared by different operating systems or by different releases of the same operating system. Any program or package which contains or requires data that doesn't need to be modified should store that data in '/usr/share' (or '/usr/local/share', if installed locally). It is recommended that a subdirectory be used in /usr/share for this purpose."

/usr/share/doc

Location of package specific documentation files. These directories often contain useful information that might not be in the man pages. They may also contain templates and configuration files for certain utilities making configuration that much easier.

/usr/share/info

Location of 'info' pages. This style of documentation seems to be largely ignored now. Manual pages are in far greater favour.

/usr/share/man

Manual pages. They are organised into 8 sections, which are explained below.

man1: User programs

Manual pages that describe publicly accessible commands are contained in this chapter. Most program documentation that a user will need to use is located here.

man2: System calls

This section describes all of the system calls (requests for the kernel to perform operations).

man3: Library functions and subroutines

Section 3 describes program library routines that are not direct calls to kernel services. This and chapter 2 are only really of interest to programmers.

man4: Special files

Section 4 describes the special files, related driver functions, and networking support available in the system. Typically, this includes the device files found in /dev and the kernel interface to networking protocol support.

man5: File formats

The formats for many data files are documented in the section 5. This includes various include files, program output files, and system files.

man6: Games

This chapter documents games, demos, and generally trivial programs. Different people have various notions about how essential this is.

man7: Miscellaneous

Manual pages that are difficult to classify are designated as being section 7. The troff and other text processing macro packages are found here.

man8: System administration Programs

used by system administrators for system operation and maintenance are documented here. Some of these programs are also occasionally useful for normal users.

/usr/src

The 'linux' sub-directory holds the Linux kernel sources, header-files and documentation.

/usr/src/RPM

RPM provides a substructure for building RPMs from SRPMs. Organisation of this branch is fairly logical with packages being organised according to a package's architecture.

/usr/src/RPM/BUILD

A temporary store for RPM binary files that are being built from source code.

Linux Filesystem Hierarchy

/usr/src/RPM/RPMS/athlon, /usr/src/RPM/RPMS/i386, /usr/src/RPM/RPMS/i486, /usr/src/RPM/RPMS/i586,
/usr/src/RPM/RPMS/i686, /usr/src/RPM/RPMS/noarch

These directories contain architecture dependant RPM source files.

/usr/src/RPM/SOURCES

This directory contains the source TAR files, patches, and icon files for software to be packaged.

/usr/src/RPM/SPECS

RPM SPEC files. A SPEC file is a file that contains information as well as scripts that are necessary to build a package.

/usr/src/RPM/SRPMS

Contains the source RPM files which result from a build.

/usr/src/linux

Contains the source code for the Linux kernel.

/usr/src/linux/.config

The last kernel source configuration. This file is normally created through the 'make config', 'make menuconfig' or 'make xconfig' steps during kernel compilation.

/usr/src/linux/.depend, /usr/src/linux/.hdepend

'make dep' checks the dependencies of the selections you made when you created your .config file. It ensures that the required files can be found and it builds a list that is to be used during compilation.

Should this process be successful these two files are created.

/usr/src/linux/COPYING

GNU License

/usr/src/linux/CREDITS

A partial credits–file of people that have contributed to the Linux project. It is sorted by name and formatted to allow easy grepping and beautification by scripts. The fields are: name (N), email (E), web–address (W), PGP key ID and fingerprint (P), description (D), and snail–mail address (S).

/usr/src/linux/MAINTAINERS

List of maintainers and details on how to submit kernel changes.

/usr/src/linux/Makefile

Contains data necessary for compilation of a working kernel. It allows developers and end–users to compile a kernel with a few simple steps (ie. make dep, make clean, make bzImage, make modules, make modules_install) and also not have to worry about re–compiling everything from scratch if parts of it have already been done so and are up to date.

/usr/src/linux/README

These are the release notes for Linux version 2.4. Read them carefully, as they tell you what this is all about, explain how to install the kernel, and what to do if something goes wrong.

/usr/src/linux/REPORTING–BUGS

A suggested procedure for reporting Linux bugs. You aren't obliged to use the bug reporting format, it is provided as a guide to the kind of information that can be useful to developers – no more.

/usr/src/linux/Rules.make

This file contains rules which are shared between multiple Makefiles.

/usr/src/linux/Documentation

Contains documentation that may be necessary in order to re–compile a kernel. However, it also provides quite a lot of information about your Linux system in general as well. For those who wish to seek further information on the contents of this directory you may consult the

/usr/src/linux/Documentation/00–INDEX file. Further, more detailed documentation may be found in /usr/src/linux/Documentation/Docbook. Of course, the contents of this directory is written in Docbook but may be converted to pdf, ps or html using the make targets of 'pdfdocs', 'psdocs' and 'htmldocs' respectively.

/usr/tmp

User space temporary files. This directory is not found on modern distributions at all and was most likely created as a consequence of Linux's UNIX heritage.

1.18. /var

Contains variable data like system logging files, mail and printer spool directories, and transient and temporary files. Some portions of /var are not shareable between different systems. For instance, /var/log, /var/lock, and /var/run. Other portions may be shared, notably /var/mail, /var/cache/man, /var/cache/fonts, and /var/spool/news. Why not put it into /usr? Because there might be circumstances when you may want to mount /usr as read-only, e.g. if it is on a CD or on another computer. '/var' contains variable data, i.e. files and directories the system must be able to write to during operation, whereas /usr should only contain static data. Some directories can be put onto separate partitions or systems, e.g. for easier backups, due to network topology or security concerns. Other directories have to be on the root partition, because they are vital for the boot process. 'Mountable' directories are: '/home', '/mnt', '/tmp', '/usr' and '/var'. Essential for booting are: '/bin', '/boot', '/dev', '/etc', '/lib', '/proc' and '/sbin'.

If /var cannot be made a separate partition, it is often preferable to move /var out of the root partition and into the /usr partition. (This is sometimes done to reduce the size of the root partition or when space runs low in the root partition.) However, /var must not be linked to /usr because this makes separation of /usr and /var more difficult and is likely to create a naming conflict. Instead, link /var to /usr/var.

Applications must generally not add directories to the top level of /var. Such directories should only be added if they have some system-wide implication, and in consultation with the FHS mailing list.

/var/backups

Directory containing backups of various key system files such as /etc/shadow, /etc/group, /etc/inetd.conf and dpkg.status. They are normally renamed to something like dpkg.status.0, group.bak, gshadow.bak, inetd.conf.bak, passwd.bak, shadow.bak

/var/cache

Is intended for cached data from applications. Such data is locally generated as a result of time-consuming I/O or calculation. This data can generally be regenerated or be restored. Unlike /var/spool, files here can be deleted without data loss. This data remains valid between invocations of the application and rebooting of the system. The existence of a separate directory for cached data allows system administrators to set different disk and backup policies from other directories in /var.

/var/cache/fonts

Locally-generated fonts. In particular, all of the fonts which are automatically generated by mktexpk must be located in appropriately-named subdirectories of /var/cache/ fonts.

/var/cache/man

A cache for man pages that are formatted on demand. The source for manual pages is usually stored in /usr/share/man/; some manual pages might come with a pre-formatted version, which is stored in /usr/share/man/cat* (this is fairly rare now). Other manual pages need to be formatted when they are first viewed; the formatted version is then stored in /var/man so that the next person to view the same page won't have to wait for it to be formatted (/var/catman is often cleaned in the same way temporary directories are cleaned).

/var/cache/'package-name'

Package specific cache data.

/var/cache/www

WWW proxy or cache data.

/var/crash

Linux Filesystem Hierarchy

This directory will eventually hold system crash dumps. Currently, system crash dumps are not supported under Linux. However, development is already complete and is awaiting unification into the Linux kernel.

/var/db

Data bank store.

/var/games

Any variable data relating to games in /usr is placed here. It holds variable data that was previously found in /usr. Static data, such as help text, level descriptions, and so on, remains elsewhere though, such as in /usr/share/games. The separation of /var/games and /var/lib as in release FSSTND 1.2 allows local control of backup strategies, permissions, and disk usage, as well as allowing inter-host sharing and reducing clutter in /var/lib. Additionally, /var/games is the path traditionally used by BSD.

/var/lib

Holds dynamic data libraries/files like the rpm/dpkg database and game scores. Furthermore, this hierarchy holds state information pertaining to an application or the system. State information is data that programs modify while they run, and that pertains to one specific host. Users shouldn't ever need to modify files in /var/lib to configure a package's operation. State information is generally used to preserve the condition of an application (or a group of inter-related applications) between invocations and between different instances of the same application. An application (or a group of inter-related applications) use a subdirectory of /var/lib for their data. There is one subdirectory, /var/lib/misc, which is intended for state files that don't need a subdirectory; the other subdirectories should only be present if the application in question is included in the distribution. /var/lib/'name' is the location that must be used for all distribution packaging support. Different distributions may use different names, of course.

/var/local

Variable data for local programs (i.e., programs that have been installed by the system administrator) that are installed in /usr/local (as opposed to a remotely mounted '/var' partition). Note that even locally installed programs should use the other /var directories if they are appropriate, e.g., /var/lock.

/var/lock

Many programs follow a convention to create a lock file in /var/lock to indicate that they are using a particular device or file. This directory holds those lock files (for some devices) and hopefully other programs will notice the lock file and won't attempt to use the device or file.

Lock files should be stored within the /var/lock directory structure. Lock files for devices and other resources shared by multiple applications, such as the serial device lock files that were originally found in either /usr/spool/locks or /usr/spool/uucp, must now be stored in /var/lock. The naming convention which must be used is LCK.. followed by the base name of the device file. For example, to lock /dev/ttyS0 the file LCK..ttyS0 would be created. The format used for the contents of such lock files must be the HDB UUCP lock file format. The HDB format is to store the process identifier (PID) as a ten byte ASCII decimal number, with a trailing newline. For example, if process 1230 holds a lock file, it would contain the eleven characters: space, space, space, space, space, space, one, two, three, zero, and newline.

/var/log

Log files from the system and various programs/services, especially login (/var/log/wtmp, which logs all logins and logouts into the system) and syslog (/var/log/messages, where all kernel and system program message are usually stored). Files in /var/log can often grow indefinitely, and may require cleaning at regular intervals. Something that is now normally managed via log rotation utilities such as 'logrotate'. This utility also allows for the automatic rotation compression, removal and mailing of log files. Logrotate can be set to handle a log file daily, weekly, monthly or when the log file gets to a certain size. Normally, logrotate runs as a daily cron job. This is a good place to start troubleshooting general technical problems.

Linux Filesystem Hierarchy

/var/log/auth.log	Record of all logins and logouts by normal users and system processes.
/var/log/btmp	Log of all attempted bad logins to the system. Accessed via the lastb command.
/var/log/debug	Debugging output from various packages.
/var/log/dmesg	Kernel ring buffer. The content of this file is referred to by the dmesg command.
/var/log/gdm/	GDM log files. Normally a subset of the last X log file. See /var/log/xdm.log for mode details.
/var/log/kdm.log	KDM log file. Normally a subset of the last X log file. See /var/log/xdm.log for more details.
/var/log/messages	System logs.
/var/log/pacct	Process accounting is the bookkeeping of process activity. The raw data of process activity is maintained here. Three commands can be used to access the contents of this file dump-acct, sa (summary of process accounting) and lastcomm (list the commands executed on the system).
/var/log/utmp	Active user sessions. This is a data file and as such it can not be viewed normally. A human-readable form can be created via the dump-utmp command or through the w, who or users commands.
/var/log/wtmp	Log of all users who have logged into and out of the system. The last command can be used to access a human readable form of this file. It also lists every connection and run-level change.
/var/log/xdm.log	XDM log file. Normally subset of the last X startup log and pretty much useless in light of the details the X logs is able to provide us with. Only consult this file if you have XDM specific issues otherwise just use the X logfile.
/var/log/XFree86.0.log, /var/log/XFree86.?.log	X startup logfile. An excellent resource for uncovering problems with X configuration. Log files are numbered according to when they were last used. For example, the last log file would be stored in /var/log/XFree86.0.log, the next /var/log/XFree86.9.log, so on and so forth.
/var/log/syslog	The 'system' log file. The contents of this file is managed via the syslogd daemon which more often than not takes care of all log manipulation on most systems.
/var/mail	Contains user mailbox files. The mail files take the form /var/mail/'username' (Note that /var/mail may be a symbolic link to another directory). User mailbox files in this location are stored in the standard UNIX mailbox format. The reason for the location of this directory was to bring the FHS inline with nearly every UNIX implementation (it was previously located in /var/spool/mail). This change is important for inter-operability since a single /var/mail is often shared between multiple hosts and multiple UNIX implementations (despite NFS locking issues).
/var/opt	Variable data of the program packages in /opt must be installed in /var/opt/'package-name', where 'package-name' is the name of the subtree in /opt where the static data from an add-on software package is stored, except where superceded by another file in /etc. No structure is imposed on the internal arrangement of /var/opt/'package-name'.
/var/run	Contains the process identification files (PIDs) of system services and other information about the system that is valid until the system is next booted. For example, /var/run/utmp contains information about users currently logged in.

Linux Filesystem Hierarchy

/var/spool

Holds spool files, for instance for mail, news, and printing (lpd) and other queued work. Spool files store data to be processed after the job currently occupying a device is finished or the appropriate cron job is started. Each different spool has its own subdirectory below /var/spool, e.g., the cron tables are stored in /var/spool/cron/crontabs.

/var/tmp

Temporary files that are large or that need to exist for a longer time than what is allowed for /tmp.
(Although the system administrator might not allow very old files in /var/tmp either.)

/var/named

Database for BIND. The Berkeley Internet Name Domain (BIND) implements an Internet domain name server. BIND is the most widely used name server software on the Internet, and is supported by the Internet Software Consortium, www.isc.org.

/var/yp

Database for NIS (Network Information Services). NIS is mostly used to let several machines in a network share the same account information (eg. /etc/passwd). NIS was formerly called Yellow Pages (YP).

The following directories, or symbolic links to directories, are required in /var for FSSTND compliance:

/var/cache	Application cache data
/var/lib	Variable state information
/var/local	Variable data for /usr/local
/var/lock	Lock files
/var/log	Log files and directories
/var/opt	Variable data for /opt
/var/run	Data relevant to running processes
/var/spool	Application spool data
/var/tmp	Temporary files preserved between system reboots

Several directories are 'reserved' in the sense that they must not be used arbitrarily by some new application, since they would conflict with historical and/or local practice. They are:

/var/backups
/var/cron
/var-msgs
/var/preserve

The following directories, or symbolic links to directories, must be in /var, if the corresponding subsystem is installed:

account	Process accounting logs (optional)
crash	System crash dumps (optional)
games	Variable game data (optional)
mail	User mailbox files (optional)
yp	Network Information Service (NIS) database files (optional)

1.19. /srv

/srv contains site-specific data which is served by this system.

This main purpose of specifying this is so that users may find the location of the data files for particular service, and so that services which require a single tree for readonly data, writable data

Linux Filesystem Hierarchy

and scripts (such as cgi scripts) can be reasonably placed. Data that is only of interest to a specific user should go in that users' home directory.

The methodology used to name subdirectories of /srv is unspecified as there is currently no consensus on how this should be done. One method for structuring data under /srv is by protocol, eg. ftp, rsync, www, and cvs. On large systems it can be useful to structure /srv by administrative context, such as /srv/physics/www, /srv/compsci/cvs, etc. This setup will differ from host to host. Therefore, no program should rely on a specific subdirectory structure of /srv existing or data necessarily being stored in /srv. However /srv should always exist on FHS compliant systems and should be used as the default location for such data.

Distributions must take care not to remove locally placed files in these directories without administrator permission.

This is particularly important as these areas will often contain both files initially installed by the distributor, and those added by the administrator.

1.20. /tmp

This directory contains mostly files that are required temporarily. Many programs use this to create lock files and for temporary storage of data. Do not remove files from this directory unless you know exactly what you are doing! Many of these files are important for currently running programs and deleting them may result in a system crash. Usually it won't contain more than a few KB anyway. On most systems, this directory is cleared out at boot or at shutdown by the local system. The basis for this was historical precedent and common practice. However, it was not made a requirement because system administration is not within the scope of the FSSTND. For this reason people and programs must not assume that any files or directories in /tmp are preserved between invocations of the program. The reasoning behind this is for compliance with IEEE standard P1003.2 (POSIX, part 2).

Glossary

ARPA

The Advanced Research and Projects Agency of the United States Department of Defense. Also known as DARPA (the "D" stands for "Defense"), it originated in the late 1960s and early 1970s the proposal and standards for the Internet. For this reason, the Internet was initially referred to as ARPANet, and connected the military with the various centers of research around the United States in a way that was intended to have a high degree of survivability against a nuclear attack.

BASH

The Bourne Again Shell and is based on the Bourne shell, sh, the original command interpreter.

Bourne Shell

The Bourne shell is the original Unix shell (command execution program, often called a command interpreter) that was developed at AT&T. Named for its developer, Stephen Bourne, the Bourne shell is also known by its program name, sh. The shell prompt (character displayed to indicate readiness for input) used is the \$ symbol. The Bourne shell family includes the Bourne, Korn shell, bash, and zsh shells. Bourne Again Shell (bash) is the free version of the Bourne shell distributed with Linux systems. Bash is similar to the original, but has added features such as command line editing. Its name is sometimes spelled as Bourne Again SHell, the capitalized Hell referring to the difficulty some people have with it.

CLI

A CLI (command line interface) is a user interface to a computer's operating system or an application in which the user responds to a visual prompt by typing in a command on a specified line, receives a response back from the system, and then enters another command, and so forth. The MS-DOS Prompt application in a Windows operating system is an example of the provision of a command line interface. Today, most users prefer the graphical user interface (GUI) offered by Windows, Mac OS, BeOS, and others. Typically, most of today's Unix-based systems offer both a command line interface and a graphical user interface.

core

A core file is created when a program terminates unexpectedly, due to a bug, or a violation of the operating system's or hardware's protection mechanisms. The operating system kills the program and creates a core file that programmers can use to figure out what went wrong. It contains a detailed description of the state that the program was in when it died. If you would like to determine what program a core file came from, use the file command, like this: \$ file core That will tell you the name of the program that produced the core dump. You may want to write the maintainer(s) of the program, telling them that their program dumped core. To Enable or Disable Core Dumps you must use the ulimit command in bash, the limit command in tcsh, or the rlimit command in ksh. See the appropriate manual page for details. This setting affects all programs run from the shell (directly or indirectly), not the whole system. If you wish to enable or disable core dumping for all processes by default, you can change the default setting in /usr/include/linux/sched.h. Refer to definition of INIT_TASK, and look also in /usr/include/linux/resource.h. PAM support optimizes the system's environment, including the amount of memory a user is allowed. In some distributions this parameter is configurable in the /etc/security/limits.conf file. For more information, refer to the Linux Administrator's Security Guide.

daemon

A process lurking in the background, usually unnoticed, until something triggers it into action. For example, the \cmd{update} daemon wakes up every thirty seconds or so to flush the buffer cache, and the \cmd{sendmail} daemon awakes whenever someone sends mail.

DARPA

The Defense Advanced Research Projects Agency is the central research and development organization for the Department of Defense (DoD). It manages and directs selected basic and applied

Linux Filesystem Hierarchy

research and development projects for DoD, and pursues research and technology where risk and payoff are both very high and where success may provide dramatic advances for traditional military roles and missions.

DHCP

Dynamic Host Control Protocol, is a protocol like BOOTP (actually dhcpcd includes much of the functionality of BOOTPD). It assigns IP addresses to clients based on lease times. DHCP is used extensively by Microsoft and more recently also by Apple. It is probably essential in any multi-platform environment.

DNS

Domain Name System translates Internet domain and host names to IP addresses. DNS implements a distributed database to store name and address information for all public hosts on the Net. DNS assumes IP addresses do not change (i.e., are statically assigned rather than dynamically assigned). The DNS database resides on a hierarchy of special-purpose servers. When visiting a Web site or other device on the Net, a piece of software called the DNS resolver (usually built into the network operating system) first contacts a DNS server to determine the server's IP address. If the DNS server does not contain the needed mapping, it will in turn forward the request to a DNS server at the next higher level in the hierarchy. After potentially several forwarding and delegation messages are sent within the DNS hierarchy, the IP address for the given host eventually is delivered to the resolver. DNS also includes support for caching requests and for redundancy. Most network operating systems allow one to enter the IP addresses of primary, secondary, and tertiary DNS servers, each of which can service initial requests from clients. Many ISPs maintain their own DNS servers and use DHCP to automatically assign the addresses of these servers to dial-in clients, so most home users need not be aware of the details behind DNS configuration. Registered domain names and addresses must be renewed periodically, and should a dispute occur between two parties over ownership of a given name, such as in trademarking, ICANN's Uniform Domain-Name Dispute-Resolution Policy can be invoked. Also known as Domain Name System, Domain Name Service, Domain Name Server.

environment variable

A variable that is available to any program that is started by the shell.

ESD

Enlightened Sound Daemon. This program is designed to mix together several digitized audio streams for playback by a single device.

filesystem

The methods and data structures that an operating system uses to keep track of files on a disk or partition; the way the files are organized on the disk. Also used to describe a partition or disk that is used to store the files or the type of the filesystem.

FSSTND

Often the group, which creates the Linux File System Structure document, or the document itself, is referred to as the 'FSSTND'. This is short for "file system standard". This document has helped to standardize the layout of file systems on Linux systems everywhere. Since the original release of the standard, most distributors have adopted it in whole or in part, much to the benefit of all Linux users. It is now often referred to as the FHS (Filesystem Hierarchy Standard) document though since its incorporation into the LSB (Linux Standards Base) Project.

GUI

Graphical User Interface. The use of pictures rather than just words to represent the input and output of a program. A program with a GUI runs under some windowing system (e.g. The X Window System, Microsoft Windows, Acorn RISC OS, NEXTSTEP). The program displays certain icons, buttons, dialogue boxes etc. in its windows on the screen and the user controls it mainly by moving a pointer on the screen (typically controlled by a mouse) and selecting certain objects by pressing buttons on the mouse while the pointer is pointing at them. Though Apple Computer would like to claim they invented the GUI with their Macintosh operating system, the concept originated in the early 1970s at Xerox's PARC laboratory.

Linux Filesystem Hierarchy

hard link

A directory entry, which maps a filename to an inode number. A file may have multiple names or hard links. The link count gives the number of names by which a file is accessible. Hard links do not allow multiple names for directories and do not allow multiple names in different filesystems.

init

'init' process is the first user level process started by the kernel. init has many important duties, such as starting getty (so that users can log in), implementing run levels, and taking care of orphaned processes. This chapter explains how init is configured and how you can make use of the different run levels. init is one of those programs that are absolutely essential to the operation of a Linux system, but that you still can mostly ignore. Usually, you only need to worry about init if you hook up serial terminals, dial-in (not dial-out) modems, or if you want to change the default run level. When the kernel has started (has been loaded into memory, has started running, and has initialized all device drivers and data structures and such), it finishes its own part of the boot process by starting a user level program, init. Thus, init is always the first process (its process number is always 1). The kernel looks for init in a few locations that have been historically used for it, but the proper location for it is /sbin/init. If the kernel can't find init, it tries to run /bin/sh, and if that also fails, the startup of the system fails. When init starts, it completes the boot process by doing a number of administrative tasks, such as checking filesystems, cleaning up /tmp, starting various services, and starting a getty for each terminal and virtual console where users should be able to log in. After the system is properly up, init restarts getty for each terminal after a user has logged out (so that the next user can log in). init also adopts orphan processes: when a process starts a child process and dies before its child, the child immediately becomes a child of init. This is important for various technical reasons, but it is good to know it, since it makes it easier to understand process lists and process tree graphs. init itself is not allowed to die. You can't kill init even with SIGKILL. There are a few variants of init available. Most Linux distributions use sysvinit (written by Miquel van Smoorenburg), which is based on the System V init design. The BSD versions of Unix have a different init. The primary difference is run levels: System V has them, BSD doesn't.

inode

An inode is the address of a disk block. When you see the inode information through ls, ls prints the address of the first block in the file. You can use this information to tell if two files are really the same file with different names (links). A file has several components: a name, contents, and administrative information such as permissions and modification times. The administrative information is stored in the inode (over the years, the hyphen fell out of "i-node"), along with essential system data such as how long it is, where on the disc the contents of the file are stored, and so on. There are three times in the inode: the time that the contents of the file were last modified (written); the time that the file was last used (read or executed); and the time that the inode itself was last changed, for example to set the permissions. Altering the contents of the file does not affect its usage time and changing the permissions affects only the inode change time. It is important to understand inodes, not only to appreciate the options on ls, but because in a strong sense the inodes are the files. All the directory hierarchy does is provide convenient names for files. The system's internal name for the file is its i-number: the number of the inode holding the file's information.

kernel

Part of an operating system that implements the interaction with hardware and the sharing of resources.

libraries

Executables should have no undefined symbols, only useful symbols; all useful programs refer to symbols they do not define (eg. printf or write). These references are resolved by pulling object files from libraries into the executable.

link

A symbolic link (alias in MacOS and shortcut under Windows) is a file that points to another file; this is a commonly used tool. A hard-link rarely created by the user, is a filename that points to a block of

Linux Filesystem Hierarchy

data that has several other filenames as well.

man page

Every version of UNIX comes with an extensive collection of online help pages called man pages (short for manual pages). The man pages are the authoritative documentation about your UNIX system. They contain complete information about both the kernel and all the utilities.

MTA

Mail Transfer Agents. Alongside the web, mail is the top reason for the popularity of the Internet. E-mail is an inexpensive and fast method of time-shifted messaging which, much like the Web, is actually based around sending and receiving plain text files. The protocol used is called the Simple Mail Transfer Protocol (SMTP). The server programs that implement SMTP to move mail from one server to another are called MTAs. Once upon a time users would have to Telnet into an SMTP server and use a command line mail program like 'mutt' or 'pine' to check their mail. Now, GUI based e-mail clients like Mozilla, Kmail and Outlook allow users to check their email off of a local SMTP sever. Additional protocols like POP3 and IMAP4 are used between the SMTP server and desktop mail client to allow clients to manipulate files on, and download from, their local mail server. The programs that implement POP3 and IMAP4 are called Mail Delivery Agents (MDAs). They are generally separate from MTAs.

NFS

Network File System, is the UNIX equivalent of Server Message Block (SMB). It is a way through which different machines can import and export local files between each other. Like SMB though, NFS sends information including user passwords unencrypted, so it's best to limit its usage to within your local network.

operating system

Software that shares a computer system's resources (processor, memory, disk space, network bandwidth, and so on) between users and the application programs they run. Controls access to the system to provide security.

PAM

Pluggable Authentication Modules. A suite of shared libraries that determine how a user will be authenticated. For example, conventionally UNIX users authenticate themselves by supplying a password at the password prompt after they have typed their name at the login prompt. In many circumstances, such as internal access to workstations, this simple form of authentication is considered sufficient. In other cases, more information is warranted. If a user wants to log in to an internal system from an external source, like the Internet, more or alternative information may be required – perhaps a one-time password. PAM provides this type of capability and much more. Most important, PAM modules allow you to configure your environment with the necessary level of security.

PATH

The shell looks for commands and programs in a list of file paths stored in the PATH environment variable. An environment variable stores information in a place where other programs and commands can access it. Environment variables store information such as the shell that you are using, your login name, and your current working directory. To see a list of all the environment variables currently defined; type 'set' at the prompt. When you type a command at the shell prompt, the shell will look for that command's program file in each directory listed in the PATH variable, in order. The first program found matching the command you typed will be run. If the command's program file is not in a directory listed in your PATH environment variable, the shell returns a "commands not found" error. By default, the shell does not look in your current working directory or your home directory for commands. This is really a security mechanism so that you don't execute programs by accident. What if a malicious user put a harmful program called ls in your home directory? If you typed ls and the shell looked for the fake program in your home directory before the real program in the /bin directory, what do you think would happen? If you thought bad things, you are on the right track. Since your PATH doesn't have the current directory as one of its search locations, programs in your current

Linux Filesystem Hierarchy

directory must be called with an absolute path of a relative path specified as './program-name'. To see what directories are part of your PATH enter this command: # echo \$PATH
/usr/local/sbin:/usr/local/bin:/usr/sbin:/usr/bin:/sbin:/bin:/usr/bin/X11

pipes and sockets

Special files that programs use to communicate with one another. They are rarely seen, but you might be able to see a socket or two in the /dev/ directory.

process identifier

Shown in the heading of the ps command as PID. The unique number assigned to every process running in the system.

rpc

Remote Procedure Calls. It enables a system to make calls to programs such as NFS across the network transparently, enabling each system to interpret the calls as if they were local. In this case, it would make exported filesystems appear as though they were local.

set group ID (SGID)

The SGID permission causes a script to run with its group set to the group of the script, rather than the group of the user who started it. It is normally considered extremely bad practice to run a program in this way as it can pose many security problems. Later versions of the Linux kernel will even prohibit the running of shell scripts that have this attribute set.

set user ID (SUID)

The SUID permission causes a script to run as the user who is the owner of the script, rather than the user who started it. It is normally considered extremely bad practice to run a program in this way as it can pose many security problems. Later versions of the Linux kernel will even prohibit the running of shell scripts that have this attribute set.

signal

Software interrupts sent to a program to indicate that an important event has occurred. The events can vary from user requests to illegal memory access errors. Some signals, like the interrupt signal, indicate that a user has asked the program to do something that is not in the usual flow of control.

SSH

The Secure Shell, or SSH, provides a way of running command line and graphical applications, and transferring files, over an encrypted connection, all that will be seen is junk. It is both a protocol and a suite of small command line applications, which can be used for various functions. SSH replaces the old Telnet application, and can be used for secure remote administration of machines across the Internet. However, it also has other features. SSH increases the ease of running applications remotely by setting up X permissions automatically. If you can log into a machine, it allows you to run a graphical application on it, unlike Telnet, which requires users to have an understanding of the X authentication mechanisms that are manipulated through the xauth and xhost commands. SSH also has inbuilt compression, which allows your graphic applications to run much faster over the network. SCP (Secure Copy) and SFTP (Secure FTP) allow transfer of files over the remote link, either via SSH's own command line utilities or graphical tools like Gnome's GFTP. Like Telnet, SSH is cross-platform. You can find SSH server and clients for Linux, Unix and all flavours of Windows, BeOS, PalmOS, Java and embedded Oses used in routers.

STDERR

Standard error. A special type of output used for error messages. The file descriptor for STDERR is 2.

STDIN

Standard input. User input is read from STDIN. The file descriptor for STDIN is 0.

STDOUT

Standard output. The output of scripts is usually to STDOUT. The file descriptor for STDOUT is 1.

symbol table

The part of an object table that gives the value of each symbol (usually as a section name and an offset) is called the symbol table. Executables may also have a symbol table, with this one giving the final values of the symbols. Debuggers use the symbol table to present addresses to the user in a

Linux Filesystem Hierarchy

symbolic, rather than a numeric form. It is possible to strip the symbol table from executables resulting in a smaller sized executable but this prevents meaningful debugging.

symbolic link or soft link

A special filetype, which is a small pointer file, allowing multiple names for the same file. Unlike hard links, symbolic links can be made for directories and can be made across filesystems. Commands that access the file being pointed to are said to follow the symbolic link. Commands that access the link itself do not follow the symbolic link.

system call

The services provided by the kernel to application programs, and the way in which they are invoked. See section 2 of the manual pages.

system program

Programs that implement high level functionality of an operating system, i.e., things that aren't directly dependent on the hardware. May sometimes require special privileges to run (e.g., for delivering electronic mail), but often just commonly thought of as part of the system (e.g., a compiler).

tcp-wrappers

Almost all of the services provided through inetd are invoked through tcp-wrappers by way of the tcp-wrappers daemon, tcpd. The tcp-wrappers mechanism provides access control list restrictions and logging for all service requests to the service it wraps. It may be used for either TCP or TCP services as long as the services are invoked through a central daemon process such as inetd. These programs log the client host name of incoming telnet, ftp, rsh, rlogin, finger etc.... requests. Security options are access control per host, domain and/or service; detection of host name spoofing or host address spoofing; booby traps to implement an early-warning system.

ZSH

Zsh was developed by Paul Falstad as a replacement for both the Bourne and C shell. It incorporates features of all the other shells (such as file name completion and a history mechanism) as well as new capabilities. Zsh is considered similar to the Korn shell. Falstad intended to create in zsh a shell that would do whatever a programmer might reasonably hope it would do. Zsh is popular with advanced users. Along with the Korn shell and the C shell, the Bourne shell remains among the three most widely used and is included with all UNIX systems. The Bourne shell is often considered the best shell for developing scripts.

Appendix A. UNIX System V Signals

<i>Symbol</i>	<i>Number</i>	<i>Action</i>	<i>Meaning</i>
SIGHUP	1	exit	Hangs up.
SIGINT	2	exit	Interrupts.
SIGQUIT	3	core dump	Quits.
SIGILL	4	core dump	Illegal instruction.
SIGTRAP	5	core dump	Trace trap.
SIGIOT	6	core dump	IOT instruction.
SIGEMT	7	core dump	MT instruction.
SIGFPE	8	core dump	Floating point exception.
SIGKILL	9	exit	Kills (cannot be caught or ignored).
SIGBUS	10	core dump	Bus error.
SIGSEGV	11	core dump	Segmentation violation.
SIGSYS	12	core dump	Bad argument to system call.
SIGPIPE	13	exit	Writes on a pipe with no one to read it.
SIGALRM	14	exit	Alarm clock.
SIGTERM	15	exit	Software termination signal.

NAME

adduser, **addgroup** – add a user or group to the system

SYNOPSIS

adduser [options] [--home DIR] [--shell SHELL] [--no-create-home] [--uid ID] [--firstuid ID] [--lastuid ID] [--ingroup GROUP | --gid ID] [--disabled-password] [--disabled-login] [--gecos GECOS] [--add_extra_groups] [--encrypt-home] user

adduser --system [options] [--home DIR] [--shell SHELL] [--no-create-home] [--uid ID] [--group | --ingroup GROUP | --gid ID] [--disabled-password] [--disabled-login] [--gecos GECOS] user

addgroup [options] [--gid ID] group

addgroup --system [options] [--gid ID] group

adduser [options] user group

COMMON OPTIONS

[--quiet] [--debug] [--force-badname] [--help|-h] [--version] [--conf FILE]

DESCRIPTION

adduser and **addgroup** add users and groups to the system according to command line options and configuration information in */etc/adduser.conf*. They are friendlier front ends to the low level tools like **useradd**, **groupadd** and **usermod** programs, by default choosing Debian policy conformant UID and GID values, creating a home directory with skeletal configuration, running a custom script, and other features. **adduser** and **addgroup** can be run in one of five modes:

Add a normal user

If called with one non-option argument and without the **--system** or **--group** options, **adduser** will add a normal user.

adduser will choose the first available UID from the range specified for normal users in the configuration file. The UID can be overridden with the **--uid** option.

The range specified in the configuration file may be overridden with the **--firstuid** and **--lastuid** options.

By default, each user in Debian GNU/Linux is given a corresponding group with the same name. User-groups allow group writable directories to be easily maintained by placing the appropriate users in the new group, setting the set-group-ID bit in the directory, and ensuring that all users use a umask of 002. If this option is turned off by setting **USERGROUPS** to *no*, all users' GIDs are set to **USERS_GID**. Users' primary groups can also be overridden from the command line with the **--gid** or **--ingroup** options to set the group by id or name, respectively. Also, users can be added to one or more groups defined in adduser.conf either by setting **ADD_EXTRA_GROUPS** to 1 in adduser.conf, or by passing **--add_extra_groups** on the commandline.

adduser will create a home directory subject to **DHOME**, **GROUPTHOMES**, and **LETTERHOMES**. The home directory can be overridden from the command line with the **--home** option, and the shell with the **--shell** option. The home directory's set-group-ID bit is set if **USERGROUPS** is *yes* so that any files created in the user's home directory will have the correct group.

adduser will copy files from **SKEL** into the home directory and prompt for finger (gecos) information and a password. The gecos may also be set with the **--gecos** option. With the **--disabled-login** option, the account will be created but will be disabled until a password is set. The **--disabled-password** option will not set a password, but login is still possible (for example with SSH RSA keys). To set up an encrypted home directory for the new user, add the **--encrypt-home** option. For more information, refer to the **-b** option of **cryptfs-setup-private(1)**.

If the file **/usr/local/sbin/adduser.local** exists, it will be executed after the user account has been set up in order to do any local setup. The arguments passed to **adduser.local** are:

username uid gid home-directory

The environment variable VERBOSE is set according to the following rule:

0 if **--quiet** is specified

1 if neither

--quiet nor **--debug** is specified

2 if **--debug** is specified

(The same applies to the variable DEBUG, but DEBUG is deprecated and will be removed in a later version of **adduser**.)

Add a system user

If called with one non-option argument and the **--system** option, **adduser** will add a system user. If a user with the same name already exists in the system uid range (or, if the uid is specified, if a user with that uid already exists), **adduser** will exit with a warning. This warning can be suppressed by adding **--quiet**.

adduser will choose the first available UID from the range specified for system users in the configuration file (FIRST_SYSTEM_UID and LAST_SYSTEM_UID). If you want to have a specific UID, you can specify it using the **--uid** option.

By default, system users are placed in the **nogroup** group. To place the new system user in an already existing group, use the **--gid** or **--ingroup** options. To place the new system user in a new group with the same ID, use the **--group** option.

A home directory is created by the same rules as for normal users. The new system user will have the shell */usr/sbin/nologin* (unless overridden with the **--shell** option), and have logins disabled. Skeletal configuration files are not copied.

Add a user group

If **adduser** is called with the **--group** option and without the **--system** option, or **addgroup** is called respectively, a user group will be added.

A GID will be chosen from the range specified for system GIDS in the configuration file (FIRST_GID, LAST_GID). To override that mechanism you can give the GID using the **--gid** option.

The group is created with no users.

Add a system group

If **addgroup** is called with the **--system** option, a system group will be added.

A GID will be chosen from the range specified for system GIDS in the configuration file (FIRST_SYSTEM_GID, LAST_SYSTEM_GID). To override that mechanism you can give the GID using the **--gid** option.

The group is created with no users.

Add an existing user to an existing group

If called with two non-option arguments, **adduser** will add an existing user to an existing group.

OPTIONS

--conf FILE

Use FILE instead of */etc/adduser.conf*.

--disabled-login

Do not run passwd to set the password. The user won't be able to use her account until the password is set.

--disabled-password

Like --disabled-login, but logins are still possible (for example using SSH RSA keys) but not using password authentication.

--force-badname

By default, user and group names are checked against the configurable regular expression **NAME_REGEX** (or **NAME_REGEX_SYSTEM** if --system is specified) specified in the configuration file. This option forces **adduser** and **addgroup** to apply only a weak check for validity of the name. **NAME_REGEX** is described in **adduser.conf(5)**.

--gecos GECOS

Set the gecos field for the new entry generated. **adduser** will not ask for finger information if this option is given.

--gid ID

When creating a group, this option forces the new groupid to be the given number. When creating a user, this option will put the user in that group.

--group

When combined with --system, a group with the same name and ID as the system user is created. If not combined with --system, a group with the given name is created. This is the default action if the program is invoked as **addgroup**.

--help Display brief instructions.**--home DIR**

Use DIR as the user's home directory, rather than the default specified by the configuration file. If the directory does not exist, it is created and skeleton files are copied.

--shell SHELL

Use SHELL as the user's login shell, rather than the default specified by the configuration file.

--ingroup GROUP

Add the new user to GROUP instead of a usergroup or the default group defined by **USERS_GID** in the configuration file. This affects the users primary group. To add additional groups, see the **add_extra_groups** option.

--no-create-home

Do not create the home directory, even if it doesn't exist.

--quiet

Suppress informational messages, only show warnings and errors.

--debug

Be verbose, most useful if you want to nail down a problem with adduser.

--system

Create a system user or group.

--uid ID

Force the new userid to be the given number. **adduser** will fail if the userid is already taken.

--firstuid ID

Override the first uid in the range that the uid is chosen from (overrides **FIRST_UID** specified in the configuration file).

--lastuid ID

Override the last uid in the range that the uid is chosen from (**LAST_UID**)

--add_extra_groups

Add new user to extra groups defined in the configuration file.

--version

Display version and copyright information.

EXIT VALUES

- 0** The user exists as specified. This can have 2 causes: The user was created by adduser or the user was already present on the system before adduser was invoked. If adduser was returning 0 , invoking adduser a second time with the same parameters as before also returns 0.
- 1** Creating the user or group failed because it was already present with other UID/GID than specified. The username or groupname was rejected because of a mismatch with the configured regular expressions, see adduser.conf(5). Adduser has been aborted by a signal.
Or for many other yet undocumented reasons which are printed to console then. You may then consider to remove **--quiet** to make adduser more verbose.

FILES

- /etc/adduser.conf
Default configuration file for adduser and addgroup
- /usr/local/sbin/adduser.local
Optional custom add-ons.

NAME

adduser, **addgroup** – add a user or group to the system

SYNOPSIS

adduser [options] [--home DIR] [--shell SHELL] [--no-create-home] [--uid ID] [--firstuid ID] [--lastuid ID] [--ingroup GROUP | --gid ID] [--disabled-password] [--disabled-login] [--gecos GECOS] [--add_extra_groups] [--encrypt-home] user

adduser --system [options] [--home DIR] [--shell SHELL] [--no-create-home] [--uid ID] [--group | --ingroup GROUP | --gid ID] [--disabled-password] [--disabled-login] [--gecos GECOS] user

addgroup [options] [--gid ID] group

addgroup --system [options] [--gid ID] group

adduser [options] user group

COMMON OPTIONS

[--quiet] [--debug] [--force-badname] [--help|-h] [--version] [--conf FILE]

DESCRIPTION

adduser and **addgroup** add users and groups to the system according to command line options and configuration information in */etc/adduser.conf*. They are friendlier front ends to the low level tools like **useradd**, **groupadd** and **usermod** programs, by default choosing Debian policy conformant UID and GID values, creating a home directory with skeletal configuration, running a custom script, and other features. **adduser** and **addgroup** can be run in one of five modes:

Add a normal user

If called with one non-option argument and without the **--system** or **--group** options, **adduser** will add a normal user.

adduser will choose the first available UID from the range specified for normal users in the configuration file. The UID can be overridden with the **--uid** option.

The range specified in the configuration file may be overridden with the **--firstuid** and **--lastuid** options.

By default, each user in Debian GNU/Linux is given a corresponding group with the same name. User-groups allow group writable directories to be easily maintained by placing the appropriate users in the new group, setting the set-group-ID bit in the directory, and ensuring that all users use a umask of 002. If this option is turned off by setting **USERGROUPS** to *no*, all users' GIDs are set to **USERS_GID**. Users' primary groups can also be overridden from the command line with the **--gid** or **--ingroup** options to set the group by id or name, respectively. Also, users can be added to one or more groups defined in adduser.conf either by setting **ADD_EXTRA_GROUPS** to 1 in adduser.conf, or by passing **--add_extra_groups** on the commandline.

adduser will create a home directory subject to **DHOME**, **GROUPTHOMES**, and **LETTERHOMES**. The home directory can be overridden from the command line with the **--home** option, and the shell with the **--shell** option. The home directory's set-group-ID bit is set if **USERGROUPS** is *yes* so that any files created in the user's home directory will have the correct group.

adduser will copy files from **SKEL** into the home directory and prompt for finger (gecos) information and a password. The gecos may also be set with the **--gecos** option. With the **--disabled-login** option, the account will be created but will be disabled until a password is set. The **--disabled-password** option will not set a password, but login is still possible (for example with SSH RSA keys). To set up an encrypted home directory for the new user, add the **--encrypt-home** option. For more information, refer to the **-b** option of **cryptfs-setup-private(1)**.

If the file **/usr/local/sbin/adduser.local** exists, it will be executed after the user account has been set up in order to do any local setup. The arguments passed to **adduser.local** are:

username uid gid home-directory

The environment variable VERBOSE is set according to the following rule:

- 0 if **--quiet** is specified
- 1 if neither
 --quiet nor **--debug** is specified
- 2 if **--debug** is specified

(The same applies to the variable DEBUG, but DEBUG is deprecated and will be removed in a later version of **adduser**.)

Add a system user

If called with one non-option argument and the **--system** option, **adduser** will add a system user. If a user with the same name already exists in the system uid range (or, if the uid is specified, if a user with that uid already exists), **adduser** will exit with a warning. This warning can be suppressed by adding **--quiet**.

adduser will choose the first available UID from the range specified for system users in the configuration file (**FIRST_SYSTEM_UID** and **LAST_SYSTEM_UID**). If you want to have a specific UID, you can specify it using the **--uid** option.

By default, system users are placed in the **nogroup** group. To place the new system user in an already existing group, use the **--gid** or **--ingroup** options. To place the new system user in a new group with the same ID, use the **--group** option.

A home directory is created by the same rules as for normal users. The new system user will have the shell */usr/sbin/nologin* (unless overridden with the **--shell** option), and have logins disabled. Skeletal configuration files are not copied.

Add a user group

If **adduser** is called with the **--group** option and without the **--system** option, or **addgroup** is called respectively, a user group will be added.

A GID will be chosen from the range specified for system GIDS in the configuration file (**FIRST_GID**, **LAST_GID**). To override that mechanism you can give the GID using the **--gid** option.

The group is created with no users.

Add a system group

If **addgroup** is called with the **--system** option, a system group will be added.

A GID will be chosen from the range specified for system GIDS in the configuration file (**FIRST_SYSTEM_GID**, **LAST_SYSTEM_GID**). To override that mechanism you can give the GID using the **--gid** option.

The group is created with no users.

Add an existing user to an existing group

If called with two non-option arguments, **adduser** will add an existing user to an existing group.

OPTIONS

--conf FILE

Use FILE instead of */etc/adduser.conf*.

--disabled-login

Do not run *passwd* to set the password. The user won't be able to use her account until the password is set.

--disabled-password

Like --disabled-login, but logins are still possible (for example using SSH RSA keys) but not using password authentication.

--force-badname

By default, user and group names are checked against the configurable regular expression **NAME_REGEX** (or **NAME_REGEX_SYSTEM** if --system is specified) specified in the configuration file. This option forces **adduser** and **addgroup** to apply only a weak check for validity of the name. **NAME_REGEX** is described in **adduser.conf(5)**.

--gecos GECOS

Set the gecos field for the new entry generated. **adduser** will not ask for finger information if this option is given.

--gid ID

When creating a group, this option forces the new groupid to be the given number. When creating a user, this option will put the user in that group.

--group

When combined with --system, a group with the same name and ID as the system user is created. If not combined with --system, a group with the given name is created. This is the default action if the program is invoked as **addgroup**.

--help Display brief instructions.**--home DIR**

Use DIR as the user's home directory, rather than the default specified by the configuration file. If the directory does not exist, it is created and skeleton files are copied.

--shell SHELL

Use SHELL as the user's login shell, rather than the default specified by the configuration file.

--ingroup GROUP

Add the new user to GROUP instead of a usergroup or the default group defined by **USERS_GID** in the configuration file. This affects the users primary group. To add additional groups, see the **add_extra_groups** option.

--no-create-home

Do not create the home directory, even if it doesn't exist.

--quiet

Suppress informational messages, only show warnings and errors.

--debug

Be verbose, most useful if you want to nail down a problem with adduser.

--system

Create a system user or group.

--uid ID

Force the new userid to be the given number. **adduser** will fail if the userid is already taken.

--firstuid ID

Override the first uid in the range that the uid is chosen from (overrides **FIRST_UID** specified in the configuration file).

--lastuid ID

Override the last uid in the range that the uid is chosen from (**LAST_UID**)

--add_extra_groups

Add new user to extra groups defined in the configuration file.

--version

Display version and copyright information.

EXIT VALUES

- 0** The user exists as specified. This can have 2 causes: The user was created by adduser or the user was already present on the system before adduser was invoked. If adduser was returning 0 , invoking adduser a second time with the same parameters as before also returns 0.
- 1** Creating the user or group failed because it was already present with other UID/GID than specified. The username or groupname was rejected because of a mismatch with the configured regular expressions, see adduser.conf(5). Adduser has been aborted by a signal.
Or for many other yet undocumented reasons which are printed to console then. You may then consider to remove **--quiet** to make adduser more verbose.

FILES

- /etc/adduser.conf
Default configuration file for adduser and addgroup
- /usr/local/sbin/adduser.local
Optional custom add-ons.

NAME

/etc/adduser.conf – configuration file for **adduser(8)** and **addgroup(8)**.

DESCRIPTION

The file */etc/adduser.conf* contains defaults for the programs **adduser(8)** , **addgroup(8)** , **deluser(8)** and **delgroup(8)**. Each line holds a single value pair in the form *option = value*. Double or single quotes are allowed around the value, as is whitespace around the equals sign. Comment lines must have a hash sign (#) in the first column.

The valid configuration options are:

DHELL

The login shell to be used for all new users. Defaults to */bin/bash*.

DHOME

The directory in which new home directories should be created. Defaults to */home*.

GROUPHOMES

If this is set to *yes*, the home directories will be created as */home/[groupname]/user*. Defaults to *no*.

LETTERHOMES

If this is set to *yes*, then the home directories created will have an extra directory inserted which is the first letter of the loginname. For example: */home/u/user*. Defaults to *no*.

SKEL The directory from which skeletal user configuration files should be copied. Defaults to */etc/skel*.

FIRST_SYSTEM_UID and LAST_SYSTEM_UID

specify an inclusive range of UIDs from which system UIDs can be dynamically allocated. Default to *100 - 999*. Please note that system software, such as the users allocated by the base-passwd package, may assume that UIDs less than 100 are unallocated.

FIRST_UID and LAST_UID

specify an inclusive range of UIDs from which normal user's UIDs can be dynamically allocated. Default to *1000 - 59999*.

FIRST_SYSTEM_GID and LAST_SYSTEM_GID

specify an inclusive range of GIDs from which system GIDs can be dynamically allocated. Default to *100 - 999*.

FIRST_GID and LAST_GID

specify an inclusive range of GIDs from which normal group's GIDs can be dynamically allocated. Default to *1000 - 59999*.

USERGROUPS

If this is set to *yes*, then each created user will be given their own group to use. If this is *no*, then each created user will be placed in the group whose GID is **USERS_GID** (see below). The default is *yes*.

USERS_GID

If **USERGROUPS** is *no*, then **USERS_GID** is the GID given to all newly-created users. The default value is *100*.

DIR_MODE

If set to a valid value (e.g. *0755* or *755*), directories created will have the specified permissions as umask. Otherwise *0755* is used as default.

SETGID_HOME

If this is set to *yes*, then home directories for users with their own group (*USERGR_OUPS=yes*) will have the setgid bit set. This was the default setting for adduser versions << 3.13. Unfortunately it has some bad side effects, so we no longer do this per default. If you want it nevertheless you can still activate it here.

QUOTAUSER

If set to a nonempty value, new users will have quotas copied from that user. The default is empty.

NAME_REGEX

User and group names are checked against this regular expression. If the name doesn't match this regexp, user and group creation in adduser is refused unless --force-badname is set. With --force-badname set, only weak checks are performed. The default is the most conservative ^[a-z][-a-z0-9]*\$. When --system is specified, NAME_REGEX_SYSTEM is used instead.

NAME_REGEX_SYSTEM

Names of system users are checked against this regular expression. If --system is supplied and the name doesn't match this regexp, user creation in adduser is refused unless --force-badname is set. With --force-badname set, only weak checks are performed. The default is as for the default NAME_REGEX but also allowing uppercase letters.

SKEL_IGNORE_REGEX

Files in /etc/skel/ are checked against this regex, and not copied to the newly created home directory if they match. This is by default set to the regular expression matching files left over from unmerged config files (dpkg-(old|new|dist)).

ADD_EXTRA_GROUPS

Setting this to something other than 0 (the default) will cause adduser to add newly created non-system users to the list of groups defined by EXTRA_GROUPS (below).

EXTRA_GROUPS

This is the list of groups that new non-system users will be added to. By default, this list is 'dialout cdrom floppy audio video plugdev users games'.

NOTES**VALID NAMES**

adduser and addgroup enforce conformity to IEEE Std 1003.1-2001, which allows only the following characters to appear in group and user names: letters, digits, underscores, periods, at signs (@) and dashes. The name may not start with a dash. The "\$" sign is allowed at the end of usernames (to conform to samba).

An additional check can be adjusted via the configuration parameter NAME_REGEX to enforce a local policy.

NAME

apt-cache – query the APT cache

SYNOPSIS

```
apt-cache [-agipns] [-o=config_string] [-c=config_file] {gencaches | showpkg pkg... | showsrc pkg... |  
stats | dump | dumpavail | unmet | search regex... |  
show pkg [{=pkg_version_number} /target_release}...] |  
depends pkg [{=pkg_version_number} /target_release}...] |  
rdepends pkg [{=pkg_version_number} /target_release}...] | pkgnames [prefix] |  
dotty pkg [{=pkg_version_number} /target_release}...] |  
xvcg pkg [{=pkg_version_number} /target_release}...] | policy [pkg...] | madisonpkg... |  
{-v | --version} | {-h | --help}}
```

DESCRIPTION

apt-cache performs a variety of operations on APT's package cache. **apt-cache** does not manipulate the state of the system but does provide operations to search and generate interesting output from the package metadata. The metadata is acquired and updated via the 'update' command of e.g. **apt-get**, so that it can be outdated if the last update is too long ago, but in exchange **apt-cache** works independently of the availability of the configured sources (e.g. offline).

Unless the **-h**, or **--help** option is given, one of the commands below must be present.

gencaches

gencaches creates APT's package cache. This is done implicitly by all commands needing this cache if it is missing or outdated.

showpkg pkg...

showpkg displays information about the packages listed on the command line. Remaining arguments are package names. The available versions and reverse dependencies of each package listed are listed, as well as forward dependencies for each version. Forward (normal) dependencies are those packages upon which the package in question depends; reverse dependencies are those packages that depend upon the package in question. Thus, forward dependencies must be satisfied for a package, but reverse dependencies need not be. For instance, **apt-cache showpkg libreadline2** would produce output similar to the following:

```
Package: libreadline2
Versions: 2.1-12(/var/state/apt/lists/foo_Packages),
Reverse Depends:
    libreadline2,libreadline2
    libreadline2-altdev,libreadline2
Dependencies:
    2.1-12 - libc5 (2 5.4.0-0) ncurses3.0 (0 (null))
Provides:
    2.1-12 -
Reverse Provides:
Thus it may be seen that libreadline2, version 2.1-12, depends on libc5 and ncurses3.0 which must be installed for libreadline2 to work. In turn, libreadline2 and libreadline2-altdev depend on libreadline2. If libreadline2 is installed, libc5 and ncurses3.0 (and ldso) must also be installed; libreadline2 and libreadline2-altdev do not have to be installed. For the specific meaning of the remainder of the output it is best to consult the apt source code.
```

stats

stats displays some statistics about the cache. No further arguments are expected. Statistics reported are:

- Total package names is the number of package names found in the cache.
- Normal packages is the number of regular, ordinary package names; these are packages that bear a one-to-one correspondence between their names and the names used by other packages

for them in dependencies. The majority of packages fall into this category.

- Pure virtual packages is the number of packages that exist only as a virtual package name; that is, packages only "provide" the virtual package name, and no package actually uses the name. For instance, "mail-transport-agent" in the Debian system is a pure virtual package; several packages provide "mail-transport-agent", but there is no package named "mail-transport-agent".
- Single virtual packages is the number of packages with only one package providing a particular virtual package. For example, in the Debian system, "X11-text-viewer" is a virtual package, but only one package, xless, provides "X11-text-viewer".
- Mixed virtual packages is the number of packages that either provide a particular virtual package or have the virtual package name as the package name. For instance, in the Debian system, "debconf" is both an actual package, and provided by the debconf-tiny package.
- Missing is the number of package names that were referenced in a dependency but were not provided by any package. Missing packages may be an evidence if a full distribution is not accessed, or if a package (real or virtual) has been dropped from the distribution. Usually they are referenced from Conflicts or Breaks statements.
- Total distinct versions is the number of package versions found in the cache. If more than one distribution is being accessed (for instance, "stable" and "unstable"), this value can be considerably larger than the number of total package names.
- Total dependencies is the number of dependency relationships claimed by all of the packages in the cache.

showsdc *pkg...*

showsdc displays all the source package records that match the given package names. All versions are shown, as well as all records that declare the name to be a binary package. Use **--only-source** to display only source package names.

dump

dump shows a short listing of every package in the cache. It is primarily for debugging.

dumpavail

dumpavail prints out an available list to stdout. This is suitable for use with **dpkg(1)** and is used by the **dselect(1)** method.

unmet

unmet displays a summary of all unmet dependencies in the package cache.

show *pkg...*

show performs a function similar to **dpkg --print-avail**; it displays the package records for the named packages.

search *regex...*

search performs a full text search on all available package lists for the POSIX regex pattern given, see **regex(7)**. It searches the package names and the descriptions for an occurrence of the regular expression and prints out the package name and the short description, including virtual package names. If **--full** is given then output identical to show is produced for each matched package, and if **--names-only** is given then the long description is not searched, only the package name and provided packages are.

Separate arguments can be used to specify multiple search patterns that are and'ed together.

depends *pkg...*

depends shows a listing of each dependency a package has and all the possible other packages that can fulfill that dependency.

rdepends *pkg...*

`rdepends` shows a listing of each reverse dependency a package has.

pkgnames [prefix]

This command prints the name of each package APT knows. The optional argument is a prefix match to filter the name list. The output is suitable for use in a shell tab complete function and the output is generated extremely quickly. This command is best used with the `--generate` option.

Note that a package which APT knows of is not necessarily available to download, installable or installed, e.g. virtual packages are also listed in the generated list.

dotty pkg...

`dotty` takes a list of packages on the command line and generates output suitable for use by `dotty` from the [GraphViz](#)^[1] package. The result will be a set of nodes and edges representing the relationships between the packages. By default the given packages will trace out all dependent packages; this can produce a very large graph. To limit the output to only the packages listed on the command line, set the APT::Cache::GivenOnly option.

The resulting nodes will have several shapes; normal packages are boxes, pure virtual packages are triangles, mixed virtual packages are diamonds, missing packages are hexagons. Orange boxes mean recursion was stopped (leaf packages), blue lines are pre-depends, green lines are conflicts.

Caution, `dotty` cannot graph larger sets of packages.

xvcg pkg...

The same as `dotty`, only for `xvcg` from the [VCG tool](#)^[2].

policy [pkg...]

`policy` is meant to help debug issues relating to the preferences file. With no arguments it will print out the priorities of each source. Otherwise it prints out detailed information about the priority selection of the named package.

madison pkg...

apt-cache's `madison` command attempts to mimic the output format and a subset of the functionality of the Debian archive management tool, `madison`. It displays available versions of a package in a tabular format. Unlike the original `madison`, it can only display information for the architecture for which APT has retrieved package lists (APT::Architecture).

OPTIONS

All command line options may be set using the configuration file, the descriptions indicate the configuration option to set. For boolean options you can override the config file by using something like `-f`, `--no-f`, `-f=no` or several other variations.

-p, --pkg-cache

Select the file to store the package cache. The package cache is the primary cache used by all operations. Configuration Item: Dir::Cache::pkgcache.

-s, --src-cache

Select the file to store the source cache. The source is used only by gencaches and it stores a parsed version of the package information from remote sources. When building the package cache the source cache is used to avoid reparsing all of the package files. Configuration Item: Dir::Cache::srccache.

-q, --quiet

Quiet; produces output suitable for logging, omitting progress indicators. More q's will produce more quietness up to a maximum of 2. You can also use `-q=#` to set the quietness level, overriding the configuration file. Configuration Item: quiet.

-i, --important

Print only important dependencies; for use with `unmet` and `depends`. Causes only `Depends` and `Pre-Depends` relations to be printed. Configuration Item: APT::Cache::Important.

--no-pre-depends, --no-depends, --no-recommends, --no-suggests, --no-conflicts,

--no-breaks, --no-replaces, --no-enhances

Per default the **depends** and **rdepends** print all dependencies. This can be tweaked with these flags which will omit the specified dependency type. Configuration Item:
APT::Cache::ShowDependencyType e.g. APT::Cache::ShowRecommends.

--implicit

Per default **depends** and **rdepends** print only dependencies explicitly expressed in the metadata. With this flag it will also show dependencies implicitly added based on the encountered data. A Conflicts: foo e.g. expresses implicitly that this package also conflicts with the package foo from any other architecture. Configuration Item: APT::Cache::ShowImplicit.

-f, --full

Print full package records when searching. Configuration Item: APT::Cache::ShowFull.

-a, --all-versions

Print full records for all available versions. This is the default; to turn it off, use **--no-all-versions**. If **--no-all-versions** is specified, only the candidate version will be displayed (the one which would be selected for installation). This option is only applicable to the show command. Configuration Item: APT::Cache::AllVersions.

-g, --generate

Perform automatic package cache regeneration, rather than use the cache as it is. This is the default; to turn it off, use **--no-generate**. Configuration Item: APT::Cache::Generate.

--names-only, -n

Only search on the package and provided package names, not the long descriptions. Configuration Item: APT::Cache::NamesOnly.

--all-names

Make pkgnames print all names, including virtual packages and missing dependencies. Configuration Item: APT::Cache::AllNames.

--recurse

Make depends and rdepends recursive so that all packages mentioned are printed once. Configuration Item: APT::Cache::RecurseDepends.

--installed

Limit the output of depends and rdepends to packages which are currently installed. Configuration Item: APT::Cache::Installed.

--with-source *filename*

Adds the given file as a source for metadata. Can be repeated to add multiple files. Supported are currently *.deb, *.dsc, *.changes, Sources and Packages files as well as source package directories. Files are matched based on their name only, not their content!

Sources and Packages can be compressed in any format apt supports as long as they have the correct extension. If you need to store multiple of these files in one directory you can prefix a name of your choice with the last character being an underscore ("_"). Example: my.example_Packages.xz

Note that these sources are treated as trusted (see **apt-secure(8)**). Configuration Item:
APT::Sources::With.

-h, --help

Show a short usage summary.

-v, --version

Show the program version.

-c, --config-file

Configuration File; Specify a configuration file to use. The program will read the default configuration file and then this configuration file. If configuration settings need to be set before the default configuration files are parsed specify a file with the **APT_CONFIG** environment variable. See

apt.conf(5) for syntax information.

-o, --option

Set a Configuration Option; This will set an arbitrary configuration option. The syntax is **-o Foo::Bar=bar**. **-o** and **--option** can be used multiple times to set different options.

FILES

/etc/apt/sources.list

Locations to fetch packages from. Configuration Item: Dir::Etc::SourceList.

/etc/apt/sources.list.d/

File fragments for locations to fetch packages from. Configuration Item: Dir::Etc::SourceParts.

/var/lib/apt/lists/

Storage area for state information for each package resource specified in **sources.list(5)** Configuration Item: Dir::State::Lists.

/var/lib/apt/lists/partial/

Storage area for state information in transit. Configuration Item: Dir::State::Lists (partial will be implicitly appended)

SEE ALSO

apt.conf(5), sources.list(5), apt-get(8)

DIAGNOSTICS

apt-cache returns zero on normal operation, decimal 100 on error.

NAME

`apt-config` – APT Configuration Query program

SYNOPSIS

```
apt-config [--empty] [--format '%f "%v";%n'] [-o=config_string] [-c=config_file] { shell | dump |
    {-v | --version} | {-h | --help} }
```

DESCRIPTION

apt-config is an internal program used by various portions of the APT suite to provide consistent configurability. It accesses the main configuration file /etc/apt/apt.conf in a manner that is easy to use for scripted applications.

Unless the **-h**, or **--help** option is given, one of the commands below must be present.

shell

shell is used to access the configuration information from a shell script. It is given pairs of arguments, the first being a shell variable and the second the configuration value to query. As output it lists shell assignment commands for each value present. In a shell script it should be used as follows:

```
OPTS="-f"
RES='apt-config shell OPTS MyApp::options'
eval $RES
This will set the shell environment variable $OPTS to the value of MyApp::options with a default of -f.
```

The configuration item may be postfix with a /[fdbi]. f returns file names, d returns directories, b returns true or false and i returns an integer. Each of the returns is normalized and verified internally.

dump

Just show the contents of the configuration space.

OPTIONS

All command line options may be set using the configuration file, the descriptions indicate the configuration option to set. For boolean options you can override the config file by using something like **-f-**, **--no-f**, **-f=no** or several other variations.

--empty

Include options which have an empty value. This is the default, so use **--no-empty** to remove them from the output.

--format '%f "%v";%n'

Defines the output of each config option. %t will be replaced with its individual name, %f with its full hierarchical name and %v with its value. Use uppercase letters and special characters in the value will be encoded to ensure that it can e.g. be safely used in a quoted-string as defined by RFC822.

Additionally %n will be replaced by a newline, and %N by a tab. A % can be printed by using %%.

-h, --help

Show a short usage summary.

-v, --version

Show the program version.

-c, --config-file

Configuration File; Specify a configuration file to use. The program will read the default configuration file and then this configuration file. If configuration settings need to be set before the default configuration files are parsed specify a file with the **APT_CONFIG** environment variable. See **apt.conf(5)** for syntax information.

-o, --option

Set a Configuration Option; This will set an arbitrary configuration option. The syntax is **-o Foo::Bar=bar**. **-o** and **--option** can be used multiple times to set different options.

SEE ALSO

[apt.conf\(5\)](#)

DIAGNOSTICS

apt-config returns zero on normal operation, decimal 100 on error.

NAME

apt-get – APT package handling utility — command-line interface

SYNOPSIS

```
apt-get [-asqdyfmubV] [-o=config_string] [-c=config_file] [-t=target_release] [-a=architecture]
  {update | upgrade | dselect-upgrade | dist-upgrade |
  install pkg [{=pkg_version_number | /target_release}]]... | remove pkg... | purge pkg... |
  source pkg [{=pkg_version_number | /target_release}]]... |
  build-dep pkg [{=pkg_version_number | /target_release}]]... |
  download pkg [{=pkg_version_number | /target_release}]]... | check | clean | autoclean |
  autoremove | {-v | --version} | {-h | --help}
```

DESCRIPTION

apt-get is the command-line tool for handling packages, and may be considered the user's "back-end" to other tools using the APT library. Several "front-end" interfaces exist, such as **aptitude**(8), **synaptic**(8) and **wajig**(1).

Unless the **-h**, or **--help** option is given, one of the commands below must be present.

update

update is used to resynchronize the package index files from their sources. The indexes of available packages are fetched from the location(s) specified in `/etc/apt/sources.list`. For example, when using a Debian archive, this command retrieves and scans the `Packages.gz` files, so that information about new and updated packages is available. An update should always be performed before an upgrade or `dist-upgrade`. Please be aware that the overall progress meter will be incorrect as the size of the package files cannot be known in advance.

upgrade

upgrade is used to install the newest versions of all packages currently installed on the system from the sources enumerated in `/etc/apt/sources.list`. Packages currently installed with new versions available are retrieved and upgraded; under no circumstances are currently installed packages removed, or packages not already installed retrieved and installed. New versions of currently installed packages that cannot be upgraded without changing the install status of another package will be left at their current version. An update must be performed first so that **apt-get** knows that new versions of packages are available.

dist-upgrade

dist-upgrade in addition to performing the function of `upgrade`, also intelligently handles changing dependencies with new versions of packages; **apt-get** has a "smart" conflict resolution system, and it will attempt to upgrade the most important packages at the expense of less important ones if necessary. The `dist-upgrade` command may therefore remove some packages. The `/etc/apt/sources.list` file contains a list of locations from which to retrieve desired package files. See also **apt_preferences**(5) for a mechanism for overriding the general settings for individual packages.

dselect-upgrade

dselect-upgrade is used in conjunction with the traditional Debian packaging front-end, **dselect**(1). **dselect-upgrade** follows the changes made by **dselect**(1) to the Status field of available packages, and performs the actions necessary to realize that state (for instance, the removal of old and the installation of new packages).

install

install is followed by one or more packages desired for installation or upgrading. Each package is a package name, not a fully qualified filename (for instance, in a Debian system, `apt-utils` would be the argument provided, not `apt-utils_2.4.8_amd64.deb`). All packages required by the package(s) specified for installation will also be retrieved and installed. The `/etc/apt/sources.list` file is used to locate the desired packages. If a hyphen is appended to the package name (with no intervening space), the identified package will be removed if it is installed. Similarly a plus sign can be used to designate a package to install. These latter features may be used to override decisions made by `apt-get`'s conflict resolution system.

A specific version of a package can be selected for installation by following the package name with an equals and the version of the package to select. This will cause that version to be located and selected for install. Alternatively a specific distribution can be selected by following the package name with a slash and the version of the distribution or the Archive name (stable, testing, unstable).

Both of the version selection mechanisms can downgrade packages and must be used with care.

This is also the target to use if you want to upgrade one or more already-installed packages without upgrading every package you have on your system. Unlike the "upgrade" target, which installs the newest version of all currently installed packages, "install" will install the newest version of only the package(s) specified. Simply provide the name of the package(s) you wish to upgrade, and if a newer version is available, it (and its dependencies, as described above) will be downloaded and installed.

Finally, the **apt_preferences**(5) mechanism allows you to create an alternative installation policy for individual packages.

If no package matches the given expression and the expression contains one of '.', '?' or '*' then it is assumed to be a POSIX regular expression, and it is applied to all package names in the database. Any matches are then installed (or removed). Note that matching is done by substring so 'lo.*' matches 'how-lo' and 'lowest'. If this is undesired, anchor the regular expression with a '^' or '\$' character, or create a more specific regular expression.

Fallback to regular expressions is deprecated in APT 2.0, has been removed in **apt**(8), except for anchored expressions, and will be removed from **apt-get**(8) in a future version. Use **apt-patterns**(5) instead.

reinstall

reinstall is an alias for **install --reinstall**.

remove

remove is identical to **install** except that packages are removed instead of installed. Note that removing a package leaves its configuration files on the system. If a plus sign is appended to the package name (with no intervening space), the identified package will be installed instead of removed.

purge

purge is identical to **remove** except that packages are removed and purged (any configuration files are deleted too).

source

source causes **apt-get** to fetch source packages. APT will examine the available packages to decide which source package to fetch. It will then find and download into the current directory the newest available version of that source package while respecting the default release, set with the option **APT::Default-Release**, the **-t** option or per package with the **pkg/release** syntax, if possible.

The arguments are interpreted as binary and source package names. See the **--only-source** option if you want to change that.

Source packages are tracked separately from binary packages via deb-src lines in the **sources.list**(5) file. This means that you will need to add such a line for each repository you want to get sources from; otherwise you will probably get either the wrong (too old/too new) source versions or none at all.

If the **--compile** option is specified then the package will be compiled to a binary .deb using **dpkg-buildpackage** for the architecture as defined by the **--host-architecture** option. If **--download-only** is specified then the source package will not be unpacked.

A specific source version can be retrieved by postfixing the source name with an equals and then the version to fetch, similar to the mechanism used for the package files. This enables exact matching of

the source package name and version, implicitly enabling the APT::Get::Only-Source option.

Note that source packages are not installed and tracked in the **dpkg** database like binary packages; they are simply downloaded to the current directory, like source tarballs.

build-dep

build-dep causes apt-get to install/remove packages in an attempt to satisfy the build dependencies for a source package. By default the dependencies are satisfied to build the package natively. If desired a host-architecture can be specified with the **--host-architecture** option instead.

The arguments are interpreted as binary or source package names. See the **--only-source** option if you want to change that.

satisfy

satisfy causes apt-get to satisfy the given dependency strings. The dependency strings may have build profiles and architecture restriction list as in build dependencies. They may optionally be prefixed with "Conflicts: " to unsatisfy the dependency string. Multiple strings of the same type can be specified.

Example: apt-get satisfy "foo" "Conflicts: bar" "baz (>> 1.0) | bar (= 2.0), moo"

The legacy operator '</>' is not supported, use '<=>' instead.

check

check is a diagnostic tool; it updates the package cache and checks for broken dependencies.

download

download will download the given binary package into the current directory.

clean

clean clears out the local repository of retrieved package files. It removes everything but the lock file from /var/cache/apt/archives/ and /var/cache/apt/archives/partial/.

autoclean (and the **auto-clean** alias since 1.1)

Like **clean**, **autoclean** clears out the local repository of retrieved package files. The difference is that it only removes package files that can no longer be downloaded, and are largely useless. This allows a cache to be maintained over a long period without it growing out of control. The configuration option APT::Clean-Installed will prevent installed packages from being erased if it is set to off.

autoremove (and the **auto-remove** alias since 1.1)

autoremove is used to remove packages that were automatically installed to satisfy dependencies for other packages and are now no longer needed.

changelog

changelog tries to download the changelog of a package and displays it through **sensible-pager**. By default it displays the changelog for the version that is installed. However, you can specify the same options as for the **install** command.

indextargets

Displays by default a deb822 formatted listing of information about all data files (aka index targets) **apt-get update** would download. Supports a **--format** option to modify the output format as well as accepts lines of the default output to filter the records by. The command is mainly used as an interface for external tools working with APT to get information as well as filenames for downloaded files so they can use them as well instead of downloading them again on their own. Detailed documentation is omitted here and can instead be found in the file /usr/share/doc/apt/acquire-additional-files.md.gz shipped by the apt-doc package.

OPTIONS

All command line options may be set using the configuration file, the descriptions indicate the configuration option to set. For boolean options you can override the config file by using something like **-f**, **--no-f**, **-f=no** or several other variations.

--no-install-recommends

Do not consider recommended packages as a dependency for installing. Configuration Item: APT::Install-Recommends.

--install-suggests

Consider suggested packages as a dependency for installing. Configuration Item: APT::Install-Suggests.

-d, --download-only

Download only; package files are only retrieved, not unpacked or installed. Configuration Item: APT::Get::Download-Only.

-f, --fix-broken

Fix; attempt to correct a system with broken dependencies in place. This option, when used with install/remove, can omit any packages to permit APT to deduce a likely solution. If packages are specified, these have to completely correct the problem. The option is sometimes necessary when running APT for the first time; APT itself does not allow broken package dependencies to exist on a system. It is possible that a system's dependency structure can be so corrupt as to require manual intervention (which usually means using **dpkg --remove** to eliminate some of the offending packages). Use of this option together with **-m** may produce an error in some situations.

Configuration Item: APT::Get::Fix-Broken.

-m, --ignore-missing, --fix-missing

Ignore missing packages; if packages cannot be retrieved or fail the integrity check after retrieval (corrupted package files), hold back those packages and handle the result. Use of this option together with **-f** may produce an error in some situations. If a package is selected for installation (particularly if it is mentioned on the command line) and it could not be downloaded then it will be silently held back. Configuration Item: APT::Get::Fix-Missing.

--no-download

Disables downloading of packages. This is best used with **--ignore-missing** to force APT to use only the .debs it has already downloaded. Configuration Item: APT::Get::Download.

-q, --quiet

Quiet; produces output suitable for logging, omitting progress indicators. More q's will produce more quiet up to a maximum of 2. You can also use **-q=#** to set the quiet level, overriding the configuration file. Note that quiet level 2 implies **-y**; you should never use **-qq** without a no-action modifier such as **-d, --print-uris** or **-s** as APT may decide to do something you did not expect. Configuration Item: quiet.

-s, --simulate, --just-print, --dry-run, --recon, --no-act

No action; perform a simulation of events that would occur based on the current system state but do not actually change the system. Locking will be disabled (**Debug::NoLocking**) so the system state could change while **apt-get** is running. Simulations can also be executed by non-root users which might not have read access to all apt configuration distorting the simulation. A notice expressing this warning is also shown by default for non-root users (**APT::Get::Show-User-Simulation-Note**). Configuration Item: APT::Get::Simulate.

Simulated runs print out a series of lines, each representing a **dpkg** operation: configure (Conf), remove (Remv) or unpack (Inst). Square brackets indicate broken packages, and empty square brackets indicate breaks that are of no consequence (rare).

-y, --yes, --assume-yes

Automatic yes to prompts; assume "yes" as answer to all prompts and run non-interactively. If an undesirable situation, such as changing a held package, trying to install an unauthenticated package or removing an essential package occurs then apt-get will abort. Configuration Item: APT::Get::Assume-Yes.

--assume-no

Automatic "no" to all prompts. Configuration Item: APT::Get::Assume-No.

--no-show-upgraded

Do not show a list of all packages that are to be upgraded. Configuration Item:
APT::Get::Show-Upgraded.

-V, --verbose-versions

Show full versions for upgraded and installed packages. Configuration Item:
APT::Get::Show-Versions.

-a, --host-architecture

This option controls the architecture packages are built for by **apt-get source --compile** and how cross-builddependencies are satisfied. By default is it not set which means that the host architecture is the same as the build architecture (which is defined by APT::Architecture). Configuration Item:
APT::Get::Host-Architecture.

-P, --build-profiles

This option controls the activated build profiles for which a source package is built by **apt-get source --compile** and how build dependencies are satisfied. By default no build profile is active. More than one build profile can be activated at a time by concatenating them with a comma. Configuration Item:
APT::Build-Profiles.

-b, --compile, --build

Compile source packages after downloading them. Configuration Item: APT::Get::Compile.

--ignore-hold

Ignore package holds; this causes **apt-get** to ignore a hold placed on a package. This may be useful in conjunction with dist-upgrade to override a large number of undesired holds. Configuration Item:
APT::Ignore-Hold.

--with-new-pkgs

Allow installing new packages when used in conjunction with upgrade. This is useful if the update of an installed package requires new dependencies to be installed. Instead of holding the package back upgrade will upgrade the package and install the new dependencies. Note that upgrade with this option will never remove packages, only allow adding new ones. Configuration Item:
APT::Get::Upgrade-Allow-New.

--no-upgrade

Do not upgrade packages; when used in conjunction with install, no-upgrade will prevent packages on the command line from being upgraded if they are already installed. Configuration Item:
APT::Get::Upgrade.

--only-upgrade

Do not install new packages; when used in conjunction with install, only-upgrade will install upgrades for already installed packages only and ignore requests to install new packages. Configuration Item:
APT::Get::Only-Upgrade.

--allow-downgrades

This is a dangerous option that will cause apt to continue without prompting if it is doing downgrades. It should not be used except in very special situations. Using it can potentially destroy your system! Configuration Item: APT::Get::allow-downgrades. Introduced in APT 1.1.

--allow-remove-essential

Force yes; this is a dangerous option that will cause apt to continue without prompting if it is removing essentials. It should not be used except in very special situations. Using it can potentially destroy your system! Configuration Item: APT::Get::allow-remove-essential. Introduced in APT 1.1.

--allow-change-held-packages

Force yes; this is a dangerous option that will cause apt to continue without prompting if it is changing held packages. It should not be used except in very special situations. Using it can potentially destroy your system! Configuration Item: APT::Get::allow-change-held-packages. Introduced in APT 1.1.

--force-yes

Force yes; this is a dangerous option that will cause apt to continue without prompting if it is doing

something potentially harmful. It should not be used except in very special situations. Using force-yes can potentially destroy your system! Configuration Item: APT::Get::force-yes. This is deprecated and replaced by **--allow-unauthenticated**, **--allow-downgrades**, **--allow-remove-essential**, **--allow-change-held-packages** in 1.1.

--print-uris

Instead of fetching the files to install their URIs are printed. Each URI will have the path, the destination file name, the size and the expected MD5 hash. Note that the file name to write to will not always match the file name on the remote site! This also works with the source and update commands. When used with the update command the MD5 and size are not included, and it is up to the user to decompress any compressed files. Configuration Item: APT::Get::Print-URIs.

--purge

Use purge instead of remove for anything that would be removed. An asterisk ("*") will be displayed next to packages which are scheduled to be purged. **remove --purge** is equivalent to the **purge** command. Configuration Item: APT::Get::Purge.

--reinstall

Re-install packages that are already installed and at the newest version. Configuration Item: APT::Get::ReInstall.

--list-cleanup

This option is on by default; use **--no-list-cleanup** to turn it off. When it is on, **apt-get** will automatically manage the contents of /var/lib/apt/lists to ensure that obsolete files are erased. The only reason to turn it off is if you frequently change your sources list. Configuration Item: APT::Get::List-Cleanup.

-t, --target-release, --default-release

This option controls the default input to the policy engine; it creates a default pin at priority 990 using the specified release string. This overrides the general settings in /etc/apt/preferences. Specifically pinned packages are not affected by the value of this option. In short, this option lets you have simple control over which distribution packages will be retrieved from. Some common examples might be **-t '2.1***, **-t unstable** or **-t sid**. Configuration Item: APT::Default-Release; see also the **apt_preferences(5)** manual page.

--trivial-only

Only perform operations that are 'trivial'. Logically this can be considered related to **--assume-yes**; where **--assume-yes** will answer yes to any prompt, **--trivial-only** will answer no. Configuration Item: APT::Get::Trivial-Only.

--mark-auto

After successful installation, mark all freshly installed packages as automatically installed, which will cause each of the packages to be removed when no more manually installed packages depend on this package. This is equally to running **apt-mark auto** for all installed packages. Configuration Item: APT::Get::Mark-Auto.

--no-remove

If any packages are to be removed apt-get immediately aborts without prompting. Configuration Item: APT::Get::Remove.

--auto-remove, --autoremove

If the command is either install or remove, then this option acts like running the autoremove command, removing unused dependency packages. Configuration Item: APT::Get::AutomaticRemove.

--only-source

Only has meaning for the source and build-dep commands. Indicates that the given source names are not to be mapped through the binary table. This means that if this option is specified, these commands will only accept source package names as arguments, rather than accepting binary package names and looking up the corresponding source package. Configuration Item: APT::Get::Only-Source.

--diff-only, --dsc-only, --tar-only

Download only the diff, dsc, or tar file of a source archive. Configuration Item: APT::Get::Diff-Only, APT::Get::Dsc-Only, and APT::Get::Tar-Only.

--arch-only

Only process architecture-dependent build-dependencies. Configuration Item: APT::Get::Arch-Only.

--indep-only

Only process architecture-independent build-dependencies. Configuration Item: APT::Get::Indep-Only.

--allow-unauthenticated

Ignore if packages can't be authenticated and don't prompt about it. This can be useful while working with local repositories, but is a huge security risk if data authenticity isn't ensured in another way by the user itself. The usage of the **Trusted** option for **sources.list(5)** entries should usually be preferred over this global override. Configuration Item: APT::Get::AllowUnauthenticated.

--no-allow-insecure-repositories

Forbid the update command to acquire unverifiable data from configured sources. APT will fail at the update command for repositories without valid cryptographically signatures. See also **apt-secure(8)** for details on the concept and the implications. Configuration Item:

Acquire::AllowInsecureRepositories.

--allow-releaseinfo-change

Allow the update command to continue downloading data from a repository which changed its information of the release contained in the repository indicating e.g a new major release. APT will fail at the update command for such repositories until the change is confirmed to ensure the user is prepared for the change. See also **apt-secure(8)** for details on the concept and configuration.

Specialist options (**--allow-releaseinfo-change-field**) exist to allow changes only for certain fields like origin, label, codename, suite, version and defaultpin. See also **apt_preferences(5)**. Configuration Item: Acquire::AllowReleaseInfoChange.

--show-progress

Show user friendly progress information in the terminal window when packages are installed, upgraded or removed. For a machine parseable version of this data see README.progress-reporting in the apt doc directory. Configuration Items: Dpkg::Progress and Dpkg::Progress-Fancy.

--with-source *filename*

Adds the given file as a source for metadata. Can be repeated to add multiple files. See **--with-source** description in **apt-cache(8)** for further details.

-eany, --error-on=any

Fail the update command if any error occurred, even a transient one.

-h, --help

Show a short usage summary.

-v, --version

Show the program version.

-c, --config-file

Configuration File; Specify a configuration file to use. The program will read the default configuration file and then this configuration file. If configuration settings need to be set before the default configuration files are parsed specify a file with the **APT_CONFIG** environment variable. See **apt.conf(5)** for syntax information.

-o, --option

Set a Configuration Option; This will set an arbitrary configuration option. The syntax is **-o Foo::Bar=bar**. **-o** and **--option** can be used multiple times to set different options.

FILES

/etc/apt/sources.list

Locations to fetch packages from. Configuration Item: Dir::Etc::SourceList.

/etc/apt/sources.list.d/

File fragments for locations to fetch packages from. Configuration Item: Dir::Etc::SourceParts.

/etc/apt/apt.conf

APT configuration file. Configuration Item: Dir::Etc::Main.

/etc/apt/apt.conf.d/

APT configuration file fragments. Configuration Item: Dir::Etc::Parts.

/etc/apt/preferences

Version preferences file. This is where you would specify "pinning", i.e. a preference to get certain packages from a separate source or from a different version of a distribution. Configuration Item: Dir::Etc::Preferences.

/etc/apt/preferences.d/

File fragments for the version preferences. Configuration Item: Dir::Etc::PreferencesParts.

/var/cache/apt/archives/

Storage area for retrieved package files. Configuration Item: Dir::Cache::Archives.

/var/cache/apt/archives/partial/

Storage area for package files in transit. Configuration Item: Dir::Cache::Archives (partial will be implicitly appended)

/var/lib/apt/lists/

Storage area for state information for each package resource specified in **sources.list(5)** Configuration Item: Dir::State::Lists.

/var/lib/apt/lists/partial/

Storage area for state information in transit. Configuration Item: Dir::State::Lists (partial will be implicitly appended)

NAME

apt-mark – show, set and unset various settings for a package

SYNOPSIS

```
apt-mark {-f=filename | {auto | manual} pkg... | {showauto | showmanual} [pkg...] } | {-v | --version} |
{-h | --help}

apt-mark {hold | unhold | install | remove | purge} pkg... |
{showhold | showinstall | showremove | showpurge} [pkg...]
```

DESCRIPTION

apt-mark can be used as a unified front-end to set various settings for a package, such as marking a package as being automatically/manually installed or changing **dpkg** selections such as hold, install, deinstall and purge which are respected e.g. by **apt-get dselect-upgrade** or **aptitude**.

AUTOMATICALLY AND MANUALLY INSTALLED PACKAGES

When you request that a package is installed, and as a result other packages are installed to satisfy its dependencies, the dependencies are marked as being automatically installed, while the package you installed explicitly is marked as manually installed. Once an automatically installed package is no longer depended on by any manually installed package it is considered no longer needed and e.g. **apt-get** or **aptitude** will at least suggest removing them.

auto

auto is used to mark a package as being automatically installed, which will cause the package to be removed when no more manually installed packages depend on this package.

manual

manual is used to mark a package as being manually installed, which will prevent the package from being automatically removed if no other packages depend on it.

minimize-manual

minimize-manual is used to mark (transitive) dependencies of metapackages as automatically installed. This can be used after an installation for example, to minimize the number of manually installed packages; or continuously on systems managed by system configuration metapackages.

showauto

showauto is used to print a list of automatically installed packages with each package on a new line. All automatically installed packages will be listed if no package is given. If packages are given only those which are automatically installed will be shown.

showmanual

showmanual can be used in the same way as **showauto** except that it will print a list of manually installed packages instead.

Options**-f=*filename*, --file=*filename***

Read/Write package stats from the filename given with the parameter *filename* instead of from the default location, which is `extended_states` in the directory defined by the Configuration Item: `Dir::State`.

PREVENT CHANGES FOR A PACKAGE**hold**

hold is used to mark a package as held back, which will prevent the package from being automatically installed, upgraded or removed.

unhold

unhold is used to cancel a previously set hold on a package to allow all actions again.

showhold

showhold is used to print a list of packages on hold in the same way as for the other show commands.

SCHEDULE PACKAGES FOR INSTALL, REMOVE AND PURGE

Some front-ends like **apt-get dselect-upgrade** can be used to apply previously scheduled changes to the install state of packages. Such changes can be scheduled with the **install**, **remove** (also known as **deinstall**) and **purge** commands. Packages with a specific selection can be displayed with **showinstall**, **showremove** and **showpurge** respectively. More information about these so called dpkg selections can be found in **dpkg(1)**.

OPTIONS

-h, --help

Show a short usage summary.

-v, --version

Show the program version.

-c, --config-file

Configuration File; Specify a configuration file to use. The program will read the default configuration file and then this configuration file. If configuration settings need to be set before the default configuration files are parsed specify a file with the **APT_CONFIG** environment variable. See **apt.conf(5)** for syntax information.

-o, --option

Set a Configuration Option; This will set an arbitrary configuration option. The syntax is **-o Foo::Bar=bar**. **-o** and **--option** can be used multiple times to set different options.

FILES

/var/lib/apt/extended_states

Status list of auto-installed packages. Configuration Item: Dir::State::extended_states.

SEE ALSO

apt-get(8), aptitude(8), apt.conf(5)

DIAGNOSTICS

apt-mark returns zero on normal operation, non-zero on error.

NAME

apt – command-line interface

SYNOPSIS

```
apt [-h] [-o=config_string] [-c=config_file] [-t=target_release] [-a=architecture] {list | search | show |
    update | install pkg [{=pkg_version_number | /target_release}]}... | remove pkg... | upgrade |
    full-upgrade | edit-sources | {-v | --version} | {-h | --help}}
```

DESCRIPTION

apt provides a high-level commandline interface for the package management system. It is intended as an end user interface and enables some options better suited for interactive usage by default compared to more specialized APT tools like **apt-get(8)** and **apt-cache(8)**.

Much like **apt** itself, its manpage is intended as an end user interface and as such only mentions the most used commands and options partly to not duplicate information in multiple places and partly to avoid overwhelming readers with a cornucopia of options and details.

update (apt-get(8))

update is used to download package information from all configured sources. Other commands operate on this data to e.g. perform package upgrades or search in and display details about all packages available for installation.

upgrade (apt-get(8))

upgrade is used to install available upgrades of all packages currently installed on the system from the sources configured via **sources.list(5)**. New packages will be installed if required to satisfy dependencies, but existing packages will never be removed. If an upgrade for a package requires the removal of an installed package the upgrade for this package isn't performed.

full-upgrade (apt-get(8))

full-upgrade performs the function of upgrade but will remove currently installed packages if this is needed to upgrade the system as a whole.

install, reinstall, remove, purge (apt-get(8))

Performs the requested action on one or more packages specified via **regex(7)**, **glob(7)** or exact match. The requested action can be overridden for specific packages by appending a plus (+) to the package name to install this package or a minus (-) to remove it.

A specific version of a package can be selected for installation by following the package name with an equals (=) and the version of the package to select. Alternatively the version from a specific release can be selected by following the package name with a forward slash (/) and codename (bullseye, bookworm, sid ...) or suite name (stable, testing, unstable). This will also select versions from this release for dependencies of this package if needed to satisfy the request.

Removing a package removes all packaged data, but leaves usually small (modified) user configuration files behind, in case the remove was an accident. Just issuing an installation request for the accidentally removed package will restore its function as before in that case. On the other hand you can get rid of these leftovers by calling **purge** even on already removed packages. Note that this does not affect any data or configuration stored in your home directory.

autoremove (apt-get(8))

autoremove is used to remove packages that were automatically installed to satisfy dependencies for other packages and are now no longer needed as dependencies changed or the package(s) needing them were removed in the meantime.

You should check that the list does not include applications you have grown to like even though they were once installed just as a dependency of another package. You can mark such a package as manually installed by using **apt-mark(8)**. Packages which you have installed explicitly via **install** are also never proposed for automatic removal.

satisfy (apt-get(8))

satisfy satisfies dependency strings, as used in Build-Depends. It also handles conflicts, by prefixing an argument with "Conflicts: ".

Example: apt satisfy "foo, bar (>= 1.0)" "Conflicts: baz, fuzz"

search (apt-cache(8))

search can be used to search for the given **regex(7)** term(s) in the list of available packages and display matches. This can e.g. be useful if you are looking for packages having a specific feature. If you are looking for a package including a specific file try **apt-file(1)**.

show (apt-cache(8))

Show information about the given package(s) including its dependencies, installation and download size, sources the package is available from, the description of the packages content and much more. It can e.g. be helpful to look at this information before allowing **apt(8)** to remove a package or while searching for new packages to install.

list

list is somewhat similar to **dkg-query --list** in that it can display a list of packages satisfying certain criteria. It supports **glob(7)** patterns for matching package names as well as options to list installed (**--installed**), upgradeable (**--upgradeable**) or all available (**--all-versions**) versions.

edit-sources (work-in-progress)

edit-sources lets you edit your **sources.list(5)** files in your preferred text editor while also providing basic sanity checks.

SCRIPT USAGE AND DIFFERENCES FROM OTHER APT TOOLS

The **apt(8)** commandline is designed as an end-user tool and it may change behavior between versions. While it tries not to break backward compatibility this is not guaranteed either if a change seems beneficial for interactive use.

All features of **apt(8)** are available in dedicated APT tools like **apt-get(8)** and **apt-cache(8)** as well. **apt(8)** just changes the default value of some options (see **apt.conf(5)** and specifically the Binary scope). So you should prefer using these commands (potentially with some additional options enabled) in your scripts as they keep backward compatibility as much as possible.

SEE ALSO

apt-get(8), **apt-cache(8)**, **sources.list(5)**, **apt.conf(5)**, **apt-config(8)**, The APT User's guide in /usr/share/doc/apt-doc/, **apt_preferences(5)**, the APT Howto.

DIAGNOSTICS

apt returns zero on normal operation, decimal 100 on error.

NAME

apt.conf – Configuration file for APT

DESCRIPTION

/etc/apt/apt.conf is the main configuration file shared by all the tools in the APT suite of tools, though it is by no means the only place options can be set. The suite also shares a common command line parser to provide a uniform environment.

When an APT tool starts up it will read the configuration files in the following order:

1. the file specified by the **APT_CONFIG** environment variable (if any)
2. all files in Dir::Etc::Parts in alphanumeric ascending order which have either no or "conf" as filename extension and which only contain alphanumeric, hyphen (-), underscore (_) and period (.) characters. Otherwise APT will print a notice that it has ignored a file, unless that file matches a pattern in the Dir::Ignore-Files-Silently configuration list – in which case it will be silently ignored.
3. the main configuration file specified by Dir::Etc::main
4. all options set in the binary specific configuration subtree are moved into the root of the tree.
5. the command line options are applied to override the configuration directives or to load even more configuration files.

SYNTAX

The configuration file is organized in a tree with options organized into functional groups. Option specification is given with a double colon notation; for instance APT::Get::Assume-Yes is an option within the APT tool group, for the Get tool. Options do not inherit from their parent groups.

Syntactically the configuration language is modeled after what the ISC tools such as bind and dhcp use. Lines starting with // are treated as comments (ignored), as well as all text between /* and */, just like C/C++ comments. Lines starting with # are also treated as comments. Each line is of the form APT::Get::Assume-Yes "true";. The quotation marks and trailing semicolon are required. The value must be on one line, and there is no kind of string concatenation. Values must not include backslashes or extra quotation marks. Option names are made up of alphanumeric characters and the characters "/-:_+". A new scope can be opened with curly braces, like this:

```
APT {
  Get {
    Assume-Yes "true";
    Fix-Broken "true";
  };
};
```

with newlines placed to make it more readable. Lists can be created by opening a scope and including a single string enclosed in quotes followed by a semicolon. Multiple entries can be included, separated by a semicolon.

```
DPkg::Pre-Install-Pkgs {"/usr/sbin/dpkg-preconfigure --apt";};
```

In general the sample configuration file /usr/share/doc/apt/examples/configure-index.gz is a good guide for how it should look.

Case is not significant in names of configuration items, so in the previous example you could use dpkg::pre-install-pkgs.

Names for the configuration items are optional if a list is defined as can be seen in the DPkg::Pre-Install-Pkgs example above. If you don't specify a name a new entry will simply add a new option to the list. If you specify a name you can override the option in the same way as any other option by

reassigning a new value to the option.

Two special commands are defined: #include (which is deprecated and not supported by alternative implementations) and #clear. #include will include the given file, unless the filename ends in a slash, in which case the whole directory is included. #clear is used to erase a part of the configuration tree. The specified element and all its descendants are erased. (Note that these lines also need to end with a semicolon.)

The #clear command is the only way to delete a list or a complete scope. Reopening a scope (or using the syntax described below with an appended ::) will *not* override previously written entries. Options can only be overridden by addressing a new value to them – lists and scopes can't be overridden, only cleared.

All of the APT tools take an –o option which allows an arbitrary configuration directive to be specified on the command line. The syntax is a full option name (APT::Get::Assume-Yes for instance) followed by an equals sign then the new value of the option. To append a new element to a list, add a trailing :: to the name of the list. (As you might suspect, the scope syntax can't be used on the command line.)

Note that appending items to a list using :: only works for one item per line, and that you should not use it in combination with the scope syntax (which adds :: implicitly). Using both syntaxes together will trigger a bug which some users unfortunately depend on: an option with the unusual name "::" which acts like every other option with a name. This introduces many problems; for one thing, users who write multiple lines in this *wrong* syntax in the hope of appending to a list will achieve the opposite, as only the last assignment for this option "::" will be used. Future versions of APT will raise errors and stop working if they encounter this misuse, so please correct such statements now while APT doesn't explicitly complain about them.

THE APT GROUP

This group of options controls general APT behavior as well as holding the options for all of the tools.

Architecture

System Architecture; sets the architecture to use when fetching files and parsing package lists. The internal default is the architecture apt was compiled for.

Architectures

All Architectures the system supports. For instance, CPUs implementing the amd64 (also called x86-64) instruction set are also able to execute binaries compiled for the i386 (x86) instruction set. This list is used when fetching files and parsing package lists. The initial default is always the system's native architecture (APT::Architecture), and foreign architectures are added to the default list when they are registered via **dpkg --add-architecture**.

Compressor

This scope defines which compression formats are supported, how compression and decompression can be performed if support for this format isn't built into apt directly and a cost-value indicating how costly it is to compress something in this format. As an example the following configuration stanza would allow apt to download and uncompress as well as create and store files with the low-cost .reversed file extension which it will pass to the command **rev** without additional commandline parameters for compression and uncompression:

```
APT::Compressor::rev {
    Name "rev";
    Extension ".reversed";
    Binary "rev";
    CompressArg {};
    UncompressArg {};
    Cost "10";
};
```

Build-Profiles

List of all build profiles enabled for build-dependency resolution, without the "profile." namespace prefix. By default this list is empty. The **DEB_BUILD_PROFILES** as used by **dpkg-buildpackage(1)** overrides the list notation.

Default–Release

Default release to install packages from if more than one version is available. Contains release name, codename or release version. Examples: 'stable', 'testing', 'unstable', 'bullseye', 'bookworm', '4.0', '5.0*'. See also `apt_preferences(5)`.

Ignore–Hold

Ignore held packages; this global option causes the problem resolver to ignore held packages in its decision making.

Clean–Installed

Defaults to on. When turned on the autoclean feature will remove any packages which can no longer be downloaded from the cache. If turned off then packages that are locally installed are also excluded from cleaning – but note that APT provides no direct means to reinstall them.

Immediate–Configure

Defaults to on, which will cause APT to install essential and important packages as soon as possible in an install/upgrade operation, in order to limit the effect of a failing `dpkg(1)` call. If this option is disabled, APT treats an important package in the same way as an extra package: between the unpacking of the package A and its configuration there can be many other unpack or configuration calls for other unrelated packages B, C etc. If these cause the `dpkg(1)` call to fail (e.g. because package B's maintainer scripts generate an error), this results in a system state in which package A is unpacked but unconfigured – so any package depending on A is now no longer guaranteed to work, as its dependency on A is no longer satisfied.

The immediate configuration marker is also applied in the potentially problematic case of circular dependencies, since a dependency with the immediate flag is equivalent to a Pre–Dependency. In theory this allows APT to recognise a situation in which it is unable to perform immediate configuration, abort, and suggest to the user that the option should be temporarily deactivated in order to allow the operation to proceed. Note the use of the word "theory" here; in the real world this problem has rarely been encountered, in non–stable distribution versions, and was caused by wrong dependencies of the package in question or by a system in an already broken state; so you should not blindly disable this option, as the scenario mentioned above is not the only problem it can help to prevent in the first place.

Before a big operation like `dist–upgrade` is run with this option disabled you should try to explicitly install the package APT is unable to configure immediately; but please make sure you also report your problem to your distribution and to the APT team with the bug link below, so they can work on improving or correcting the upgrade process.

Force–LoopBreak

Never enable this option unless you *really* know what you are doing. It permits APT to temporarily remove an essential package to break a Conflicts/Conflicts or Conflicts/Pre–Depends loop between two essential packages. *Such a loop should never exist and is a grave bug.* This option will work if the essential packages are not `tar`, `gzip`, `libc`, `dpkg`, `dash` or anything that those packages depend on.

Cache–Start, Cache–Grow, Cache–Limit

APT uses since version 0.7.26 a resizable memory mapped cache file to store the available information. Cache–Start acts as a hint of the size the cache will grow to, and is therefore the amount of memory APT will request at startup. The default value is 20971520 bytes (~20 MB). Note that this amount of space needs to be available for APT; otherwise it will likely fail ungracefully, so for memory restricted devices this value should be lowered while on systems with a lot of configured sources it should be increased. Cache–Grow defines in bytes with the default of 1048576 (~1 MB) how much the cache size will be increased in the event the space defined by Cache–Start is not enough. This value will be applied again and again until either the cache is big enough to store all information or the size of the cache reaches the Cache–Limit. The default of Cache–Limit is 0 which stands for no limit. If Cache–Grow is set to 0 the automatic growth of the cache is disabled.

Build–Essential

Defines which packages are considered essential build dependencies.

Get

The Get subsection controls the **apt-get(8)** tool; please see its documentation for more information about the options here.

Cache

The Cache subsection controls the **apt-cache(8)** tool; please see its documentation for more information about the options here.

CDROM

The CDROM subsection controls the **apt-cdrom(8)** tool; please see its documentation for more information about the options here.

THE ACQUIRE GROUP

The Acquire group of options controls the download of packages as well as the various "acquire methods" responsible for the download itself (see also **sources.list(5)**).

Check–Date

Security related option defaulting to true, enabling time-related checks. Disabling it means that the machine's time cannot be trusted, and APT will hence disable all time-related checks, such as **Check–Valid–Until** and verifying that the Date field of a release file is not in the future.

Max–FutureTime

Maximum time (in seconds) before its creation (as indicated by the Date header) that the Release file should be considered valid. The default value is 10. Archive specific settings can be made by appending the label of the archive to the option name. Preferably, the same can be achieved for specific **sources.list(5)** entries by using the **Date–Max–Future** option there.

Check–Valid–Until

Security related option defaulting to true, as giving a Release file's validation an expiration date prevents replay attacks over a long timescale, and can also for example help users to identify mirrors that are no longer updated – but the feature depends on the correctness of the clock on the user system. Archive maintainers are encouraged to create Release files with the Valid–Until header, but if they don't or a stricter value is desired the Max–ValidTime option below can be used. The **Check–Valid–Until** option of **sources.list(5)** entries should be preferred to disable the check selectively instead of using this global override.

Max–ValidTime

Maximum time (in seconds) after its creation (as indicated by the Date header) that the Release file should be considered valid. If the Release file itself includes a Valid–Until header the earlier date of the two is used as the expiration date. The default value is 0 which stands for "valid forever". Archive specific settings can be made by appending the label of the archive to the option name. Preferably, the same can be achieved for specific **sources.list(5)** entries by using the **Valid–Until–Max** option there.

Min–ValidTime

Minimum time (in seconds) after its creation (as indicated by the Date header) that the Release file should be considered valid. Use this if you need to use a seldom updated (local) mirror of a more frequently updated archive with a Valid–Until header instead of completely disabling the expiration date checking. Archive specific settings can and should be used by appending the label of the archive to the option name. Preferably, the same can be achieved for specific **sources.list(5)** entries by using the **Valid–Until–Min** option there.

AllowTLS

Allow use of the internal TLS support in the http method. If set to false, this completely disables support for TLS in apt's own methods (excluding the curl-based https method). No TLS-related functions will be called anymore.

PDiff

Try to download deltas called PDiff for indexes (like Packages files) instead of downloading whole ones. True by default. Preferably, this can be set for specific **sources.list(5)** entries or index files by

using the **PDiff**s option there.

Two sub-options to limit the use of PDiff are also available: FileLimit can be used to specify a maximum number of PDiff files should be downloaded to update a file. SizeLimit on the other hand is the maximum percentage of the size of all patches compared to the size of the targeted file. If one of these limits is exceeded the complete file is downloaded instead of the patches.

By-Hash

Try to download indexes via an URI constructed from a hashsum of the expected file rather than downloaded via a well-known stable filename. True by default, but automatically disabled if the source indicates no support for it. Usage can be forced with the special value "force". Preferably, this can be set for specific **sources.list**(5) entries or index files by using the **By-Hash** option there.

Queue-Mode

Queuing mode; Queue-Mode can be one of host or access which determines how APT parallelizes outgoing connections. host means that one connection per target host will be opened, access means that one connection per URI type will be opened.

Retries

Number of retries to perform. If this is non-zero APT will retry failed files the given number of times.

Source-Symlinks

Use symlinks for source archives. If set to true then source archives will be symlinked when possible instead of copying. True is the default.

http https

The options in these scopes configure APT's acquire transports for the protocols HTTP and HTTPS and are documented in the **apt-transport-http**(1) and **apt-transport-https**(1) manpages respectively.

ftp

ftp::Proxy sets the default proxy to use for FTP URIs. It is in the standard form of `ftp://[[:user][[:pass]@]host[:port]/]`. Per host proxies can also be specified by using the form `ftp::Proxy::<host>` with the special keyword DIRECT meaning to use no proxies. If no one of the above settings is specified, **ftp_proxy** environment variable will be used. To use an FTP proxy you will have to set the `ftp::ProxyLogin` script in the configuration file. This entry specifies the commands to send to tell the proxy server what to connect to. Please see `/usr/share/doc/apt/examples/configure-index.gz` for an example of how to do this. The substitution variables representing the corresponding URI component are `$(PROXY_USER)`, `$(PROXY_PASS)`, `$(SITE_USER)`, `$(SITE_PASS)`, `$(SITE)` and `$(SITE_PORT)`.

The option timeout sets the timeout timer used by the method; this value applies to the connection as well as the data timeout.

Several settings are provided to control passive mode. Generally it is safe to leave passive mode on; it works in nearly every environment. However, some situations require that passive mode be disabled and port mode FTP used instead. This can be done globally or for connections that go through a proxy or for a specific host (see the sample config file for examples).

It is possible to proxy FTP over HTTP by setting the **ftp_proxy** environment variable to an HTTP URL – see the discussion of the http method above for syntax. You cannot set this in the configuration file and it is not recommended to use FTP over HTTP due to its low efficiency.

The setting ForceExtended controls the use of RFC2428 EPSV and EPRT commands. The default is false, which means these commands are only used if the control connection is IPv6. Setting this to true forces their use even on IPv4 connections. Note that most FTP servers do not support RFC2428.

cdrom

For URIs using the cdrom method, the only configurable option is the mount point, `cdrom::Mount`, which must be the mount point for the CD-ROM (or DVD, or whatever) drive as specified in

/etc/fstab. It is possible to provide alternate mount and unmount commands if your mount point cannot be listed in the fstab. The syntax is to put

```
/cdrom/:Mount "foo";
```

within the cdrom block. It is important to have the trailing slash. Unmount commands can be specified using UMount.

gpgv

For GPGV URIs the only configurable option is gpgv::Options, which passes additional parameters to gpgv.

CompressionTypes

List of compression types which are understood by the acquire methods. Files like Packages can be available in various compression formats. By default the acquire methods can decompress and recompress many common formats like **xz** and **gzip**; with this scope the supported formats can be queried, modified as well as support for more formats added (see also **APT::Compressor**). The syntax for this is:

```
Acquire::CompressionTypes::FileExtension "Methodname";
```

Also, the Order subgroup can be used to define in which order the acquire system will try to download the compressed files. The acquire system will try the first and proceed with the next compression type in this list on error, so to prefer one over the other type simply add the preferred type first – types not already added will be implicitly appended to the end of the list, so e.g.

```
Acquire::CompressionTypes::Order:: "gz";
```

can be used to prefer **gzip** compressed files over all other compression formats. If **xz** should be preferred over **gzip** and **bzip2** the configure setting should look like this:

```
Acquire::CompressionTypes::Order { "xz"; "gz"; };
```

It is not needed to add bz2 to the list explicitly as it will be added automatically.

Note that the Dir::Bin::*Methodname* will be checked at run time. If this option has been set and support for this format isn't directly built into apt, the method will only be used if this file exists; e.g. for the bzip2 method (the inbuilt) setting is:

```
Dir::Bin::bzip2 "/bin/bzip2";
```

Note also that list entries specified on the command line will be added at the end of the list specified in the configuration files, but before the default entries. To prefer a type in this case over the ones specified in the configuration files you can set the option direct – not in list style. This will not override the defined list; it will only prefix the list with this type.

The special type uncompressed can be used to give uncompressed files a preference, but note that most archives don't provide uncompressed files so this is mostly only usable for local mirrors.

GzipIndexes

When downloading gzip compressed indexes (Packages, Sources, or Translations), keep them gzip compressed locally instead of unpacking them. This saves quite a lot of disk space at the expense of more CPU requirements when building the local package caches. False by default.

Languages

The Languages subsection controls which Translation files are downloaded and in which order APT tries to display the description-translations. APT will try to display the first available description in

the language which is listed first. Languages can be defined with their short or long language codes. Note that not all archives provide Translation files for every language – the long language codes are especially rare.

The default list includes "environment" and "en". "environment" has a special meaning here: it will be replaced at runtime with the language codes extracted from the LC_MESSAGES environment variable. It will also ensure that these codes are not included twice in the list. If LC_MESSAGES is set to "C" only the Translation-en file (if available) will be used. To force APT to use no Translation file use the setting Acquire::Languages=none. "none" is another special meaning code which will stop the search for a suitable Translation file. This tells APT to download these translations too, without actually using them unless the environment specifies the languages. So the following example configuration will result in the order "en, de" in an English locale or "de, en" in a German one. Note that "fr" is downloaded, but not used unless APT is used in a French locale (where the order would be "fr, de, en").

```
Acquire::Languages { "environment"; "de"; "en"; "none"; "fr"; };
```

Note: To prevent problems resulting from APT being executed in different environments (e.g. by different users or by other programs) all Translation files which are found in /var/lib/apt/lists/ will be added to the end of the list (after an implicit "none").

ForceIPv4

When downloading, force to use only the IPv4 protocol.

ForceIPv6

When downloading, force to use only the IPv6 protocol.

MaxReleaseFileSize

The maximum file size of Release/Release.gpg/InRelease files. The default is 10MB.

EnableSrvRecords

This option controls if apt will use the DNS SRV server record as specified in RFC 2782 to select an alternative server to connect to. The default is "true".

AllowInsecureRepositories

Allow update operations to load data files from repositories without sufficient security information. The default value is "false". Concept, implications as well as alternatives are detailed in [apt-secure\(8\)](#).

AllowWeakRepositories

Allow update operations to load data files from repositories which provide security information, but these are deemed no longer cryptographically strong enough. The default value is "false". Concept, implications as well as alternatives are detailed in [apt-secure\(8\)](#).

AllowDowngradeToInsecureRepositories

Allow that a repository that was previously gpg signed to become unsigned during an update operation. When there is no valid signature for a previously trusted repository apt will refuse the update. This option can be used to override this protection. You almost certainly never want to enable this. The default is false. Concept, implications as well as alternatives are detailed in [apt-secure\(8\)](#).

Changelogs::URI scope

Acquiring changelogs can only be done if an URI is known from where to get them. Preferable the Release file indicates this in a 'Changelogs' field. If this isn't available the Label/Origin field of the Release file is used to check if a Acquire::Changelogs::URI::Label::*LABEL* or Acquire::Changelogs::URI::Origin::*ORIGIN* option exists and if so this value is taken. The value in the Release file can be overridden with Acquire::Changelogs::URI::Override::Label::*LABEL* or Acquire::Changelogs::URI::Override::Origin::*ORIGIN*. The value should be a normal URI to a text file, except that package specific data is replaced with the placeholder @CHANGEPATH@. The value for it is: 1. if the package is from a component (e.g. main) this is the first part otherwise it is omitted, 2. the first letter of source package name, except if the source package name starts with 'lib' in which

case it will be the first four letters. 3. The complete source package name. 4. the complete name again and 5. the source version. The first (if present), second, third and fourth part are separated by a slash ('/') and between the fourth and fifth part is an underscore ('_'). The special value 'no' is available for this option indicating that this source can't be used to acquire changelog files from. Another source will be tried if available in this case.

BINARY SPECIFIC CONFIGURATION

Especially with the introduction of the **apt** binary it can be useful to set certain options only for a specific binary as even options which look like they would effect only a certain binary like

APT::Get::Show-Versions effect **apt-get** as well as **apt**.

Setting an option for a specific binary only can be achieved by setting the option inside the **Binary::specific-binary** scope. Setting the option **APT::Get::Show-Versions** for the **apt** only can e.g. by done by setting **Binary::apt::APT::Get::Show-Versions** instead.

Note that as seen in the DESCRIPTION section further above you can't set binary-specific options on the commandline itself nor in configuration files loaded via the commandline.

DIRECTORIES

The **Dir::State** section has directories that pertain to local state information. **lists** is the directory to place downloaded package lists in and **status** is the name of the **dpkg(1)** status file. **preferences** is the name of the APT preferences file. **Dir::State** contains the default directory to prefix on all sub-items if they do not start with / or ../../

Dir::Cache contains locations pertaining to local cache information, such as the two package caches **srcpkgcache** and **pkgcache** as well as the location to place downloaded archives, **Dir::Cache::archives**. Generation of caches can be turned off by setting **pkgcache** or **srcpkgcache** to "". This will slow down startup but save disk space. It is probably preferable to turn off the **pkgcache** rather than the **srcpkgcache**. Like **Dir::State** the default directory is contained in **Dir::Cache**

Dir::Etc contains the location of configuration files, **sourcelist** gives the location of the sourcelist and **main** is the default configuration file (setting has no effect, unless it is done from the config file specified by **APT_CONFIG**).

The **Dir::Parts** setting reads in all the config fragments in lexical order from the directory specified. After this is done then the main config file is loaded.

Binary programs are pointed to by **Dir::Bin**. **Dir::Bin::Methods** specifies the location of the method handlers and gzip, bzip2, lzma, dpkg, apt-get dpkg-source dpkg-buildpackage and apt-cache specify the location of the respective programs.

The configuration item **RootDir** has a special meaning. If set, all paths will be relative to **RootDir**, *even paths that are specified absolutely*. So, for instance, if **RootDir** is set to /tmp/staging and **Dir::State::status** is set to /var/lib/dpkg/status, then the status file will be looked up in /tmp/staging/var/lib/dpkg/status. If you want to prefix only relative paths, set **Dir** instead.

The **Ignore-Files-Silently** list can be used to specify which files APT should silently ignore while parsing the files in the fragment directories. Per default a file which ends with .disabled, ~, .bak or .dpkg-[a-z]+ is silently ignored. As seen in the last default value these patterns can use regular expression syntax.

APT IN DSELECT

When APT is used as a **dselect(1)** method several configuration directives control the default behavior. These are in the DSelect section.

Clean

Cache Clean mode; this value may be one of always, prompt, auto, pre-auto and never. always and prompt will remove all packages from the cache after upgrading, prompt (the default) does so conditionally. auto removes only those packages which are no longer downloadable (replaced with a new version for instance). pre-auto performs this action before downloading new packages.

options

The contents of this variable are passed to **apt-get(8)** as command line options when it is run for the

install phase.

Updateoptions

The contents of this variable are passed to **apt-get(8)** as command line options when it is run for the update phase.

PromptAfterUpdate

If true the [U]date operation in **dselect(1)** will always prompt to continue. The default is to prompt only on error.

HOW APT CALLS DPKG(1)

Several configuration directives control how APT invokes **dpkg(1)**. These are in the DPkg section.

options

This is a list of options to pass to **dpkg(1)**. The options must be specified using the list notation and each list item is passed as a single argument to **dpkg(1)**.

Path

This is a string that defines the **PATH** environment variable used when running dpkg. It may be set to any valid value of that environment variable; or the empty string, in which case the variable is not changed.

Pre-Invoke, Post-Invoke

This is a list of shell commands to run before/after invoking **dpkg(1)**. Like options this must be specified in list notation. The commands are invoked in order using /bin/sh; should any fail APT will abort.

Pre-Install-Pkgs

This is a list of shell commands to run before invoking **dpkg(1)**. Like options this must be specified in list notation. The commands are invoked in order using /bin/sh; should any fail APT will abort. APT will pass the filenames of all .deb files it is going to install to the commands, one per line on the requested file descriptor, defaulting to standard input.

Version 2 of this protocol sends more information through the requested file descriptor: a line with the text **VERSION 2**, the APT configuration space, and a list of package actions with filename and version information.

Each configuration directive line has the form key=value. Special characters (equal signs, newlines, nonprintable characters, quotation marks, and percent signs in key and newlines, nonprintable characters, and percent signs in value) are %–encoded. Lists are represented by multiple key::=value lines with the same key. The configuration section ends with a blank line.

Package action lines consist of five fields in Version 2: package name (without architecture qualification even if foreign), old version, direction of version change (< for upgrades, > for downgrades, = for no change), new version, action. The version fields are “-” for no version at all (for example when installing a package for the first time; no version is treated as earlier than any real version, so that is an upgrade, indicated as –< 1.23.4). The action field is “**CONFIGURE**” if the package is being configured, “**REMOVE**” if it is being removed, or the filename of a .deb file if it is being unpacked.

In Version 3 after each version field follows the architecture of this version, which is “-” if there is no version, and a field showing the MultiArch type “same”, “foreign”, “allowed” or “none”. Note that “none” is an incorrect typename which is just kept to remain compatible, it should be read as “no” and users are encouraged to support both.

The version of the protocol to be used for the command *cmd* can be chosen by setting DPkg::Tools::options::*cmd*::Version accordingly, the default being version 1. If APT isn't supporting the requested version it will send the information in the highest version it has support for instead.

The file descriptor to be used to send the information can be requested with DPkg::Tools::options::cmd::InfoFD which defaults to 0 for standard input and is available since version 0.9.11. Support for the option can be detected by looking for the environment variable **APT_HOOK_INFO_FD** which contains the number of the used file descriptor as a confirmation.

Run–Directory

APT chdirs to this directory before invoking **dpkg(1)**, the default is `.`

Build–options

These options are passed to **dpkg-buildpackage(1)** when compiling packages; the default is to disable signing and produce all binaries.

DPkg::ConfigurePending

If this option is set APT will call **dpkg --configure --pending** to let **dpkg(1)** handle all required configurations and triggers. This option is activated by default, but deactivating it could be useful if you want to run APT multiple times in a row – e.g. in an installer. In this scenario you could deactivate this option in all but the last run.

PERIODIC AND ARCHIVES OPTIONS

APT::Periodic and APT::Archives groups of options configure behavior of apt periodic updates, which is done by the `/usr/lib/apt/apt.systemd.daily` script. See the top of this script for the brief documentation of these options.

DEBUG OPTIONS

Enabling options in the Debug:: section will cause debugging information to be sent to the standard error stream of the program utilizing the apt libraries, or enable special program modes that are primarily useful for debugging the behavior of apt. Most of these options are not interesting to a normal user, but a few may be:

- Debug::pkgProblemResolver enables output about the decisions made by dist-upgrade, upgrade, install, remove, purge.
- Debug::NoLocking disables all file locking. This can be used to run some operations (for instance, `apt-get -s install`) as a non-root user.
- Debug::pkgDPkgPM prints out the actual command line each time that apt invokes **dpkg(1)**.
- Debug::IdentCdrom disables the inclusion of statfs data in CD-ROM IDs.

A full list of debugging options to apt follows.

Debug::Acquire::cdrom

Print information related to accessing cdrom:// sources.

Debug::Acquire::ftp

Print information related to downloading packages using FTP.

Debug::Acquire::http

Print information related to downloading packages using HTTP.

Debug::Acquire::https

Print information related to downloading packages using HTTPS.

Debug::Acquire::gpgv

Print information related to verifying cryptographic signatures using gpg.

Debug::aptcdrom

Output information about the process of accessing collections of packages stored on CD-ROMs.

Debug::BuildDeps

Describes the process of resolving build-dependencies in **apt-get(8)**.

Debug::Hashes

Output each cryptographic hash that is generated by the apt libraries.

Debug::IdentCDROM

Do not include information from statfs, namely the number of used and free blocks on the CD-ROM filesystem, when generating an ID for a CD-ROM.

Debug::NoLocking

Disable all file locking. For instance, this will allow two instances of “apt-get update” to run at the same time.

Debug::pkgAcquire

Log when items are added to or removed from the global download queue.

Debug::pkgAcquire::Auth

Output status messages and errors related to verifying checksums and cryptographic signatures of downloaded files.

Debug::pkgAcquire::Diffs

Output information about downloading and applying package index list diffs, and errors relating to package index list diffs.

Debug::pkgAcquire::RRed

Output information related to patching apt package lists when downloading index diffs instead of full indices.

Debug::pkgAcquire::Worker

Log all interactions with the sub-processes that actually perform downloads.

Debug::pkgAutoRemove

Log events related to the automatically-installed status of packages and to the removal of unused packages.

Debug::pkgDepCache::AutoInstall

Generate debug messages describing which packages are being automatically installed to resolve dependencies. This corresponds to the initial auto-install pass performed in, e.g., apt-get install, and not to the full apt dependency resolver; see Debug::pkgProblemResolver for that.

Debug::pkgDepCache::Marker

Generate debug messages describing which packages are marked as keep/install/remove while the ProblemResolver does his work. Each addition or deletion may trigger additional actions; they are shown indented two additional spaces under the original entry. The format for each line is MarkKeep, MarkDelete or MarkInstall followed by package-name <a.b.c -> d.e.f | x.y.z> (section) where a.b.c is the current version of the package, d.e.f is the version considered for installation and x.y.z is a newer version, but not considered for installation (because of a low pin score). The later two can be omitted if there is none or if it is the same as the installed version. section is the name of the section the package appears in.

Debug::pkgDPkgPM

When invoking **dpkg**(1), output the precise command line with which it is being invoked, with arguments separated by a single space character.

Debug::pkgDPkgProgressReporting

Output all the data received from **dpkg**(1) on the status file descriptor and any errors encountered while parsing it.

Debug::pkgOrderList

Generate a trace of the algorithm that decides the order in which apt should pass packages to **dpkg**(1).

Debug::pkgPackageManager

Output status messages tracing the steps performed when invoking **dpkg**(1).

Debug::pkgPolicy

Output the priority of each package list on startup.

Debug::pkgProblemResolver

Trace the execution of the dependency resolver (this applies only to what happens when a complex

dependency problem is encountered).

Debug::pkgProblemResolver::ShowScores

Display a list of all installed packages with their calculated score used by the pkgProblemResolver.

The description of the package is the same as described in Debug::pkgDepCache::Marker

Debug::sourceList

Print information about the vendors read from /etc/apt/vendors.list.

Debug::RunScripts

Display the external commands that are called by apt hooks. This includes e.g. the config options DPkg::{Pre,Post}-Invoke or APT::Update::{Pre,Post}-Invoke.

EXAMPLES

/usr/share/doc/apt/examples/configure-index.gz is a configuration file showing example values for all possible options.

FILES

/etc/apt/apt.conf

APT configuration file. Configuration Item: Dir::Etc::Main.

/etc/apt/apt.conf.d/

APT configuration file fragments. Configuration Item: Dir::Etc::Parts.

NAME

base64 – base64 encode/decode data and print to standard output

SYNOPSIS

base64 [*OPTION*]... [*FILE*]

DESCRIPTION

Base64 encode or decode *FILE*, or standard input, to standard output.

With no *FILE*, or when *FILE* is `-`, read standard input.

Mandatory arguments to long options are mandatory for short options too.

-d, --decode

decode data

-i, --ignore-garbage

when decoding, ignore non-alphabet characters

-w, --wrap=COLS

wrap encoded lines after COLS character (default 76). Use 0 to disable line wrapping

--help display this help and exit

--version

output version information and exit

The data are encoded as described for the base64 alphabet in RFC 4648. When decoding, the input may contain newlines in addition to the bytes of the formal base64 alphabet. Use **--ignore-garbage** to attempt to recover from any other non-alphabet bytes in the encoded stream.

NAME

bash-builtins – bash built-in commands, see **bash(1)**

SYNOPSIS

bash defines the following built-in commands: `:`, `.`, `[`, alias, bg, bind, break, builtin, case, cd, command, compgen, complete, continue, declare, dirs, disown, echo, enable, eval, exec, exit, export, fc, fg, getopt, hash, help, history, if, jobs, kill, let, local, logout, popd, printf, pushd, pwd, read, readonly, return, set, shift, shopt, source, suspend, test, times, trap, type, typeset, ulimit, umask, unalias, unset, until, wait, while.

BASH BUILTIN COMMANDS

Unless otherwise noted, each builtin command documented in this section as accepting options preceded by `-` accepts `--` to signify the end of the options. The `:`, **true**, **false**, and **test**/! builtins do not accept options and do not treat `--` specially. The **exit**, **logout**, **r eturn**, **b reak**, **c ontinue**, **l et**, and **s hift** builtins accept and process arguments beginning with `-` without requiring `--`. Other builtins that accept arguments but are not specified as accepting options interpret arguments beginning with `-` as invalid options and require `--` to prevent this interpretation.

: [*arguments*]

No effect; the command does nothing beyond expanding *arguments* and performing any specified redirections. The return status is zero.

. *filename* [*arguments*]

source *filename* [*arguments*]

Read and execute commands from *filename* in the current shell environment and return the exit status of the last command executed from *filename*. If *filename* does not contain a slash, filenames in **PATH** are used to find the directory containing *filename*. The file searched for in **PATH** need not be executable. When **bash** is not in *posix mode*, the current directory is searched if no file is found in **PATH**. If the **sourc epath** option to the **shopt** builtin command is turned off, the **PATH** is not searched. If any *arguments* are supplied, they become the positional parameters when *filename* is executed. Otherwise the positional parameters are unchanged. If the **-T** option is enabled, **source** inherits any trap on **DEBUG**; if it is not, any **DEBUG** trap string is saved and restored around the call to **source**, and **source** unsets the **DEBUG** trap while it executes. If **-T** is not set, and the sourced file changes the **DEBUG** trap, the new value is retained when **source** completes. The return status is the status of the last command exited within the script (0 if no commands are executed), and false if *filename* is not found or cannot be read.

alias [**-p**] [*name*[**=value**] ...]

Alias with no arguments or with the **-p** option prints the list of aliases in the form **alias** *name***=value** on standard output. When arguments are supplied, an alias is defined for each *name* whose *value* is given. A trailing space *invalue* causes the next word to be checked for alias substitution when the alias is expanded. For each *name* in the argument list for which no *value* is supplied, the name and value of the alias is printed. **Alias** returns true unless a *name* is given for which no alias has been defined.

bg [*jobspec* ...]

Resume each suspended job *jobspec* in the background, as if it had been started with **&**. If *jobspec* is not present, the shell's notion of the *current job* is used. **bg** *jobspec* returns 0 unless run when job control is disabled or, when run with job control enabled, any specified *jobspec* was not found or was started without job control.

bind [**-m** *keymap*] [**-lpsvPSVX**]

bind [**-m** *keymap*] [**-q** *function*] [**-u** *function*] [**-r** *keyseq*]

bind [**-m** *keymap*] [**-f** *filename*]

bind [**-m** *keymap*] [**-x** *keyseq:shell-command*]

bind [**-m** *keymap*] [*keyseq:function-name*]

bind [**-m** *keymap*] [*keyseq:readline-command*]

Display current **readline** key and function bindings, bind a key sequence to a **readline** function or macro, or set a **readline** variable. Each non-option argument is a command as it would appear in *.inputrc*, but each binding or command must be passed as a separate argument; e.g., `'"\C-x\C-r"`:

re-read-init-file'. Options, if supplied, have the following meanings:

-m keymap

Use *keymap* as the keymap to be affected by the subsequent bindings. Acceptable *keymap* names are *emacs*, *emacs-standard*, *emacs-meta*, *emacs-ctlx*, *vi*, *vi-move*, *vi-command*, and *vi-insert*. *vi* is equivalent to *vi-command* (*vi-move* is also a synonym); *emacs* is equivalent to *emacs-standard*.

-l List the names of all **readline** functions.

-p Display **readline** function names and bindings in such a way that they can be re-read.

-P List current **readline** function names and bindings.

-s Display **readline** key sequences bound to macros and the strings they output in such a way that they can be re-read.

-S Display **readline** key sequences bound to macros and the strings they output.

-v Display **readline** variable names and values in such a way that they can be re-read.

-V List current **readline** variable names and values.

-f filename

Read key bindings from *filename*.

-q function

Query about which keys invoke the named *function*.

-u function

Unbind all keys bound to the named *function*.

-r keyseq

Remove any current binding for *keyseq*.

-x keyseq:shell-command

Cause *shell-command* to be executed whenever *keyseq* is entered. When *shell-command* is executed, the shell sets the **READLINE_LINE** variable to the contents of the **readline** line buffer and the **READLINE_POINT** and **READLINE_MARK** variables to the current location of the insertion point and the saved insertion point (the mark), respectively. If the executed command changes the value of any of **READLINE_LINE**, **READLINE_POINT**, or **READLINE_MARK**, those new values will be reflected in the editing state.

-X List all key sequences bound to shell commands and the associated commands in a format that can be reused as input.

The return value is 0 unless an unrecognized option is given or an error occurred.

break [n]

Exit from within a **for**, **while**, **until**, or **select** loop. If *n* is specified, break *n* levels. *n* must be ≥ 1 . If *n* is greater than the number of enclosing loops, all enclosing loops are exited. The return value is 0 unless *n* is not greater than or equal to 1.

builtin shell-builtin [arguments]

Execute the specified shell builtin, passing it *arguments*, and return its exit status. This is useful when defining a function whose name is the same as a shell builtin, retaining the functionality of the builtin within the function. The **cd** builtin is commonly redefined this way. The return status is false if *shell-builtin* is not a shell builtin command.

caller [expr]

Returns the context of any active subroutine call (a shell function or a script executed with the . or **source** builtins). Without *expr*, **caller** displays the line number and source filename of the current subroutine call. If a non-negative integer is supplied as *expr*, **caller** displays the line number, subroutine name, and source file corresponding to that position in the current execution call stack. This extra information may be used, for example, to print a stack trace. The current frame is frame 0. The return value is 0 unless the shell is not executing a subroutine call or *expr* does not correspond to a valid position in the call stack.

cd [-L|[-P [-e]] [-@]] [dir]

Change the current directory to *dir*. If *dir* is not supplied, the value of the **HOME** shell variable is the default. Any additional arguments following *dir* are ignored. The variable **CDPATH** defines the search path for the directory containing *dir*: each directory name in **CDPATH** is searched for *dir*. Alternative directory names in **CDPATH** are separated by a colon (:). A null directory name in **CDPATH** is the same as the current directory, i.e., “.”. If *dir* begins with a slash (/), then **CDPATH** is not used. The **-P** option causes **cd** to use the physical directory structure by resolving symbolic links while traversing *dir* and before processing instances of .. in *dir* (see also the **-P** option to the **set** builtin command); the **-L** option forces symbolic links to be followed by resolving the link after processing instances of .. in *dir*. If .. appears in *dir*, it is processed by removing the immediately previous pathname component from *dir*, back to a slash or the beginning of *dir*. If the **-e** option is supplied with **-P**, and the current working directory cannot be successfully determined after a successful directory change, **cd** will return an unsuccessful status. On systems that support it, the **-@** option presents the extended attributes associated with a file as a directory. An argument of – is converted to **\$OLDPWD** before the directory change is attempted. If a non-empty directory name from **CDPATH** is used, or if – is the first argument, and the directory change is successful, the absolute pathname of the new working directory is written to the standard output. The return value is true if the directory was successfully changed; false otherwise.

command [-pVv] command [arg ...]

Run *command* with *args* suppressing the normal shell function lookup. Only builtin commands or commands found in the **PATH** are executed. If the **-p** option is given, the search for *command* is performed using a default value for **PATH** that is guaranteed to find all of the standard utilities. If either the **-V** or **-v** option is supplied, a description of *command* is printed. The **-v** option causes a single word indicating the command or filename used to invoke *command* to be displayed; the **-V** option produces a more verbose description. If the **-V** or **-v** option is supplied, the exit status is 0 if *command* was found, and 1 if not. If neither option is supplied and an error occurred or *command* cannot be found, the exit status is 127. Otherwise, the exit status of the **command** builtin is the exit status of *command*.

compgen [option] [word]

Generate possible completion matches for *word* according to the *options*, which may be any option accepted by the **complete** builtin with the exception of **-p** and **-r**, and write the matches to the standard output. When using the **-F** or **-C** options, the various shell variables set by the programmable completion facilities, while available, will not have useful values.

The matches will be generated in the same way as if the programmable completion code had generated them directly from a completion specification with the same flags. If *word* is specified, only those completions matching *word* will be displayed.

The return value is true unless an invalid option is supplied, or no matches were generated.

complete [-abcdefgjksuv] [-o comp-option] [-DEI] [-A action] [-G globpat] [-W wordlist]

[-F function] [-C command] [-X filterpat] [-P prefix] [-S suffix] name [name ...]

complete -pr [-DEI] [name ...]

Specify how arguments to each *name* should be completed. If the **-p** option is supplied, or if no options are supplied, existing completion specifications are printed in a way that allows them to be reused as input. The **-r** option removes a completion specification for each *name*, or, if no *names* are supplied, all completion specifications. The **-D** option indicates that other supplied options and actions should apply to the “default” command completion; that is, completion attempted on a command for which no completion has previously been defined. The **-E** option indicates that other supplied options and actions should apply to “empty” command completion; that is, completion attempted on a blank line. The **-I** option indicates that other supplied options and actions should apply to completion on the initial non-assignment word on the line, or after a command delimiter such as ; or |, which is usually command name completion. If multiple options are supplied, the **-D** option takes precedence over **-E**, and both take precedence over **-I**. If any of **-D**,

-E, or **-I** are supplied, any other *name* arguments are ignored; these completions only apply to the case specified by the option.

The process of applying these completion specifications when word completion is attempted is described above under **Programmable Completion**.

Other options, if specified, have the following meanings. The arguments to the **-G**, **-W**, and **-X** options (and, if necessary, the **-P** and **-S** options) should be quoted to protect them from expansion before the **complete** builtin is invoked.

-o comp-option

The *comp-option* controls several aspects of the compspec's behavior beyond the simple generation of completions. *comp-option* may be one of:

bashdefault

Perform the rest of the default **bash** completions if the compspec generates no matches.

default Use readline's default filename completion if the compspec generates no matches.

dirnames

Perform directory name completion if the compspec generates no matches.

filenames

Tell readline that the compspec generates filenames, so it can perform any filename-specific processing (like adding a slash to directory names, quoting special characters, or suppressing trailing spaces). Intended to be used with shell functions.

noquote Tell readline not to quote the completed words if they are filenames (quoting filenames is the default).

nosort Tell readline not to sort the list of possible completions alphabetically.

nospace Tell readline not to append a space (the default) to words completed at the end of the line.

plusdirs After any matches defined by the compspec are generated, directory name completion is attempted and any matches are added to the results of the other actions.

-A action

The *action* may be one of the following to generate a list of possible completions:

alias Alias names. May also be specified as **-a**.

arrayvar

Array variable names.

binding Readline key binding names.

builtin Names of shell builtin commands. May also be specified as **-b**.

command

Command names. May also be specified as **-c**.

directory

Directory names. May also be specified as **-d**.

disabled

Names of disabled shell builtins.

enabled Names of enabled shell builtins.

export Names of exported shell variables. May also be specified as **-e**.

file File names. May also be specified as **-f**.

function

Names of shell functions.

group Group names. May also be specified as **-g**.

helptopic

Help topics as accepted by the **help** builtin.

hostname

Hostnames, as taken from the file specified by the **HOSTFILE** shell variable.

job Job names, if job control is active. May also be specified as **-j**.

keyword

Shell reserved words. May also be specified as **-k**.

running Names of running jobs, if job control is active.

service Service names. May also be specified as **-s**.

setopt Valid arguments for the **-o** option to the **set** builtin.

shopt Shell option names as accepted by the **shopt** builtin.

signal Signal names.

stopped Names of stopped jobs, if job control is active.

user User names. May also be specified as **-u**.

variable Names of all shell variables. May also be specified as **-v**.

-C command

command is executed in a subshell environment, and its output is used as the possible completions.

-F function

The shell function *function* is executed in the current shell environment. When the function is executed, the first argument (**\$1**) is the name of the command whose arguments are being completed, the second argument (**\$2**) is the word being completed, and the third argument (**\$3**) is the word preceding the word being completed on the current command line. When it finishes, the possible completions are retrieved from the value of the **COMPREPLY** array variable.

-G globpat

The pathname expansion pattern *globpat* is expanded to generate the possible completions.

-P prefix

prefix is added at the beginning of each possible completion after all other options have been applied.

-S suffix *suffix* is appended to each possible completion after all other options have been applied.**-W wordlist**

The *wordlist* is split using the characters in the **IFS** special variable as delimiters, and each resultant word is expanded. Shell quoting is honored within *wordlist*, in order to provide a mechanism for the words to contain shell metacharacters or characters in the value of **IFS**. The possible completions are the members of the resultant list which match the word being completed.

-X filterpat

filterpat is a pattern as used for pathname expansion. It is applied to the list of possible completions generated by the preceding options and arguments, and each completion matching *filterpat* is removed from the list. A leading **!** in *filterpat* negates the pattern; in this case, any completion not matching *filterpat* is removed.

The return value is true unless an invalid option is supplied, an option other than **-p** or **-r** is supplied without a *name* argument, an attempt is made to remove a completion specification for a *name* for which no specification exists, or an error occurs adding a completion specification.

compopt [-o option] [-DEI] [+o option] [name]

Modify completion options for each *name* according to the *options*, or for the currently-executing completion if no *names* are supplied. If no *options* are given, display the completion options for each *name* or the current completion. The possible values of *option* are those valid for the **complete** builtin described above. The **-D** option indicates that other supplied options should apply to the “default” command completion; that is, completion attempted on a command for which no completion has previously been defined. The **-E** option indicates that other supplied options should apply to “empty” command completion; that is, completion attempted on a blank line. The **-I** option indicates that other supplied options should apply to completion on the initial non-assignment word on the line, or after a command delimiter such as ; or |, which is usually

command name completion.

The return value is true unless an invalid option is supplied, an attempt is made to modify the options for a *name* for which no completion specification exists, or an output error occurs.

continue [*n*]

Resume the next iteration of the enclosing **for**, **while**, **until**, or **select** loop. If *n* is specified, resume at the *n*th enclosing loop. *n* must be ≥ 1 . If *n* is greater than the number of enclosing loops, the last enclosing loop (the “top-level” loop) is resumed. The return value is 0 unless *n* is not greater than or equal to 1.

declare [–aAfGgiIlNrtux] [–p] [*name*[=value] ...]

typeset [–aAfGgiIlNrtux] [–p] [*name*[=value] ...]

Declare variables and/or give them attributes. If *nonames* are given then display the values of variables. The **-p** option will display the attributes and values of each *name*. When **-p** is used with *name* arguments, additional options, other than **-f** and **-F**, are ignored. When **-p** is supplied without *name* arguments, it will display the attributes and values of all variables having the attributes specified by the additional options. If no other options are supplied with **-p**, **declare** will display the attributes and values of all shell variables. The **-f** option will restrict the display to shell functions. The **-F** option inhibits the display of function definitions; only the function name and attributes are printed. If the **extdebug** shell option is enabled using **shopt**, the source file name and line number where each *name* is defined are displayed as well. The **-F** option implies **-f**. The **-g** option forces variables to be created or modified at the global scope, even when **declare** is executed in a shell function. It is ignored in all other cases. The **-I** option causes local variables to inherit the attributes (except the *nameref* attribute) and value of any existing variable with the same *name* at a surrounding scope. If there is no existing variable, the local variable is initially unset. The following options can be used to restrict output to variables with the specified attribute or to give variables attributes:

- a** Each *name* is an indexed array variable (see **Arrays** above).
- A** Each *name* is an associative array variable (see **Arrays** above).
- f** Use function names only.
- i** The variable is treated as an integer; arithmetic evaluation (see **ARITHMETIC EVALUATION** above) is performed when the variable is assigned a value.
- l** When the variable is assigned a value, all upper-case characters are converted to lower-case. The upper-case attribute is disabled.
- n** Give each *name* the *nameref* attribute, making it a name reference to another variable. That other variable is defined by the value of *name*. All references, assignments, and attribute modifications to *name*, except those using or changing the **-n** attribute itself, are performed on the variable referenced by *name*’s value. The *nameref* attribute cannot be applied to array variables.
- r** Make *names* readonly. These names cannot then be assigned values by subsequent assignment statements or unset.
- t** Give each *name* the *trace* attribute. Traced functions inherit the **DEBUG** and **RETURN** traps from the calling shell. The trace attribute has no special meaning for variables.
- u** When the variable is assigned a value, all lower-case characters are converted to upper-case. The lower-case attribute is disabled.
- x** Mark *names* for export to subsequent commands via the environment.

Using ‘+’ instead of ‘-’ turns off the attribute instead, with the exceptions that **+a** and **+A** may not be used to destroy array variables and **+r** will not remove the readonly attribute. When used in a function, **declare** and **typeset** make each *name* local, as with the **local** command, unless the **-g** option is supplied. If a variable name is followed by *=value*, the value of the variable is set to *value*. When using **-a** or **-A** and the compound assignment syntax to create array variables, additional attributes do not take effect until subsequent assignments. The return value is 0 unless an invalid option is encountered, an attempt is made to define a function using **-f** *foo=bar*, an attempt is made to assign a value to a readonly variable, an attempt is made to assign a value to an

array variable without using the compound assignment syntax (see **Arrays** above), one of the *names* is not a valid shell variable name, an attempt is made to turn off readonly status for a readonly variable, an attempt is made to turn off array status for an array variable, or an attempt is made to display a non-existent function with **-f**.

dirs [**-clpv**] [**+n**] [**-n**]

Without options, displays the list of currently remembered directories. The default display is on a single line with directory names separated by spaces. Directories are added to the list with the **pushd** command; the **popd** command removes entries from the list. The current directory is always the first directory in the stack.

- c** Clears the directory stack by deleting all of the entries.
- l** Produces a listing using full pathnames; the default listing format uses a tilde to denote the home directory.
- p** Print the directory stack with one entry per line.
- v** Print the directory stack with one entry per line, prefixing each entry with its index in the stack.
- +n** Displays the *n*th entry counting from the left of the list shown by **dirs** when invoked without options, starting with zero.
- n** Displays the *n*th entry counting from the right of the list shown by **dirs** when invoked without options, starting with zero.

The return value is 0 unless an invalid option is supplied or *n* indexes beyond the end of the directory stack.

disown [**-ar**] [**-h**] [*jobspec* ... | *pid* ...]

Without options, remove each *jobspec* from the table of active jobs. If *jobspec* is not present, and neither the **-a** nor the **-r** option is supplied, the *current job* is used. If the **-h** option is given, each *jobspec* is not removed from the table, but is marked so that **SIGHUP** is not sent to the job if the shell receives a **SIGHUP**. If *nojobspec* is supplied, the **-a** option means to remove or mark all jobs; the **-r** option without a *jobspec* argument restricts operation to running jobs. The return value is 0 unless a *jobspec* does not specify a valid job.

echo [**-neE**] [*arg* ...]

Output the *args*, separated by spaces, followed by a newline. The return status is 0 unless a write error occurs. If **-n** is specified, the trailing newline is suppressed. If the **-e** option is given, interpretation of the following backslash-escaped characters is enabled. The **-E** option disables the interpretation of these escape characters, even on systems where they are interpreted by default. The **xpg_echo** shell option may be used to dynamically determine whether or not **echo** expands these escape characters by default. **echo** does not interpret -- to mean the end of options. **echo** interprets the following escape sequences:

- \a** alert (bell)
- \b** backspace
- \c** suppress further output
- \e**
- \E** an escape character
- \f** form feed
- \n** new line
- \r** carriage return
- \t** horizontal tab
- \v** vertical tab
- ** backslash
- \0nnn** the eight-bit character whose value is the octal value *nnn* (zero to three octal digits)
- \xHH** the eight-bit character whose value is the hexadecimal value *HH* (one or two hex digits)
- \uHHHH** the Unicode (ISO/IEC 10646) character whose value is the hexadecimal value *HHHH* (one to four hex digits)

\UHHHHHHHHH

the Unicode (ISO/IEC 10646) character whose value is the hexadecimal value *HHHHH-HHH* (one to eight hex digits)

enable [**-a**] [**-dnps**] [**-f** *filename*] [*name* ...]

Enable and disable builtin shell commands. Disabling a builtin allows a disk command which has the same name as a shell builtin to be executed without specifying a full pathname, even though the shell normally searches for builtins before disk commands. If **-n** is used, each *name* is disabled; otherwise, *names* are enabled. For example, to use the **test** binary found via the **PATH** instead of the shell builtin version, run **enable -n test**. The **-f** option means to load the new builtin command *name* from shared object *filename*, on systems that support dynamic loading. The **-d** option will delete a builtin previously loaded with **-f**. If no *name* arguments are given, or if the **-p** option is supplied, a list of shell builtins is printed. With no other option arguments, the list consists of all enabled shell builtins. If **-n** is supplied, only disabled builtins are printed. If **-a** is supplied, the list printed includes all builtins, with an indication of whether or not each is enabled. If **-s** is supplied, the output is restricted to the POSIX *special* builtins. The return value is 0 unless a *name* is not a shell builtin or there is an error loading a new builtin from a shared object.

eval [*arg* ...]

The *args* are read and concatenated together into a single command. This command is then read and executed by the shell, and its exit status is returned as the value of **eval**. If there are no arguments, **eval** returns 0.

exec [**-cl**] [**-a** *name*] [*command* [*arguments*]]

If *command* is specified, it replaces the shell. No new process is created. The *arguments* become the arguments to *command*. If the **-l** option is supplied, the shell places a dash at the beginning of the zeroth argument passed to *command*. This is what *login(1)* does. The **-c** option causes *command* to be executed with an empty environment. If **-a** is supplied, the shell passes *name* as the zeroth argument to the executed command. If *command* cannot be executed for some reason, a non-interactive shell exits, unless the **execfail** shell option is enabled. In that case, it returns failure. An interactive shell returns failure if the file cannot be executed. A subshell exits unconditionally if **exec** fails. If *command* is not specified, any redirections take effect in the current shell, and the return status is 0. If there is a redirection error, the return status is 1.

exit [*n*] Cause the shell to exit with a status of *n*. If *n* is omitted, the exit status is that of the last command executed. A trap on **EXIT** is executed before the shell terminates.

export [**-fn**] [*name*[=*word*]] ...

export -p

The supplied *names* are marked for automatic export to the environment of subsequently executed commands. If the **-f** option is given, the *names* refer to functions. If no *names* are given, or if the **-p** option is supplied, a list of names of all exported variables is printed. The **-n** option causes the export property to be removed from each *name*. If a variable name is followed by **=word**, the value of the variable is set to *word*. **export** returns an exit status of 0 unless an invalid option is encountered, one of the *names* is not a valid shell variable name, or **-f** is supplied with a *name* that is not a function.

fc [**-e** *ename*] [**-lnr**] [*first*] [*last*]

fc -s [*pat=rep*] [*cmd*]

The first form selects a range of commands from *first* to *last* from the history list and displays or edits and re-executes them. *First* and *last* may be specified as a string (to locate the last command beginning with that string) or as a number (an index into the history list, where a negative number is used as an offset from the current command number). When listing, a *first* or *last* of 0 is equivalent to **-1** and **-0** is equivalent to the current command (usually the **fc** command); otherwise 0 is equivalent to **-1** and **-0** is invalid. If *last* is not specified, it is set to the current command for listing (so that **fc -1 -10** prints the last 10 commands) and to *first* otherwise. If *first* is not specified, it is set to the previous command for editing and **-16** for listing.

The **-n** option suppresses the command numbers when listing. The **-r** option reverses the order of the commands. If the **-l** option is given, the commands are listed on standard output. Otherwise, the editor given by *ename* is invoked on a file containing those commands. If *ename* is not given, the value of the **FCEDIT** variable is used, and the value of **EDITOR** if **FCEDIT** is not set. If neither variable is set, *vi* is used. When editing is complete, the edited commands are echoed and executed.

In the second form, *command* is re-executed after each instance of *pat* is replaced by *rep*. *Command* is interpreted the same as *first* above. A useful alias to use with this is `r='fc -s'`, so that typing `r cc` runs the last command beginning with *cc* and typing `r` re-executes the last command.

If the first form is used, the return value is 0 unless an invalid option is encountered or *first* or *last* specify history lines out of range. If the **-e** option is supplied, the return value is the value of the last command executed or failure if an error occurs with the temporary file of commands. If the second form is used, the return status is that of the command re-executed, unless *cmd* does not specify a valid history line, in which case **fc** returns failure.

fg [*jobspec*]

Resume *jobspec* in the foreground, and make it the current job. If *jobspec* is not present, the shell's notion of the *current job* is used. The return value is that of the command placed into the foreground, or failure if run when job control is disabled or, when run with job control enabled, if *jobspec* does not specify a valid job or *jobspec* specifies a job that was started without job control.

getopts *optstring name [arg ...]*

getopts is used by shell procedures to parse positional parameters. *optstring* contains the option characters to be recognized; if a character is followed by a colon, the option is expected to have an argument, which should be separated from it by white space. The colon and question mark characters may not be used as option characters. Each time it is invoked, **getopts** places the next option in the shell variable *name*, initializing *name* if it does not exist, and the index of the next argument to be processed into the variable **OPTIND**. **OPTIND** is initialized to 1 each time the shell or a shell script is invoked. When an option requires an argument, **getopts** places that argument into the variable **OPTARG**. The shell does not reset **OPTIND** automatically; it must be manually reset between multiple calls to **getopts** within the same shell invocation if a new set of parameters is to be used.

When the end of options is encountered, **getopts** exits with a return value greater than zero. **OPTIND** is set to the index of the first non-option argument, and *name* is set to `?`.

getopts normally parses the positional parameters, but if more arguments are supplied as *arg* values, **getopts** parses those instead.

getopts can report errors in two ways. If the first character of *optstring* is a colon, *silent* error reporting is used. In normal operation, diagnostic messages are printed when invalid options or missing option arguments are encountered. If the variable **OPTERR** is set to 0, no error messages will be displayed, even if the first character of *optstring* is not a colon.

If an invalid option is seen, **getopts** places `?` into *name* and, if not silent, prints an error message and unsets **OPTARG**. If **getopts** is silent, the option character found is placed in **OPTARG** and no diagnostic message is printed.

If a required argument is not found, and **getopts** is not silent, a question mark (`?`) is placed in *name*, **OPTARG** is unset, and a diagnostic message is printed. If **getopts** is silent, then a colon (`:`) is placed in *name* and **OPTARG** is set to the option character found.

getopts returns true if an option, specified or unspecified, is found. It returns false if the end of

options is encountered or an error occurs.

hash [**-lr**] [**-p** *filename*] [**-dt**] [*name*]

Each time **hash** is invoked, the full pathname of the command *name* is determined by searching the directories in **\$PATH** and remembered. Any previously-remembered pathname is discarded. If the **-p** option is supplied, no path search is performed, and *filename* is used as the full filename of the command. The **-r** option causes the shell to forget all remembered locations. The **-d** option causes the shell to forget the remembered location of each *name*. If the **-t** option is supplied, the full pathname to which each *name* corresponds is printed. If multiple *name* arguments are supplied with **-t**, the *name* is printed before the hashed full pathname. The **-l** option causes output to be displayed in a format that may be reused as input. If no arguments are given, or if only **-l** is supplied, information about remembered commands is printed. The return status is true unless a *name* is not found or an invalid option is supplied.

help [**-dms**] [*pattern*]

Display helpful information about builtin commands. If *pattern* is specified, **help** gives detailed help on all commands matching *pattern*; otherwise help for all the builtins and shell control structures is printed.

- d** Display a short description of each *pattern*
- m** Display the description of each *pattern* in a manpage-like format
- s** Display only a short usage synopsis for each *pattern*

The return status is 0 unless no command matches *pattern*.

history [*n*]

history -c

history -d *offset*

history -d *start-end*

history -anrw [*filename*]

history -p *arg* [*arg* ...]

history -s *arg* [*arg* ...]

With no options, display the command history list with line numbers. Lines listed with a * have been modified. An argument of *n* lists only the last *n* lines. If the shell variable **HISTTIMEFORMAT** is set and not null, it is used as a format string for **strftime(3)** to display the time stamp associated with each displayed history entry. No intervening blank is printed between the formatted time stamp and the history line. If *filename* is supplied, it is used as the name of the history file; if not, the value of **HISTFILE** is used. Options, if supplied, have the following meanings:

- c** Clear the history list by deleting all the entries.

-d *offset*

Delete the history entry at position *offset*. If *offset* is negative, it is interpreted as relative to one greater than the last history position, so negative indices count back from the end of the history, and an index of -1 refers to the current **history -d** command.

-d *start-end*

Delete the history entries between positions *start* and *end*, inclusive. Positive and negative values for *start* and *end* are interpreted as described above.

- a** Append the “new” history lines to the history file. These are history lines entered since the beginning of the current **bash** session, but not already appended to the history file.
- n** Read the history lines not already read from the history file into the current history list. These are lines appended to the history file since the beginning of the current **bash** session.
- r** Read the contents of the history file and append them to the current history list.
- w** Write the current history list to the history file, overwriting the history file’s contents.
- p** Perform history substitution on the following *args* and display the result on the standard output. Does not store the results in the history list. Each *arg* must be quoted to disable normal history expansion.
- s** Store the *args* in the history list as a single entry. The last command in the history list is removed before the *args* are added.

If the **HISTTIMEFORMAT** variable is set, the time stamp information associated with each history entry is written to the history file, marked with the history comment character. When the history file is read, lines beginning with the history comment character followed immediately by a digit are interpreted as timestamps for the following history entry. The return value is 0 unless an invalid option is encountered, an error occurs while reading or writing the history file, an invalid *offset* is supplied as an argument to **-d**, or the history expansion supplied as an argument to **-p** fails.

jobs [**-Inprs**] [*jobspec* ...]

jobs **-x** *command* [*args* ...]

The first form lists the active jobs. The options have the following meanings:

-l List process IDs in addition to the normal information.

-n Display information only about jobs that have changed status since the user was last notified of their status.

-p List only the process ID of the job's process group leader.

-r Display only running jobs.

-s Display only stopped jobs.

If *jobspec* is given, output is restricted to information about that job. The return status is 0 unless an invalid option is encountered or an invalid *jobspec* is supplied.

If the **-x** option is supplied, **jobs** replaces any *jobspec* found in *command* or *args* with the corresponding process group ID, and executes *command* passing it *args*, returning its exit status.

kill [**-s** *sigspec* | **-n** *signum* | **-sigspec**] [*pid* | *jobspec*] ...

kill **-l**|**-L** [*sigspec* | *exit_status*]

Send the signal named by *sigspec* or *signum* to the processes named by *pid* or *jobspec*. *sigspec* is either a case-insensitive signal name such as **SIGKILL** (with or without the **SIG** prefix) or a signal number; *signum* is a signal number. If *sigspec* is not present, then **SIGTERM** is assumed. An argument of **-l** lists the signal names. If any arguments are supplied when **-l** is given, the names of the signals corresponding to the arguments are listed, and the return status is 0. The *exit_status* argument to **-L** is a number specifying either a signal number or the exit status of a process terminated by a signal. The **-L** option is equivalent to **-l**. **kill** returns true if at least one signal was successfully sent, or false if an error occurs or an invalid option is encountered.

let *arg* [*arg* ...]

Each *arg* is an arithmetic expression to be evaluated (see **ARITHMETIC EVALUATION** above). If the last *arg* evaluates to 0, **let** returns 1; 0 is returned otherwise.

local [*option*] [*name*[=*value*] ... | -]

For each argument, a local variable named *name* is created, and assigned *value*. The *option* can be any of the options accepted by **declare**. When **local** is used within a function, it causes the variable *name* to have a visible scope restricted to that function and its children. If *name* is -, the set of shell options is made local to the function in which **local** is invoked: shell options changed using the **set** builtin inside the function are restored to their original values when the function returns. The restore is effected as if a series of **set** commands were executed to restore the values that were in place before the function. With no operands, **local** writes a list of local variables to the standard output. It is an error to use **local** when not within a function. The return status is 0 unless **local** is used outside a function, an invalid *name* is supplied, or *name* is a readonly variable.

logout Exit a login shell.

mapfile [**-d** *delim*] [**-n** *count*] [**-O** *origin*] [**-s** *count*] [**-t**] [**-u** *fd*] [**-C** *callback*] [**-c** *quantum*] [*array*]

readarray [**-d** *delim*] [**-n** *count*] [**-O** *origin*] [**-s** *count*] [**-t**] [**-u** *fd*] [**-C** *callback*] [**-c** *quantum*] [*array*]

Read lines from the standard input into the indexed array variable *array*, or from file descriptor *fd* if the **-u** option is supplied. The variable **MAPFILE** is the default *array*. Options, if supplied, have the following meanings:

-d The first character of *delim* is used to terminate each input line, rather than newline. If *delim* is the empty string, **mapfile** will terminate a line when it reads a NUL character.

- n** Copy at most *count* lines. If *count* is 0, all lines are copied.
- O** Begin assigning to *array* at index *origin*. The default index is 0.
- s** Discard the first *count* lines read.
- t** Remove a trailing *delim* (default newline) from each line read.
- u** Read lines from file descriptor *fd* instead of the standard input.
- C** Evaluate *callback* each time *quantum* lines are read. The **-c** option specifies *quantum*.
- c** Specify the number of lines read between each call to *callback*.

If **-C** is specified without **-c**, the default quantum is 5000. When *callback* is evaluated, it is supplied the index of the next array element to be assigned and the line to be assigned to that element as additional arguments. *callback* is evaluated after the line is read but before the array element is assigned.

If not supplied with an explicit origin, **mapfile** will clear *array* before assigning to it.

mapfile returns successfully unless an invalid option or option argument is supplied, *array* is invalid or unassignable, or if *array* is not an indexed array.

popd [**-n**] [**+n**] [**-n**]

Removes entries from the directory stack. With no arguments, removes the top directory from the stack, and performs a **cd** to the new top directory. Arguments, if supplied, have the following meanings:

- n** Suppresses the normal change of directory when removing directories from the stack, so that only the stack is manipulated.
- +n** Removes the *n*th entry counting from the left of the list shown by **dirs**, starting with zero. For example: **popd +0** removes the first directory, **popd +1** the second.
- n** Removes the *n*th entry counting from the right of the list shown by **dirs**, starting with zero. For example: **popd -0** removes the last directory, **popd -1** the next to last.

If the **popd** command is successful, a **dirs** is performed as well, and the return status is 0. **popd** returns false if an invalid option is encountered, the directory stack is empty, a non-existent directory stack entry is specified, or the directory change fails.

printf [**-v** *var*] *format* [*arguments*]

Write the formatted *arguments* to the standard output under the control of the *format*. The **-v** option causes the output to be assigned to the variable *var* rather than being printed to the standard output.

The *format* is a character string which contains three types of objects: plain characters, which are simply copied to standard output, character escape sequences, which are converted and copied to the standard output, and format specifications, each of which causes printing of the next successive *argument*. In addition to the standard **printf(1)** format specifications, **printf** interprets the following extensions:

- %b** causes **printf** to expand backslash escape sequences in the corresponding *argument* in the same way as **echo -e**.
- %q** causes **printf** to output the corresponding *argument* in a format that can be reused as shell input.
- %(*datefmt*)T**

causes **printf** to output the date-time string resulting from using *datefmt* as a format string for **strftime(3)**. The corresponding *argument* is an integer representing the number of seconds since the epoch. Two special argument values may be used: **-1** represents the current time, and **-2** represents the time the shell was invoked. If no argument is specified, conversion behaves as if **-1** had been given. This is an exception to the usual **printf** behavior.

The **%b**, **%q**, and **%T** directives all use the field width and precision arguments from the format specification and write that many bytes from (or use that wide a field for) the expanded argument, which usually contains more characters than the original.

Arguments to non-string format specifiers are treated as C constants, except that a leading plus or minus sign is allowed, and if the leading character is a single or double quote, the value is the ASCII value of the following character.

The *format* is reused as necessary to consume all of the *arguments*. If the *format* requires more *arguments* than are supplied, the extra format specifications behave as if a zero value or null string, as appropriate, had been supplied. The return value is zero on success, non-zero on failure.

pushd [-n] [+n] [-n]

pushd [-n] [dir]

Adds a directory to the top of the directory stack, or rotates the stack, making the new top of the stack the current working directory. With no arguments, **pushd** exchanges the top two directories and returns 0, unless the directory stack is empty. Arguments, if supplied, have the following meanings:

- n** Suppresses the normal change of directory when rotating or adding directories to the stack, so that only the stack is manipulated.
- +n** Rotates the stack so that the *n*th directory (counting from the left of the list shown by **dirs**, starting with zero) is at the top.
- n** Rotates the stack so that the *n*th directory (counting from the right of the list shown by **dirs**, starting with zero) is at the top.
- dir** Adds *dir* to the directory stack at the top, making it the new current working directory as if it had been supplied as the argument to the **cd** builtin.

If the **pushd** command is successful, a **dirs** is performed as well. If the first form is used, **pushd** returns 0 unless the cd to *dir* fails. With the second form, **pushd** returns 0 unless the directory stack is empty, a non-existent directory stack element is specified, or the directory change to the specified new current directory fails.

pwd [-LP]

Print the absolute pathname of the current working directory. The pathname printed contains no symbolic links if the **-P** option is supplied or the **-o physical** option to the **set** builtin command is enabled. If the **-L** option is used, the pathname printed may contain symbolic links. The return status is 0 unless an error occurs while reading the name of the current directory or an invalid option is supplied.

read [-ers] [-a *aname*] [-d *delim*] [-i *text*] [-n *nchars*] [-N *nchars*] [-p *prompt*] [-t *timeout*] [-u *fd*] [*name* ...]

One line is read from the standard input, or from the file descriptor *fd* supplied as an argument to the **-u** option, split into words as described above under **Word Splitting**, and the first word is assigned to the first *name*, the second word to the second *name*, and so on. If there are more words than names, the remaining words and their intervening delimiters are assigned to the last *name*. If there are fewer words read from the input stream than names, the remaining names are assigned empty values. The characters in **IFS** are used to split the line into words using the same rules the shell uses for expansion (described above under **Word Splitting**). The backslash character (\) may be used to remove any special meaning for the next character read and for line continuation. Options, if supplied, have the following meanings:

-a *aname*

The words are assigned to sequential indices of the array variable *aname*, starting at 0. *aname* is unset before any new values are assigned. Other *name* arguments are ignored.

-d *delim*

The first character of *delim* is used to terminate the input line, rather than newline. If *delim* is the empty string, **read** will terminate a line when it reads a NUL character.

-e

If the standard input is coming from a terminal, **readline** (see **READLINE** above) is used to obtain the line. Readline uses the current (or default, if line editing was not previously active) editing settings, but uses Readline's default filename completion.

-i *text*

If **readline** is being used to read the line, *text* is placed into the editing buffer before editing begins.

-n *nchars*

read returns after reading *nchars* characters rather than waiting for a complete line of input, but honors a delimiter if fewer than *nchars* characters are read before the delimiter.

-N *nchars*

read returns after reading exactly *nchars* characters rather than waiting for a complete line of input, unless EOF is encountered or **read** times out. Delimiter characters encountered in the input are not treated specially and do not cause **read** to return until *nchars* characters are read. The result is not split on the characters in **IFS**; the intent is that the variable is assigned exactly the characters read (with the exception of backslash; see the **-r** option below).

-p *prompt*

Display *prompt* on standard error, without a trailing newline, before attempting to read any input. The prompt is displayed only if input is coming from a terminal.

-r

Backslash does not act as an escape character. The backslash is considered to be part of the line. In particular, a backslash-newline pair may not then be used as a line continuation.

-s

Silent mode. If input is coming from a terminal, characters are not echoed.

-t *timeout*

Cause **read** to time out and return failure if a complete line of input (or a specified number of characters) is not read within *timeout* seconds. *timeout* may be a decimal number with a fractional portion following the decimal point. This option is only effective if **read** is reading input from a terminal, pipe, or other special file; it has no effect when reading from regular files. If **read** times out, **read** saves any partial input read into the specified variable *name*. If *timeout* is 0, **read** returns immediately, without trying to read any data. The exit status is 0 if input is available on the specified file descriptor, non-zero otherwise. The exit status is greater than 128 if the timeout is exceeded.

-u *fd*

Read input from file descriptor *fd*.

If no *names* are supplied, the line read, without the ending delimiter but otherwise unmodified, is assigned to the variable **REPLY**. The exit status is zero, unless end-of-file is encountered, **read** times out (in which case the status is greater than 128), a variable assignment error (such as assigning to a readonly variable) occurs, or an invalid file descriptor is supplied as the argument to **-u**.

readonly [-aAf] [-p] [*name[=word]* ...]

The given *names* are marked readonly; the values of these *names* may not be changed by subsequent assignment. If the **-f** option is supplied, the functions corresponding to the *names* are so marked. The **-a** option restricts the variables to indexed arrays; the **-A** option restricts the variables to associative arrays. If both options are supplied, **-A** takes precedence. If no *name* arguments are given, or if the **-p** option is supplied, a list of all readonly names is printed. The other options may be used to restrict the output to a subset of the set of readonly names. The **-p** option causes output to be displayed in a format that may be reused as input. If a variable name is followed by *=word*, the value of the variable is set to *word*. The return status is 0 unless an invalid option is encountered, one of the *names* is not a valid shell variable name, or **-f** is supplied with a *name* that is not a function.

return [*n*]

Causes a function to stop executing and return the value specified by *n* to its caller. If *n* is omitted, the return status is that of the last command executed in the function body. If **return** is executed by a trap handler, the last command used to determine the status is the last command executed before the trap handler. If **return** is executed during a **DEBUG** trap, the last command used to determine the status is the last command executed by the trap handler before **return** was invoked. If **return** is used outside a function, but during execution of a script by the **. (source)** command, it causes the shell to stop executing that script and return either *n* or the exit status of the last command executed within the script as the exit status of the script. If *n* is supplied, the return value is its least significant 8 bits. The return status is non-zero if **return** is supplied a non-numeric

argument, or is used outside a function and not during execution of a script by . or **source**. Any command associated with the **RETURN** trap is executed before execution resumes after the function or script.

```
set [--abefhkmnptuvxBCEHPT] [-o option-name] [arg ...]
set [+abefhkmnptuvxBCEHPT] [+o option-name] [arg ...]
```

Without options, the name and value of each shell variable are displayed in a format that can be reused as input for setting or resetting the currently-set variables. Read-only variables cannot be reset. In *Posix mode*, only shell variables are listed. The output is sorted according to the current locale. When options are specified, they set or unset shell attributes. Any arguments remaining after option processing are treated as values for the positional parameters and are assigned, in order, to \$1, \$2, ... \$n. Options, if specified, have the following meanings:

- a** Each variable or function that is created or modified is given the **export** attribute and marked for export to the environment of subsequent commands.
- b** Report the status of terminated background jobs immediately, rather than before the next primary prompt. This is effective only when job control is enabled.
- e** Exit immediately if a *pipeline* (which may consist of a single *simple command*), a *list*, or a *compound command* (see **SHELL GRAMMAR** above), exits with a non-zero status. The shell does not exit if the command that fails is part of the command list immediately following a **while** or **until** keyword, part of the test following the **if** or **elif** reserved words, part of any command executed in a **&&** or **||** list except the command following the final **&&** or **||**, any command in a pipeline but the last, or if the command's return value is being inverted with !. If a compound command other than a subshell returns a non-zero status because a command failed while **-e** was being ignored, the shell does not exit. A trap on **ERR**, if set, is executed before the shell exits. This option applies to the shell environment and each subshell environment separately (see **COMMAND EXECUTION ENVIRONMENT** above), and may cause subshells to exit before executing all the commands in the subshell.

If a compound command or shell function executes in a context where **-e** is being ignored, none of the commands executed within the compound command or function body will be affected by the **-e** setting, even if **-e** is set and a command returns a failure status. If a compound command or shell function sets **-e** while executing in a context where **-e** is ignored, that setting will not have any effect until the compound command or the command containing the function call completes.

- f** Disable pathname expansion.
- h** Remember the location of commands as they are looked up for execution. This is enabled by default.
- k** All arguments in the form of assignment statements are placed in the environment for a command, not just those that precede the command name.
- m** Monitor mode. Job control is enabled. This option is on by default for interactive shells on systems that support it (see **JOB CONTROL** above). All processes run in a separate process group. When a background job completes, the shell prints a line containing its exit status.
- n** Read commands but do not execute them. This may be used to check a shell script for syntax errors. This is ignored by interactive shells.

-o option-name

The *option-name* can be one of the following:

allexport

Same as **-a**.

braceexpand

Same as **-B**.

emacs Use an emacs-style command line editing interface. This is enabled by default when the shell is interactive, unless the shell is started with the **--noediting** option. This also affects the editing interface used for **read -e**.

errexit	Same as -e .
errtrace	Same as -E .
functrace	
	Same as -T .
hashall	Same as -h .
histexpand	
	Same as -H .
history	Enable command history, as described above under HISTORY . This option is on by default in interactive shells.
ignoreeof	The effect is as if the shell command <code>IGNOREEOF=10</code> had been executed (see Shell Variables above).
keyword	
	Same as -k .
monitor	Same as -m .
noclobber	
	Same as -C .
noexec	Same as -n .
noglob	Same as -f .
nolog	Currently ignored.
notify	Same as -b .
nounset	Same as -u .
onecmd	Same as -t .
physical	Same as -P .
pipefail	If set, the return value of a pipeline is the value of the last (rightmost) command to exit with a non-zero status, or zero if all commands in the pipeline exit successfully. This option is disabled by default.
posix	Change the behavior of bash where the default operation differs from the POSIX standard to match the standard (<i>posix mode</i>). See SEE ALSO below for a reference to a document that details how posix mode affects bash's behavior.
privileged	
	Same as -p .
verbose	Same as -v .
vi	Use a vi-style command line editing interface. This also affects the editing interface used for read -e .
xtrace	Same as -x .
If -o is supplied with no <i>option-name</i> , the values of the current options are printed. If +o is supplied with no <i>option-name</i> , a series of set commands to recreate the current option settings is displayed on the standard output.	
-p	Turn on <i>privileged</i> mode. In this mode, the \$ENV and \$BASH_ENV files are not processed, shell functions are not inherited from the environment, and the SHELLOPTS , BASHOPTS , CDPATH , and GLOBIGNORE variables, if they appear in the environment, are ignored. If the shell is started with the effective user (group) id not equal to the real user (group) id, and the -p option is not supplied, these actions are taken and the effective user id is set to the real user id. If the -p option is supplied at startup, the effective user id is not reset. Turning this option off causes the effective user and group ids to be set to the real user and group ids.
-t	Exit after reading and executing one command.
-u	Treat unset variables and parameters other than the special parameters "@" and "*" as an error when performing parameter expansion. If expansion is attempted on an unset variable or parameter, the shell prints an error message, and, if not interactive, exits with a non-zero status.

- v** Print shell input lines as they are read.
- x** After expanding each *simple command*, **for** command, **case** command, **select** command, or arithmetic **for** command, display the expanded value of **PS4**, followed by the command and its expanded arguments or associated word list.
- B** The shell performs brace expansion (see **Brace Expansion** above). This is on by default.
- C** If set, **bash** does not overwrite an existing file with the **>**, **>&**, and **<>** redirection operators. This may be overridden when creating output files by using the redirection operator **>|** instead of **>**.
- E** If set, any trap on **ERR** is inherited by shell functions, command substitutions, and commands executed in a subshell environment. The **ERR** trap is normally not inherited in such cases.
- H** Enable ! style history substitution. This option is on by default when the shell is interactive.
- P** If set, the shell does not resolve symbolic links when executing commands such as **cd** that change the current working directory. It uses the physical directory structure instead. By default, **bash** follows the logical chain of directories when performing commands which change the current directory.
- T** If set, any traps on **DEBUG** and **RETURN** are inherited by shell functions, command substitutions, and commands executed in a subshell environment. The **DEBUG** and **RETURN** traps are normally not inherited in such cases.
- If no arguments follow this option, then the positional parameters are unset. Otherwise, the positional parameters are set to the *args*, even if some of them begin with a **-**.
- Signal the end of options, cause all remaining *args* to be assigned to the positional parameters. The **-x** and **-v** options are turned off. If there are no *args*, the positional parameters remain unchanged.

The options are off by default unless otherwise noted. Using + rather than – causes these options to be turned off. The options can also be specified as arguments to an invocation of the shell. The current set of options may be found in **\$-**. The return status is always true unless an invalid option is encountered.

shift [n]

The positional parameters from *n+1* ... are renamed to **\$1** Parameters represented by the numbers **\$#** down to **\$#-n+1** are unset. *n* must be a non-negative number less than or equal to **\$#**. If *n* is 0, no parameters are changed. If *n* is not given, it is assumed to be 1. If *n* is greater than **\$#**, the positional parameters are not changed. The return status is greater than zero if *n* is greater than **\$#** or less than zero; otherwise 0.

shopt [-pqsu] [-o] [optname ...]

Toggle the values of settings controlling optional shell behavior. The settings can be either those listed below, or, if the **-o** option is used, those available with the **-o** option to the **set** builtin command. With no options, or with the **-p** option, a list of all settable options is displayed, with an indication of whether or not each is set; if *optnames* are supplied, the output is restricted to those options. The **-p** option causes output to be displayed in a form that may be reused as input. Other options have the following meanings:

- s** Enable (set) each *optname*.
- u** Disable (unset) each *optname*.
- q** Suppresses normal output (quiet mode); the return status indicates whether the *optname* is set or unset. If multiple *optname* arguments are given with **-q**, the return status is zero if all *optnames* are enabled; non-zero otherwise.
- o** Restricts the values of *optname* to be those defined for the **-o** option to the **set** builtin.

If either **-s** or **-u** is used with no *optname* arguments, **shopt** shows only those options which are set or unset, respectively. Unless otherwise noted, the **shopt** options are disabled (unset) by default.

The return status when listing options is zero if all *optnames* are enabled, non-zero otherwise. When setting or unsetting options, the return status is zero unless an *optname* is not a valid shell option.

The list of **shop** options is:

assoc_expand_once

If set, the shell suppresses multiple evaluation of associative array subscripts during arithmetic expression evaluation, while executing builtins that can perform variable assignments, and while executing builtins that perform array dereferencing.

auto_cd If set, a command name that is the name of a directory is executed as if it were the argument to the **cd** command. This option is only used by interactive shells.

cdable_vars

If set, an argument to the **cd** builtin command that is not a directory is assumed to be the name of a variable whose value is the directory to change to.

cdspell If set, minor errors in the spelling of a directory component in a **cd** command will be corrected. The errors checked for are transposed characters, a missing character, and one character too many. If a correction is found, the corrected filename is printed, and the command proceeds. This option is only used by interactive shells.

checkhash

If set, **bash** checks that a command found in the hash table exists before trying to execute it. If a hashed command no longer exists, a normal path search is performed.

checkjobs

If set, **bash** lists the status of any stopped and running jobs before exiting an interactive shell. If any jobs are running, this causes the exit to be deferred until a second exit is attempted without an intervening command (see **JOB CONTROL** above). The shell always postpones exiting if any jobs are stopped.

checkwinsize

If set, **bash** checks the window size after each external (non-builtin) command and, if necessary, updates the values of **LINES** and **COLUMNS**. This option is enabled by default.

cmdhist If set, **bash** attempts to save all lines of a multiple-line command in the same history entry. This allows easy re-editing of multi-line commands. This option is enabled by default, but only has an effect if command history is enabled, as described above under **HISTORY**.

compat31

compat32

compat40

compat41

compat42

compat43

compat44

These control aspects of the shell's compatibility mode (see **SHELL COMPATIBILITY MODE** below).

complete_fullquote

If set, **bash** quotes all shell metacharacters in filenames and directory names when performing completion. If not set, **bash** removes metacharacters such as the dollar sign from the set of characters that will be quoted in completed filenames when these metacharacters appear in shell variable references in words to be completed. This means that dollar signs in variable names that expand to directories will not be quoted; however, any dollar signs appearing in filenames will not be quoted, either. This is active only when bash is using backslashes to quote completed filenames. This variable is set by default, which is the default bash behavior in versions through 4.2.

direxpand

If set, **bash** replaces directory names with the results of word expansion when performing filename completion. This changes the contents of the readline editing buffer. If not set, **bash** attempts to preserve what the user typed.

dirspell If set, **bash** attempts spelling correction on directory names during word completion if the directory name initially supplied does not exist.

dotglob If set, **bash** includes filenames beginning with a ‘.’ in the results of pathname expansion. The filenames “.” and “..” must always be matched explicitly, even if **dotglob** is set.

execfail If set, a non-interactive shell will not exit if it cannot execute the file specified as an argument to the **exec** builtin command. An interactive shell does not exit if **exec** fails.

expand_aliases

If set, aliases are expanded as described above under **ALIASES**. This option is enabled by default for interactive shells.

extdebug

If set at shell invocation, or in a shell startup file, arrange to execute the debugger profile before the shell starts, identical to the **--debugger** option. If set after invocation, behavior intended for use by debuggers is enabled:

1. The **-F** option to the **declare** builtin displays the source file name and line number corresponding to each function name supplied as an argument.
2. If the command run by the **DEBUG** trap returns a non-zero value, the next command is skipped and not executed.
3. If the command run by the **DEBUG** trap returns a value of 2, and the shell is executing in a subroutine (a shell function or a shell script executed by the **.** or **source** builtins), the shell simulates a call to **return**.
4. **BASH_ARGC** and **BASH_ARGV** are updated as described in their descriptions above.
5. Function tracing is enabled: command substitution, shell functions, and subshells invoked with (*command*) inherit the **DEBUG** and **RETURN** traps.
6. Error tracing is enabled: command substitution, shell functions, and subshells invoked with (*command*) inherit the **ERR** trap.

extglob If set, the extended pattern matching features described above under **Pathname Expansion** are enabled.

extquote

If set, `$'string'` and `$"string"` quoting is performed within `$(parameter)` expansions enclosed in double quotes. This option is enabled by default.

failglob If set, patterns which fail to match filenames during pathname expansion result in an expansion error.

force_ignore

If set, the suffixes specified by the **IGNORE** shell variable cause words to be ignored when performing word completion even if the ignored words are the only possible completions. See **SHELL VARIABLES** above for a description of **IGNORE**. This option is enabled by default.

globasciiranges

If set, range expressions used in pattern matching bracket expressions (see **Pattern Matching** above) behave as if in the traditional C locale when performing comparisons. That is, the current locale's collating sequence is not taken into account, so **b** will not collate between **A** and **B**, and upper-case and lower-case ASCII characters will collate together.

globstar If set, the pattern `**` used in a pathname expansion context will match all files and zero or more directories and subdirectories. If the pattern is followed by a `/`, only directories and subdirectories match.

gnu_errfmt

If set, shell error messages are written in the standard GNU error message format.

histappend

If set, the history list is appended to the file named by the value of the **HISTFILE** variable when the shell exits, rather than overwriting the file.

histreedit

If set, and **readline** is being used, a user is given the opportunity to re-edit a failed history substitution.

histverify

If set, and **readline** is being used, the results of history substitution are not immediately passed to the shell parser. Instead, the resulting line is loaded into the **readline** editing buffer, allowing further modification.

hostcomplete

If set, and **readline** is being used, **bash** will attempt to perform hostname completion when a word containing a `@` is being completed (see **Completing** under **READLINE** above). This is enabled by default.

huponexit

If set, **bash** will send **SIGHUP** to all jobs when an interactive login shell exits.

inherit_errexit

If set, command substitution inherits the value of the **errexit** option, instead of unsetting it in the subshell environment. This option is enabled when *posix mode* is enabled.

interactive_comments

If set, allow a word beginning with `#` to cause that word and all remaining characters on that line to be ignored in an interactive shell (see **COMMENTS** above). This option is enabled by default.

lastpipe If set, and job control is not active, the shell runs the last command of a pipeline not executed in the background in the current shell environment.

lithist If set, and the **cmdhist** option is enabled, multi-line commands are saved to the history with embedded newlines rather than using semicolon separators where possible.

localvar_inherit

If set, local variables inherit the value and attributes of a variable of the same name that exists at a previous scope before any new value is assigned. The **nameref** attribute is not inherited.

localvar_unset

If set, calling **unset** on local variables in previous function scopes marks them so subsequent lookups find them unset until that function returns. This is identical to the behavior of unsetting local variables at the current function scope.

login_shell

The shell sets this option if it is started as a login shell (see **INVOCATION** above). The value may not be changed.

mailwarn

If set, and a file that **bash** is checking for mail has been accessed since the last time it was checked, the message “The mail in *mailfile* has been read” is displayed.

no_empty_cmd_completion

If set, and **readline** is being used, **bash** will not attempt to search the **PATH** for possible completions when completion is attempted on an empty line.

nocaseglob

If set, **bash** matches filenames in a case-insensitive fashion when performing pathname expansion (see **Pathname Expansion** above).

nocasematch

If set, **bash** matches patterns in a case-insensitive fashion when performing matching while executing **case** or **[[** conditional commands, when performing pattern substitution word expansions, or when filtering possible completions as part of programmable completion.

nullglob

If set, **bash** allows patterns which match no files (see **Pathname Expansion** above) to expand to a null string, rather than themselves.

progcomp

If set, the programmable completion facilities (see **Programmable Completion** above) are enabled. This option is enabled by default.

progcomp_alias

If set, and programmable completion is enabled, **bash** treats a command name that doesn't have any completions as a possible alias and attempts alias expansion. If it has an alias, **bash** attempts programmable completion using the command word resulting from the expanded alias.

promptvars

If set, prompt strings undergo parameter expansion, command substitution, arithmetic expansion, and quote removal after being expanded as described in **PROMPTING** above. This option is enabled by default.

restricted_shell

The shell sets this option if it is started in restricted mode (see **RESTRICTED SHELL** below). The value may not be changed. This is not reset when the startup files are executed, allowing the startup files to discover whether or not a shell is restricted.

shift_verbose

If set, the **shift** builtin prints an error message when the shift count exceeds the number of positional parameters.

sourcepath

If set, the **source** (.) builtin uses the value of **PATH** to find the directory containing the file supplied as an argument. This option is enabled by default.

xpg_echo

If set, the **echo** builtin expands backslash-escape sequences by default.

suspend [-f]

Suspend the execution of this shell until it receives a **SIGCONT** signal. A login shell cannot be suspended; the **-f** option can be used to override this and force the suspension. The return status is 0 unless the shell is a login shell and **-f** is not supplied, or if job control is not enabled.

test expr

[*expr*] Return a status of 0 (true) or 1 (false) depending on the evaluation of the conditional expression *expr*. Each operator and operand must be a separate argument. Expressions are composed of the primaries described in the **bash** manual page under **CONDITIONAL EXPRESSIONS**. **test** does not accept any options, nor does it accept and ignore an argument of **--** as signifying the end of options.

Expressions may be combined using the following operators, listed in decreasing order of

precedence. The evaluation depends on the number of arguments; see below. Operator precedence is used when there are five or more arguments.

! expr True if *expr* is false.

(expr) Returns the value of *expr*. This may be used to override the normal precedence of operators.

expr1 -a expr2

True if both *expr1* and *expr2* are true.

expr1 -o expr2

True if either *expr1* or *expr2* is true.

test and **[** evaluate conditional expressions using a set of rules based on the number of arguments.

0 arguments

The expression is false.

1 argument

The expression is true if and only if the argument is not null.

2 arguments

If the first argument is **!**, the expression is true if and only if the second argument is null.

If the first argument is one of the unary conditional operators listed above under **CONDITIONAL EXPRESSIONS**, the expression is true if the unary test is true. If the first argument is not a valid unary conditional operator, the expression is false.

3 arguments

The following conditions are applied in the order listed. If the second argument is one of the binary conditional operators listed above under **CONDITIONAL EXPRESSIONS**, the result of the expression is the result of the binary test using the first and third arguments as operands. The **-a** and **-o** operators are considered binary operators when there are three arguments. If the first argument is **!**, the value is the negation of the two-argument test using the second and third arguments. If the first argument is exactly **(** and the third argument is exactly **)**, the result is the one-argument test of the second argument. Otherwise, the expression is false.

4 arguments

If the first argument is **!**, the result is the negation of the three-argument expression composed of the remaining arguments. Otherwise, the expression is parsed and evaluated according to precedence using the rules listed above.

5 or more arguments

The expression is parsed and evaluated according to precedence using the rules listed above.

When used with **test** or **[**, the **<** and **>** operators sort lexicographically using ASCII ordering.

times Print the accumulated user and system times for the shell and for processes run from the shell. The return status is 0.

trap [-lp] [[arg] sigspec ...]

The command *arg* is to be read and executed when the shell receives signal(s) *sigspec*. If *arg* is absent (and there is a single *sigspec*) or **-**, each specified signal is reset to its original disposition (the value it had upon entrance to the shell). If *arg* is the null string the signal specified by each *sigspec* is ignored by the shell and by the commands it invokes. If *arg* is not present and **-p** has been supplied, then the trap commands associated with each *sigspec* are displayed. If no arguments are supplied or if only **-p** is given, **trap** prints the list of commands associated with each signal. The **-l** option causes the shell to print a list of signal names and their corresponding numbers. Each *sigspec* is either a signal name defined in *<signal.h>*, or a signal number. Signal names are case insensitive and the **SIG** prefix is optional.

If a *sigspec* is **EXIT (0)** the command *arg* is executed on exit from the shell. If a *sigspec* is **DEBUG**, the command *arg* is executed before every *simple command*, *for* command, *case* command, *select* command, every arithmetic *for* command, and before the first command executes in a shell function (see **SHELL GRAMMAR** above). Refer to the description of the **exitdebug** option to the

shopt builtin for details of its effect on the **DEBUG** trap. If a *sigspec* is **RETURN**, the command *arg* is executed each time a shell function or a script executed with the **.** or **source** builtins finishes executing.

If a *sigspec* is **ERR**, the command *arg* is executed whenever a pipeline (which may consist of a single simple command), a list, or a compound command returns a non-zero exit status, subject to the following conditions. The **ERR** trap is not executed if the failed command is part of the command list immediately following a **while** or **until** keyword, part of the test in an **if** statement, part of a command executed in a **&&** or **||** list except the command following the final **&&** or **||**, any command in a pipeline but the last, or if the command's return value is being inverted using **!**. These are the same conditions obeyed by the **errexit** (**-e**) option.

Signals ignored upon entry to the shell cannot be trapped or reset. Trapped signals that are not being ignored are reset to their original values in a subshell or subshell environment when one is created. The return status is false if any *sigspec* is invalid; otherwise **trap** returns true.

type [**-a****f****t****P**] *name* [*name* ...]

With no options, indicate how each *name* would be interpreted if used as a command name. If the **-t** option is used, **type** prints a string which is one of *alias*, *keyword*, *function*, *builtin*, or *file* if *name* is an alias, shell reserved word, function, builtin, or disk file, respectively. If the *name* is not found, then nothing is printed, and an exit status of false is returned. If the **-p** option is used, **type** either returns the name of the disk file that would be executed if *name* were specified as a command name, or nothing if **type -t** *name* would not return *file*. The **-P** option forces a **P**ATH search for each *name*, even if **type -t** *name* would not return *file*. If a command is hashed, **-p** and **-P** print the hashed value, which is not necessarily the file that appears first in **PATH**. If the **-a** option is used, **type** prints all of the places that contain an executable named *name*. This includes aliases and functions, if and only if the **-p** option is not also used. The table of hashed commands is not consulted when using **-a**. The **-f** option suppresses shell function lookup, as with the **command** builtin. **type** returns true if all of the arguments are found, false if any are not found.

ulimit [**-HS**] **-a**

ulimit [**-HS**] [**-bcdefiklmnpqrstuvxPRT** [*limit*]]

Provides control over the resources available to the shell and to processes started by it, on systems that allow such control. The **-H** and **-S** options specify that the hard or soft limit is set for the given resource. A hard limit cannot be increased by a non-root user once it is set; a soft limit may be increased up to the value of the hard limit. If neither **-H** nor **-S** is specified, both the soft and hard limits are set. The value of *limit* can be a number in the unit specified for the resource or one of the special values **hard**, **soft**, or **unlimited**, which stand for the current hard limit, the current soft limit, and no limit, respectively. If *limit* is omitted, the current value of the soft limit of the resource is printed, unless the **-H** option is given. When more than one resource is specified, the limit name and unit, if appropriate, are printed before the value. Other options are interpreted as follows:

- a** All current limits are reported; no limits are set
- b** The maximum socket buffer size
- c** The maximum size of core files created
- d** The maximum size of a process's data segment
- e** The maximum scheduling priority ("nice")
- f** The maximum size of files written by the shell and its children
- i** The maximum number of pending signals
- k** The maximum number of kqueues that may be allocated
- l** The maximum size that may be locked into memory
- m** The maximum resident set size (many systems do not honor this limit)
- n** The maximum number of open file descriptors (most systems do not allow this value to be set)
- p** The pipe size in 512-byte blocks (this may not be set)

-q	The maximum number of bytes in POSIX message queues
-r	The maximum real-time scheduling priority
-s	The maximum stack size
-t	The maximum amount of cpu time in seconds
-u	The maximum number of processes available to a single user
-v	The maximum amount of virtual memory available to the shell and, on some systems, to its children
-x	The maximum number of file locks
-P	The maximum number of pseudoterminals
-R	The maximum time a real-time process can run before blocking, in microseconds
-T	The maximum number of threads

If *limit* is given, and the **-a** option is not used, *limit* is the new value of the specified resource. If no option is given, then **-f** is assumed. Values are in 1024-byte increments, except for **-t**, which is in seconds; **-R**, which is in microseconds; **-p**, which is in units of 512-byte blocks; **-P**, **-T**, **-b**, **-k**, **-n**, and **-u**, which are unscaled values; and, when in posix mode, **-c** and **-f**, which are in 512-byte increments. The return status is 0 unless an invalid option or argument is supplied, or an error occurs while setting a new limit.

umask [**-p**] [**-S**] [*mode*]

The user file-creation mask is set to *mode*. If *mode* begins with a digit, it is interpreted as an octal number; otherwise it is interpreted as a symbolic mode mask similar to that accepted by *chmod(1)*. If *mode* is omitted, the current value of the mask is printed. The **-S** option causes the mask to be printed in symbolic form; the default output is an octal number. If the **-p** option is supplied, and *mode* is omitted, the output is in a form that may be reused as input. The return status is 0 if the mode was successfully changed or if no *mode* argument was supplied, and false otherwise.

unalias [**-a**] [*name* ...]

Remove each *name* from the list of defined aliases. If **-a** is supplied, all alias definitions are removed. The return value is true unless a supplied *name* is not a defined alias.

unset [**-fv**] [**-n**] [*name* ...]

For each *name*, remove the corresponding variable or function. If the **-v** option is given, each *name* refers to a shell variable, and that variable is removed. Read-only variables may not be unset. If **-f** is specified, each *name* refers to a shell function, and the function definition is removed. If the **-n** option is supplied, and *name* is a variable with the *nameref* attribute, *name* will be unset rather than the variable it references. **-n** has no effect if the **-f** option is supplied. If no options are supplied, each *name* refers to a variable; if there is no variable by that name, a function with that name, if any, is unset. Each unset variable or function is removed from the environment passed to subsequent commands. If any of **BASH_ALIASES**, **BASH_ARGV0**, **BASH_CMDS**, **BASH_COMMAND**, **BASH_SUBSHELL**, **BASHPID**, **COMP_WORDBREAKS**, **DIRSTACK**, **EPOCHREALTIME**, **EPOCHSECONDS**, **FUNCNAME**, **GROUPS**, **HISTCMD**, **LINENO**, **RANDOM**, **SECONDS**, or **SRANDOM** are unset, they lose their special properties, even if they are subsequently reset. The exit status is true unless a *name* is readonly.

wait [**-fn**] [**-p** *varname*] [*id* ...]

Wait for each specified child process and return its termination status. Each *id* may be a process ID or a job specification; if a job spec is given, all processes in that job's pipeline are waited for. If *id* is not given, **wait** waits for all running background jobs and the last-executed process substitution, if its process id is the same as **\$!**, and the return status is zero. If the **-n** option is supplied, **wait** waits for a single job from the list of *ids* or, if no *ids* are supplied, any job, to complete and returns its exit status. If none of the supplied arguments is a child of the shell, or if no arguments are supplied and the shell has no unwaited-for children, the exit status is 127. If the **-p** option is supplied, the process or job identifier of the job for which the exit status is returned is assigned to the variable *varname* named by the option argument. The variable will be unset initially, before any assignment. This is useful only when the **-n** option is supplied. Supplying the **-f** option, when job control is enabled, forces **wait** to wait for *id* to terminate before returning its status,

instead of returning when it changes status. If *id* specifies a non-existent process or job, the return status is 127. Otherwise, the return status is the exit status of the last process or job waited for.

SHELL COMPATIBILITY MODE

Bash-4.0 introduced the concept of a ‘shell compatibility level’, specified as a set of options to the shopt builtin **compat31**, **compat32**, **compat40**, **compat41**, and so on). There is only one current compatibility level -- each option is mutually exclusive. The compatibility level is intended to allow users to select behavior from previous versions that is incompatible with newer versions while they migrate scripts to use current features and behavior. It’s intended to be a temporary solution.

This section does not mention behavior that is standard for a particular version (e.g., setting **compat32** means that quoting the rhs of the regexp matching operator quotes special regexp characters in the word, which is default behavior in bash-3.2 and above).

If a user enables, say, **compat32**, it may affect the behavior of other compatibility levels up to and including the current compatibility level. The idea is that each compatibility level controls behavior that changed in that version of **bash**, but that behavior may have been present in earlier versions. For instance, the change to use locale-based comparisons with the `[[` command came in bash-4.1, and earlier versions used ASCII-based comparisons, so enabling **compat32** will enable ASCII-based comparisons as well. That granularity may not be sufficient for all uses, and as a result users should employ compatibility levels carefully. Read the documentation for a particular feature to find out the current behavior.

Bash-4.3 introduced a new shell variable: **BASH_COMPAT**. The value assigned to this variable (a decimal version number like 4.2, or an integer corresponding to the **compatNN** option, like 42) determines the compatibility level.

Starting with bash-4.4, Bash has begun deprecating older compatibility levels. Eventually, the options will be removed in favor of **BASH_COMPAT**.

Bash-5.0 is the final version for which there will be an individual shopt option for the previous version. Users should use **BASH_COMPAT** on bash-5.0 and later versions.

The following table describes the behavior changes controlled by each compatibility level setting. The **compatNN** tag is used as shorthand for setting the compatibility level to *NN* using one of the following mechanisms. For versions prior to bash-5.0, the compatibility level may be set using the corresponding **compatNN** shopt option. For bash-4.3 and later versions, the **BASH_COMPAT** variable is preferred, and it is required for bash-5.1 and later versions.

compat31

- quoting the rhs of the `[[` command’s regexp matching operator (`=~`) has no special effect

compat32

- interrupting a command list such as "a ; b ; c" causes the execution of the next command in the list (in bash-4.0 and later versions, the shell acts as if it received the interrupt, so interrupting one command in a list aborts the execution of the entire list)

compat40

- the `<` and `>` operators to the `[[` command do not consider the current locale when comparing strings; they use ASCII ordering. Bash versions prior to bash-4.1 use ASCII collation and *strcmp(3)*; bash-4.1 and later use the current locale’s collation sequence and *strcoll(3)*.

compat41

- in *posix* mode, **time** may be followed by options and still be recognized as a reserved word (this is POSIX interpretation 267)
- in *posix* mode, the parser requires that an even number of single quotes occur in the *word* portion of a double-quoted parameter expansion and treats them specially, so that characters within the single quotes are considered quoted (this is POSIX interpretation 221)

compat42

- the replacement string in double-quoted pattern substitution does not undergo quote removal, as it does in versions after bash-4.2

- in posix mode, single quotes are considered special when expanding the *word* portion of a double-quoted parameter expansion and can be used to quote a closing brace or other special character (this is part of POSIX interpretation 221); in later versions, single quotes are not special within double-quoted word expansions

compat43

- the shell does not print a warning message if an attempt is made to use a quoted compound assignment as an argument to declare (declare -a foo='(1 2)'). Later versions warn that this usage is deprecated
- word expansion errors are considered non-fatal errors that cause the current command to fail, even in posix mode (the default behavior is to make them fatal errors that cause the shell to exit)
- when executing a shell function, the loop state (while/until/etc.) is not reset, so **break** or **continue** in that function will break or continue loops in the calling context. Bash-4.4 and later reset the loop state to prevent this

compat44

- the shell sets up the values used by **BASH_ARGV** and **BASH_ARGC** so they can expand to the shell's positional parameters even if extended debugging mode is not enabled
- a subshell inherits loops from its parent context, so **break** or **continue** will cause the subshell to exit. Bash-5.0 and later reset the loop state to prevent the exit
- variable assignments preceding builtins like **export** and **readonly** that set attributes continue to affect variables with the same name in the calling environment even if the shell is not in posix mode

compat50

- Bash-5.1 changed the way **\$RANDOM** is generated to introduce slightly more randomness. If the shell compatibility level is set to 50 or lower, it reverts to the method from bash-5.0 and previous versions, so seeding the random number generator by assigning a value to **RANDOM** will produce the same sequence as in bash-5.0
- If the command hash table is empty, bash versions prior to bash-5.1 printed an informational message to that effect, even when producing output that can be reused as input. Bash-5.1 suppresses that message when the **-I** option is supplied.

NAME

bash – GNU Bourne-Again SHell

SYNOPSIS

bash [options] [command_string | file]

COPYRIGHT

Bash is Copyright © 1989-2020 by the Free Software Foundation, Inc.

DESCRIPTION

Bash is an **sh**-compatible command language interpreter that executes commands read from the standard input or from a file. **Bash** also incorporates useful features from the *Korn* and *C* shells (**ksh** and **csh**).

Bash is intended to be a conformant implementation of the Shell and Utilities portion of the IEEE POSIX specification (IEEE Standard 1003.1). **Bash** can be configured to be POSIX-conformant by default.

OPTIONS

All of the single-character shell options documented in the description of the **set** builtin command, including **-o**, can be used as options when the shell is invoked. In addition, **bash** interprets the following options when it is invoked:

- c** If the **-c** option is present, then commands are read from the first non-option argument *command_string*. If there are arguments after the *command_string*, the first argument is assigned to **\$0** and any remaining arguments are assigned to the positional parameters. The assignment to **\$0** sets the name of the shell, which is used in warning and error messages.
- i** If the **-i** option is present, the shell is *interactive*.
- l** Make **bash** act as if it had been invoked as a login shell (see **INVOCATION** below).
- r** If the **-r** option is present, the shell becomes *restricted* (see **RESTRICTED SHELL** below).
- s** If the **-s** option is present, or if no arguments remain after option processing, then commands are read from the standard input. This option allows the positional parameters to be set when invoking an interactive shell or when reading input through a pipe.
- v** Print shell input lines as they are read.
- x** Print commands and their arguments as they are executed.
- D** A list of all double-quoted strings preceded by **\$** is printed on the standard output. These are the strings that are subject to language translation when the current locale is not **C** or **POSIX**. This implies the **-n** option; no commands will be executed.

[+]-O [shopt_option]

shopt_option is one of the shell options accepted by the **shopt** builtin (see **SHELL BUILTIN COMMANDS** below). If *shopt_option* is present, **-O** sets the value of that option; **+O** unsets it. If *shopt_option* is not supplied, the names and values of the shell options accepted by **shopt** are printed on the standard output. If the invocation option is **+O**, the output is displayed in a format that may be reused as input.

- A **--** signals the end of options and disables further option processing. Any arguments after the **--** are treated as filenames and arguments. An argument of **-** is equivalent to **--**.

Bash also interprets a number of multi-character options. These options must appear on the command line before the single-character options to be recognized.

--debugger

Arrange for the debugger profile to be executed before the shell starts. Turns on extended debugging mode (see the description of the **extdebug** option to the **shopt** builtin below).

--dump-po-strings

Equivalent to **-D**, but the output is in the GNU *gettext po* (portable object) file format.

--dump-strings

Equivalent to **-D**.

--help

Display a usage message on standard output and exit successfully.

--init-file

--rcfile *file*

Execute commands from *file* instead of the system wide initialization file */etc/bash.bashrc* and the standard personal initialization file *~/.bashrc* if the shell is interactive (see **INVOCATION** below).

--login

Equivalent to **-l**.

--noediting

Do not use the GNU **readline** library to read command lines when the shell is interactive.

--noprofile

Do not read either the system-wide startup file */etc/profile* or any of the personal initialization files *~/.bash_profile*, *~/.bash_login*, or *~/.profile*. By default, **bash** reads these files when it is invoked as a login shell (see **INVOCATION** below).

--norc

Do not read and execute the system wide initialization file */etc/bash.bashrc* and the personal initialization file *~/.bashrc* if the shell is interactive. This option is on by default if the shell is invoked as **sh**.

--posix

Change the behavior of **bash** where the default operation differs from the POSIX standard to match the standard (*posix mode*). See **SEE ALSO** below for a reference to a document that details how posix mode affects bash's behavior.

--restricted

The shell becomes restricted (see **RESTRICTED SHELL** below).

--verbose

Equivalent to **-v**.

--version

Show version information for this instance of **bash** on the standard output and exit successfully.

ARGUMENTS

If arguments remain after option processing, and neither the **-c** nor the **-s** option has been supplied, the first argument is assumed to be the name of a file containing shell commands. If **bash** is invoked in this fashion, **\$0** is set to the name of the file, and the positional parameters are set to the remaining arguments. **Bash** reads and executes commands from this file, then exits. **Bash**'s exit status is the exit status of the last command executed in the script. If no commands are executed, the exit status is 0. An attempt is first made to open the file in the current directory, and, if no file is found, then the shell searches the directories in **PATH** for the script.

INVOCATION

A *login shell* is one whose first character of argument zero is a **-**, or one started with the **--login** option.

An *interactive shell* is one started without non-option arguments (unless **-s** is specified) and without the **-c** option whose standard input and error are both connected to terminals (as determined by *isatty(3)*), or one started with the **-i** option. **PS1** is set and **\$-** includes **i** if **bash** is interactive, allowing a shell script or a startup file to test this state.

The following paragraphs describe how **bash** executes its startup files. If any of the files exist but cannot be read, **bash** reports an error. Tildes are expanded in filenames as described below under **Tilde Expansion** in the **EXPANSION** section.

When **bash** is invoked as an interactive login shell, or as a non-interactive shell with the **--login** option, it first reads and executes commands from the file */etc/profile*, if that file exists. After reading that file, it looks for *~/.bash_profile*, *~/.bash_login*, and *~/.profile*, in that order, and reads and executes commands from the first one that exists and is readable. The **--noprofile** option may be used when the shell is started to inhibit this behavior.

When an interactive login shell exits, or a non-interactive login shell executes the **exit** builtin command, **bash** reads and executes commands from the file *~/.bash_logout*, if it exists.

When an interactive shell that is not a login shell is started, **bash** reads and executes commands from */etc/bash.bashrc* and *~/.bashrc*, if these files exist. This may be inhibited by using the **--norc** option. The **--rcfile file** option will force **bash** to read and execute commands from *file* instead of */etc/bash.bashrc* and *~/.bashrc*.

When **bash** is started non-interactively, to run a shell script, for example, it looks for the variable **BASH_ENV** in the environment, expands its value if it appears there, and uses the expanded value as the name of a file to read and execute. **Bash** behaves as if the following command were executed:

```
if [ -n "$BASH_ENV" ]; then . "$BASH_ENV"; fi
```

but the value of the **PATH** variable is not used to search for the filename.

If **bash** is invoked with the name **sh**, it tries to mimic the startup behavior of historical versions of **sh** as closely as possible, while conforming to the POSIX standard as well. When invoked as an interactive login shell, or a non-interactive shell with the **--login** option, it first attempts to read and execute commands from */etc/profile* and *~/.profile*, in that order. The **--noprofile** option may be used to inhibit this behavior. When invoked as an interactive shell with the name **sh**, **bash** looks for the variable **ENV**, expands its value if it is defined, and uses the expanded value as the name of a file to read and execute. Since a shell invoked as **sh** does not attempt to read and execute commands from any other startup files, the **--rcfile** option has no effect. A non-interactive shell invoked with the name **sh** does not attempt to read any other startup files. When invoked as **sh**, **bash** enters *posix* mode after the startup files are read.

When **bash** is started in *posix* mode, as with the **--posix** command line option, it follows the POSIX standard for startup files. In this mode, interactive shells expand the **ENV** variable and commands are read and executed from the file whose name is the expanded value. No other startup files are read.

Bash attempts to determine when it is being run with its standard input connected to a network connection, as when executed by the remote shell daemon, usually *rshd*, or the secure shell daemon *sshd*. If **bash** determines it is being run in this fashion, it reads and executes commands from *~/.bashrc* and *~/.bashrc*, if these files exist and are readable. It will not do this if invoked as **sh**. The **--norc** option may be used to inhibit this behavior, and the **--rcfile** option may be used to force another file to be read, but neither *rshd* nor *sshd* generally invoke the shell with those options or allow them to be specified.

If the shell is started with the effective user (group) id not equal to the real user (group) id, and the **-p** option is not supplied, no startup files are read, shell functions are not inherited from the environment, the **SHELLOPTS**, **BASHOPTS**, **CDPATH**, and **GLOBIGNORE** variables, if they appear in the environment, are ignored, and the effective user id is set to the real user id. If the **-p** option is supplied at invocation, the startup behavior is the same, but the effective user id is not reset.

DEFINITIONS

The following definitions are used throughout the rest of this document.

blank A space or tab.

word A sequence of characters considered as a single unit by the shell. Also known as a **token**.

name A *word* consisting only of alphanumeric characters and underscores, and beginning with an alphabetic character or an underscore. Also referred to as an **identifier**.

metacharacter

A character that, when unquoted, separates words. One of the following:

| & ; () < > space tab newline

control operator

A *token* that performs a control function. It is one of the following symbols:

|| & && ; ;; ;& ;;& () | |& <newline>

RESERVED WORDS

Reserved words are words that have a special meaning to the shell. The following words are recognized as reserved when unquoted and either the first word of a command (see **SHELL GRAMMAR** below), the third word of a **case** or **select** command (only **in** is valid), or the third word of a **for** command (only **in** and **do** are valid):

! case coproc do done elif else esac fi for function if in select then

until **while** { } **time** [[]]

SHELL GRAMMAR

Simple Commands

A *simple command* is a sequence of optional variable assignments followed by **blank**-separated words and redirections, and terminated by a *control operator*. The first word specifies the command to be executed, and is passed as argument zero. The remaining words are passed as arguments to the invoked command.

The return value of a *simple command* is its exit status, or 128+*n* if the command is terminated by signal *n*.

Pipelines

A *pipeline* is a sequence of one or more commands separated by one of the control operators | or |&. The format for a pipeline is:

[**time** [-p]] [!] *command* [[| |&] *command2* ...]

The standard output of *command* is connected via a pipe to the standard input of *command2*. This connection is performed before any redirections specified by the command (see **REDIRECTION** below). If |& is used, *command*'s standard error, in addition to its standard output, is connected to *command2*'s standard input through the pipe; it is shorthand for 2>&1|. This implicit redirection of the standard error to the standard output is performed after any redirections specified by the command.

The return status of a pipeline is the exit status of the last command, unless the **pipefail** option is enabled. If **pipefail** is enabled, the pipeline's return status is the value of the last (rightmost) command to exit with a non-zero status, or zero if all commands exit successfully. If the reserved word ! precedes a pipeline, the exit status of that pipeline is the logical negation of the exit status as described above. The shell waits for all commands in the pipeline to terminate before returning a value.

If the **time** reserved word precedes a pipeline, the elapsed as well as user and system time consumed by its execution are reported when the pipeline terminates. The -p option changes the output format to that specified by POSIX. When the shell is in *posix mode*, it does not recognize **time** as a reserved word if the next token begins with a '-'. The **TIMEFORMAT** variable may be set to a format string that specifies how the timing information should be displayed; see the description of **TIMEFORMAT** under **Shell Variables** below.

When the shell is in *posix mode*, **time** may be followed by a newline. In this case, the shell displays the total user and system time consumed by the shell and its children. The **TIMEFORMAT** variable may be used to specify the format of the time information.

Each command in a pipeline is executed as a separate process (i.e., in a subshell). See **COMMAND EXECUTION ENVIRONMENT** for a description of a subshell environment. If the **lastpipe** option is enabled using the **shopt** builtin (see the description of **shopt** below), the last element of a pipeline may be run by the shell process.

Lists

A *list* is a sequence of one or more pipelines separated by one of the operators ;, &, &&, or ||, and optionally terminated by one of ;, &, or <newline>.

Of these list operators, && and || have equal precedence, followed by ; and &, which have equal precedence.

A sequence of one or more newlines may appear in a *list* instead of a semicolon to delimit commands.

If a command is terminated by the control operator &, the shell executes the command in the *background* in a subshell. The shell does not wait for the command to finish, and the return status is 0. These are referred to as *asynchronous* commands. Commands separated by a ; are executed sequentially; the shell waits for each command to terminate in turn. The return status is the exit status of the last command executed.

AND and OR lists are sequences of one or more pipelines separated by the && and || control operators, respectively. AND and OR lists are executed with left associativity. An AND list has the form

command1 && *command2*

command2 is executed if, and only if, *command1* returns an exit status of zero (success).

An OR list has the form

command1 || command2

command2 is executed if, and only if, *command1* returns a non-zero exit status. The return status of AND and OR lists is the exit status of the last command executed in the list.

Compound Commands

A *compound command* is one of the following. In most cases *alist* in a command's description may be separated from the rest of the command by one or more newlines, and may be followed by a newline in place of a semicolon.

(*list*) *list* is executed in a subshell environment (see **COMMAND EXECUTION ENVIRONMENT** below). Variable assignments and builtin commands that affect the shell's environment do not remain in effect after the command completes. The return status is the exit status of *list*.

{ *list*; } *list* is simply executed in the current shell environment. *list* must be terminated with a newline or semicolon. This is known as a *group command*. The return status is the exit status of *list*. Note that unlike the metacharacters (and), { and } are *reserved words* and must occur where a reserved word is permitted to be recognized. Since they do not cause a word break, they must be separated from *list* by whitespace or another shell metacharacter.

((*expression*))

The *expression* is evaluated according to the rules described below under **ARITHMETIC EVALUATION**. If the value of the expression is non-zero, the return status is 0; otherwise the return status is 1. This is exactly equivalent to **let "expression"**.

[[*expression*]]

Return a status of 0 or 1 depending on the evaluation of the conditional expression *expression*. Expressions are composed of the primaries described below under **CONDITIONAL EXPRESSIONS**. Word splitting and pathname expansion are not performed on the words between the [[and]]; tilde expansion, parameter and variable expansion, arithmetic expansion, command substitution, process substitution, and quote removal are performed. Conditional operators such as -f must be unquoted to be recognized as primaries.

When used with [[, the < and > operators sort lexicographically using the current locale.

See the description of the *test* builtin command (section **SHELL BUILTIN COMMANDS** below) for the handling of parameters (i.e. missing parameters).

When the == and != operators are used, the string to the right of the operator is considered a pattern and matched according to the rules described below under **Pattern Matching**, as if the **extglob** shell option were enabled. The = operator is equivalent to ==. If the **nocasematch** shell option is enabled, the match is performed without regard to the case of alphabetic characters. The return value is 0 if the string matches (==) or does not match (!=) the pattern, and 1 otherwise. Any part of the pattern may be quoted to force the quoted portion to be matched as a string.

An additional binary operator, =~, is available, with the same precedence as == and !=. When it is used, the string to the right of the operator is considered a POSIX extended regular expression and matched accordingly (using the POSIX *regcomp* and *regexec* interfaces usually described in *regex(3)*). The return value is 0 if the string matches the pattern, and 1 otherwise. If the regular expression is syntactically incorrect, the conditional expression's return value is 2. If the **nocasematch** shell option is enabled, the match is performed without regard to the case of alphabetic characters. Any part of the pattern may be quoted to force the quoted portion to be matched as a string. Bracket expressions in regular expressions must be treated carefully, since normal quoting characters lose their meanings between brackets. If the pattern is stored in a shell variable, quoting the variable expansion forces the entire pattern to be matched as a string.

The pattern will match if it matches any part of the string. Anchor the pattern using the ^ and \$ regular expression operators to force it to match the entire string. The array variable **BASH_REMATCH** records which parts of the string matched the pattern. The element of **BASH_REMATCH** with index 0 contains the portion of the string matching the entire regular expression. Substrings matched by parenthesized

subexpressions within the regular expression are saved in the remaining **BASH_REMATCH** indices. The element of **BASH_REMATCH** with index *n* is the portion of the string matching the *n*th parenthesized subexpression.

Expressions may be combined using the following operators, listed in decreasing order of precedence:

(*expression*)

Returns the value of *expression*. This may be used to override the normal precedence of operators.

! *expression*

True if *expression* is false.

expression1* && *expression2

True if both *expression1* and *expression2* are true.

expression1* || *expression2

True if either *expression1* or *expression2* is true.

The **&&** and **||** operators do not evaluate *expression2* if the value of *expression1* is sufficient to determine the return value of the entire conditional expression.

for *name* [[**in [*word* ...]] ;] **do** *list* ; **done****

The list of words following **in** is expanded, generating a list of items. The variable *name* is set to each element of this list in turn, and *list* is executed each time. If the **in** *word* is omitted, the **for** command executes *list* once for each positional parameter that is set (see **PARAMETERS** below). The return status is the exit status of the last command that executes. If the expansion of the items following **in** results in an empty list, no commands are executed, and the return status is 0.

for ((*expr1* ; *expr2* ; *expr3*)) ; **do *list* ; **done****

First, the arithmetic expression *expr1* is evaluated according to the rules described below under **ARITHMETIC EVALUATION**. The arithmetic expression *expr2* is then evaluated repeatedly until it evaluates to zero. Each time *expr2* evaluates to a non-zero value, *list* is executed and the arithmetic expression *expr3* is evaluated. If any expression is omitted, it behaves as if it evaluates to 1. The return value is the exit status of the last command in *list* that is executed, or false if any of the expressions is invalid.

select *name* [**in *word*] ; **do** *list* ; **done****

The list of words following **in** is expanded, generating a list of items. The set of expanded words is printed on the standard error, each preceded by a number. If the **in** *word* is omitted, the positional parameters are printed (see **PARAMETERS** below). The **PS3** prompt is then displayed and a line read from the standard input. If the line consists of a number corresponding to one of the displayed words, then the value of *name* is set to that word. If the line is empty, the words and prompt are displayed again. If EOF is read, the command completes. Any other value read causes *name* to be set to null. The line read is saved in the variable **REPLY**. The *list* is executed after each selection until a **break** command is executed. The exit status of **select** is the exit status of the last command executed in *list*, or zero if no commands were executed.

case *word* **in [[() *pattern* [| *pattern*] ...) *list* ; ;] ... **esac****

A **case** command first expands *word*, and tries to match it against each *pattern* in turn, using the matching rules described under **Pattern Matching** below. The *word* is expanded using tilde expansion, parameter and variable expansion, arithmetic expansion, command substitution, process substitution and quote removal. Each *pattern* examined is expanded using tilde expansion, parameter and variable expansion, arithmetic expansion, command substitution, and process substitution. If the **nocasematch** shell option is enabled, the match is performed without regard to the case of alphabetic characters. When a match is found, the corresponding *list* is executed. If the **;;** operator is used, no subsequent matches are attempted after the first pattern match. Using **; &** in place of **;;** causes execution to continue with the *list* associated with the next set of patterns. Using **;; &** in place of **;;** causes the shell to test the next pattern list in the statement, if any, and execute any associated *list* on a successful match, continuing the case statement execution as if the pattern list had not matched. The exit status is zero if no pattern matches. Otherwise, it is the exit status of

the last command executed in *list*.

if *list*; **then** *list*; [**elif** *list*; **then** *list*;] ... [**else** *list*;] **fi**

The **if** *list* is executed. If its exit status is zero, the **then** *list* is executed. Otherwise, each **elif** *list* is executed in turn, and if its exit status is zero, the corresponding **then** *list* is executed and the command completes. Otherwise, the **else** *list* is executed, if present. The exit status is the exit status of the last command executed, or zero if no condition tested true.

while *list-1*; **do** *list-2*; **done**

until *list-1*; **do** *list-2*; **done**

The **while** command continuously executes the list *list-2* as long as the last command in the list *list-1* returns an exit status of zero. The **until** command is identical to the **while** command, except that the test is negated: *list-2* is executed as long as the last command in *list-1* returns a non-zero exit status. The exit status of the **while** and **until** commands is the exit status of the last command executed in *list-2*, or zero if none was executed.

Coprocesses

A *coprocess* is a shell command preceded by the **coproc** reserved word. A coprocess is executed asynchronously in a subshell, as if the command had been terminated with the & control operator, with a two-way pipe established between the executing shell and the coprocess.

The format for a coprocess is:

coproc [*NAME*] *command* [*redirections*]

This creates a coprocess named *NAME*. If *NAME* is not supplied, the default name is **COPROC**. *NAME* must not be supplied if *command* is a *simple command* (see above); otherwise, it is interpreted as the first word of the simple command. When the coprocess is executed, the shell creates an array variable (see **Arrays** below) named *NAME* in the context of the executing shell. The standard output of *command* is connected via a pipe to a file descriptor in the executing shell, and that file descriptor is assigned to *NAME*[0]. The standard input of *command* is connected via a pipe to a file descriptor in the executing shell, and that file descriptor is assigned to *NAME*[1]. This pipe is established before any redirections specified by the command (see **REDIRECTION** below). The file descriptors can be utilized as arguments to shell commands and redirections using standard word expansions. Other than those created to execute command and process substitutions, the file descriptors are not available in subshells. The process ID of the shell spawned to execute the coprocess is available as the value of the variable *NAME_PID*. The **wait** builtin command may be used to wait for the coprocess to terminate.

Since the coprocess is created as an asynchronous command, the **coproc** command always returns success. The return status of a coprocess is the exit status of *command*.

Shell Function Definitions

A shell function is an object that is called like a simple command and executes a compound command with a new set of positional parameters. Shell functions are declared as follows:

fname () *compound-command* [*redirection*]

function *fname* [() *compound-command* [*redirection*]]

This defines a function named *fname*. The reserved word **function** is optional. If the **function** reserved word is supplied, the parentheses are optional. The *body* of the function is the compound command *compound-command* (see **Compound Commands** above). That command is usually a *list* of commands between { and }, but may be any command listed under **Compound Commands** above, with one exception: If the **function** reserved word is used, but the parentheses are not supplied, the braces are required. *compound-command* is executed whenever *fname* is specified as the name of a simple command. When in *posix mode*, *fname* must be a valid shell *name* and may not be the name of one of the *POSIX special builtins*. In default mode, a function name can be any unquoted shell word that does not contain \$. Any redirections (see **REDIRECTION** below) specified when a function is defined are performed when the function is executed. The exit status of a function definition is zero unless a syntax error occurs or a readonly function with the same name already exists. When executed, the exit status of a function is the exit status of the last command executed in the body. (See **FUNCTIONS** below.)

COMMENTS

In a non-interactive shell, or an interactive shell in which the **interactive_comments** option to the **shopt** builtin is enabled (see **SHELL BUILTIN COMMANDS** below), a word beginning with # causes that word and all remaining characters on that line to be ignored. An interactive shell without the **interactive_comments** option enabled does not allow comments. The **interactive_comments** option is on by default in interactive shells.

QUOTING

Quoting is used to remove the special meaning of certain characters or words to the shell. Quoting can be used to disable special treatment for special characters, to prevent reserved words from being recognized as such, and to prevent parameter expansion.

Each of the *metacharacters* listed above under **DEFINITIONS** has special meaning to the shell and must be quoted if it is to represent itself.

When the command history expansion facilities are being used (see **HISTORY EXPANSION** below), the *history expansion* character, usually !, must be quoted to prevent history expansion.

There are three quoting mechanisms: the *escape character*, single quotes, and double quotes.

A non-quoted backslash () is the *escape character*. It preserves the literal value of the next character that follows, with the exception of <newline>. If a\<ne wline> pair appears, and the backslash is not itself quoted, the \<newline> is treated as a line continuation (that is, it is removed from the input stream and effectively ignored).

Enclosing characters in single quotes preserves the literal value of each character within the quotes. A single quote may not occur between single quotes, even when preceded by a backslash.

Enclosing characters in double quotes preserves the literal value of all characters within the quotes, with the exception of \$, ` , \, and, when history expansion is enabled, !. When the shell is *posix mode*, the ! has no special meaning within double quotes, even when history expansion is enabled. The characters \$ and ` retain their special meaning within double quotes. The backslash retains its special meaning only when followed by one of the following characters: \$, ` , " , \, or <newline>. A double quote may be quoted within double quotes by preceding it with a backslash. If enabled, history expansion will be performed unless an ! appearing in double quotes is escaped using a backslash. The backslash preceding the ! is not removed.

The special parameters * and @ have special meaning when in double quotes (see **PARAMETERS** below).

Words of the form \$'string' are treated specially. The word expands to *string*, with backslash-escaped characters replaced as specified by the ANSI C standard. Backslash escape sequences, if present, are decoded as follows:

\a	alert (bell)
\b	backspace
\e	
\E	an escape character
\f	form feed
\n	new line
\r	carriage return
\t	horizontal tab
\v	vertical tab
\\\	backslash
\'	single quote
\\"	double quote
\?	question mark
\nnn	the eight-bit character whose value is the octal value <i>nnn</i> (one to three octal digits)
\xHH	the eight-bit character whose value is the hexadecimal value <i>HH</i> (one or two hex digits)
\uHHHH	the Unicode (ISO/IEC 10646) character whose value is the hexadecimal value <i>HHHH</i> (one to four hex digits)

`\UHHHHHHHHH`

the Unicode (ISO/IEC 10646) character whose value is the hexadecimal value *HHHHHHH*
HHH (one to eight hex digits)

`\cx` a control-x character

The expanded result is single-quoted, as if the dollar sign had not been present.

A double-quoted string preceded by a dollar sign (`$$string`) will cause the string to be translated according to the current locale. The `gettext` infrastructure performs the message catalog lookup and translation, using the **LC_MESSAGES** and **TEXTDOMAIN** shell variables. If the current locale isC or **POSIX**, or if there are no translations available, the dollar sign is ignored. If the string is translated and replaced, the replacement is double-quoted.

PARAMETERS

A *parameter* is an entity that stores values. It can be an *ame*, a number , or one of the special characters listed below under **Special Parameters**. A *variable* is a parameter denoted by a *ame*. A *v* *ariable* has a *value* and zero or more *tributes*. Attributes are assigned using the **declare** builtin command (see **declare** below in **SHELL BUILTIN COMMANDS**).

A parameter is set if it has been assigned a value. The null string is a valid value. Once a variable is set, it may be unset only by using the **unset** builtin command (see **SHELL BUILTIN COMMANDS** below).

A *variable* may be assigned to by a statement of the form

`name=[value]`

If *value* is not given, the variable is assigned the null string. All *values* undergo tilde expansion, parameter and variable expansion, command substitution, arithmetic expansion, and quote removal (see **EXPANSION** below). If the variable has its **integer** attribute set, *value* is evaluated as an arithmetic expression even if the `$((...))` expansion is not used (see **Arithmetic Expansion** below). Word splitting is not performed, with the exception of `"$@"` as explained below under **Special Parameters**. Pathname expansion is not performed. Assignment statements may also appear as arguments to the **alias**, **declare**, **typeset**, **export**, **readonly**, and **local** builtin commands (*declaration commands*). When in *posix mode*, these builtins may appear in a command after one or more instances of the **command** builtin and retain these assignment statement properties.

In the context where an assignment statement is assigning a value to a shell variable or array index, the `+=` operator can be used to append to or add to the variable's previous value. This includes arguments to builtin commands such as **declare** that accept assignment statements (*declaration commands*). When `+=` is applied to a variable for which the **integer** attribute has been set, *value* is evaluated as an arithmetic expression and added to the variable's current value, which is also evaluated. When `+=` is applied to an array variable using compound assignment (see **Arrays** below), the variable's value is not unset (as it is when using `=`), and new values are appended to the array beginning at one greater than the array's maximum index (for indexed arrays) or added as additional key-value pairs in an associative array. When applied to a string-valued variable, *value* is expanded and appended to the variable's value.

A variable can be assigned the *nameref* attribute using the `-n` option to the **declare** or **local** builtin commands (see the descriptions of **declare** and **local** below) to create a *nameref*, or a reference to another variable. This allows variables to be manipulated indirectly. Whenever the *nameref* variable is referenced, assigned to, unset, or has its attributes modified (other than using or changing the *nameref* attribute itself), the operation is actually performed on the variable specified by the *nameref* variable's value. A *nameref* is commonly used within shell functions to refer to a variable whose name is passed as an argument to the function. For instance, if a variable name is passed to a shell function as its first argument, running

```
declare -n ref=$1
```

inside the function creates a *nameref* variable **ref** whose value is the variable name passed as the first argument. References and assignments to **ref**, and changes to its attributes, are treated as references, assignments, and attribute modifications to the variable whose name was passed as `$1`. If the control variable in a **for** loop has the *nameref* attribute, the list of words can be a list of shell variables, and a name reference will be established for each word in the list, in turn, when the loop is executed. Array variables cannot be

given the **nameref** attribute. However, nameref variables can reference array variables and subscripted array variables. Namerefs can be unset using the **-n** option to the **unset** builtin. Otherwise, if **unset** is executed with the name of a nameref variable as an argument, the variable referenced by the nameref variable will be unset.

Positional Parameters

A *positional parameter* is a parameter denoted by one or more digits, other than the single digit 0. Positional parameters are assigned from the shell's arguments when it is invoked, and may be reassigned using the **set** builtin command. Positional parameters may not be assigned to with assignment statements. The positional parameters are temporarily replaced when a shell function is executed (see **FUNCTIONS** below).

When a positional parameter consisting of more than a single digit is expanded, it must be enclosed in braces (see **EXPANSION** below).

Special Parameters

The shell treats several parameters specially. These parameters may only be referenced; assignment to them is not allowed.

- * Expands to the positional parameters, starting from one. When the expansion is not within double quotes, each positional parameter expands to a separate word. In contexts where it is performed, those words are subject to further word splitting and pathname expansion. When the expansion occurs within double quotes, it expands to a single word with the value of each parameter separated by the first character of the **IFS** special variable. That is, "\$*" is equivalent to "\$1\$c\$2c...", where *c* is the first character of the value of the **IFS** variable. If **IFS** is unset, the parameters are separated by spaces. If **IFS** is null, the parameters are joined without intervening separators.
- @ Expands to the positional parameters, starting from one. In contexts where word splitting is performed, this expands each positional parameter to a separate word; if not within double quotes, these words are subject to word splitting. In contexts where word splitting is not performed, this expands to a single word with each positional parameter separated by a space. When the expansion occurs within double quotes, each parameter expands to a separate word. That is, "\$@" is equivalent to "\$1" "\$2" ... If the double-quoted expansion occurs within a word, the expansion of the first parameter is joined with the beginning part of the original word, and the expansion of the last parameter is joined with the last part of the original word. When there are no positional parameters, "\$@" and \$@ expand to nothing (i.e., they are removed).
- # Expands to the number of positional parameters in decimal.
- ? Expands to the exit status of the most recently executed foreground pipeline.
- Expands to the current option flags as specified upon invocation, by the **set** builtin command, or those set by the shell itself (such as the **-i** option).
- \$ Expands to the process ID of the shell. In a () subshell, it expands to the process ID of the current shell, not the subshell.
- ! Expands to the process ID of the job most recently placed into the background, whether executed as an asynchronous command or using the **bg** builtin (see **JOB CONTROL** below).
- 0 Expands to the name of the shell or shell script. This is set at shell initialization. If **bash** is invoked with a file of commands, \$0 is set to the name of that file. If **bash** is started with the **-c** option, then \$0 is set to the first argument after the string to be executed, if one is present. Otherwise, it is set to the filename used to invoke **bash**, as given by argument zero.

Shell Variables

The following variables are set by the shell:

- At shell startup, set to the pathname used to invoke the shell or shell script being executed as passed in the environment or argument list. Subsequently, expands to the last argument to the previous simple command executed in the foreground, after expansion. Also set to the full pathname used to invoke each command executed and placed in the environment exported to that command. When checking mail, this parameter holds the name of the mail file currently being checked.
- BASH** Expands to the full filename used to invoke this instance of **bash**.

BASHOPTS

A colon-separated list of enabled shell options. Each word in the list is a valid argument for the `-s` option to the `shopt` builtin command (see **SHELL BUILTIN COMMANDS** below). The options appearing in **BASHOPTS** are those reported as *on* by `shopt`. If this variable is in the environment when **bash** starts up, each shell option in the list will be enabled before reading any startup files. This variable is read-only.

BASHPID

Expands to the process ID of the current **bash** process. This differs from `$$` under certain circumstances, such as subshells that do not require **bash** to be re-initialized. Assignments to **BASHPID** have no effect. If **ASHPID** is unset, it loses its special properties, even if it is subsequently reset.

BASH_ALIASES

An associative array variable whose members correspond to the internal list of aliases as maintained by the `alias` builtin. Elements added to this array appear in the alias list; however, unsetting array elements currently does not cause aliases to be removed from the alias list. If **BASH_ALIASES** is unset, it loses its special properties, even if it is subsequently reset.

BASH_ARGC

An array variable whose values are the number of parameters in each frame of the current **bash** execution call stack. The number of parameters to the current subroutine (shell function or script executed with `.` or `source`) is at the top of the stack. When a subroutine is executed, the number of parameters passed is pushed onto **BASH_ARGC**. The shell sets **BASH_ARGC** only when in extended debugging mode (see the description of the `extdebug` option to the `shopt` builtin below). Setting `extdebug` after the shell has started to execute a script, or referencing this variable when `extdebug` is not set, may result in inconsistent values.

BASH_ARGV

An array variable containing all of the parameters in the current **bash** execution call stack. The final parameter of the last subroutine call is at the top of the stack; the first parameter of the initial call is at the bottom. When a subroutine is executed, the parameters supplied are pushed onto **BASH_ARGV**. The shell sets **BASH_ARGV** only when in extended debugging mode (see the description of the `extdebug` option to the `shopt` builtin below). Setting `extdeb ug` after the shell has started to execute a script, or referencing this variable when `extdebug` is not set, may result in inconsistent values.

BASH_ARGV0

When referenced, this variable expands to the name of the shell or shell script (identical to `$0`; see the description of special parameter 0 above). Assignment to **ASH_ARGV0** causes the value assigned to also be assigned to `$0`. If **ASH_ARGV0** is unset, it loses its special properties, even if it is subsequently reset.

BASH_CMDS

An associative array variable whose members correspond to the internal hash table of commands as maintained by the `hash` builtin. Elements added to this array appear in the hash table; however, unsetting array elements currently does not cause command names to be removed from the hash table. If **ASH_CMDS** is unset, it loses its special properties, even if it is subsequently reset.

BASH_COMMAND

The command currently being executed or about to be executed, unless the shell is executing a command as the result of a trap, in which case it is the command executing at the time of the trap.

If **BASH_COMMAND** is unset, it loses its special properties, even if it is subsequently reset.

BASH_EXECUTION_STRING

The command argument to the `-c` invocation option.

BASH_LINENO

An array variable whose members are the line numbers in source files where each corresponding member of `FUNCNAME` was invoked. `$(BASH_LINENO[${$i}])` is the line number in the source file `$(BASH_SOURCE[${$i+1}])` where `$(FUNCNAME[${$i}])` was called (or `$(BASH_LINENO[${$i-1}])` if referenced within another shell function). Use `LINENO` to obtain the current line number.

BASH_LOADABLES_PATH

A colon-separated list of directories in which the shell looks for dynamically loadable builtins specified by the **enable** command.

BASH_REMATCH

An array variable whose members are assigned by the `=~` binary operator to the `[[` conditional command. The element with index 0 is the portion of the string matching the entire regular expression. The element with index *n* is the portion of the string matching the *n*th parenthesized subexpression.

BASH_SOURCE

An array variable whose members are the source filenames where the corresponding shell function names in the **FUNCNAME** array variable are defined. The shell function `${FUNCNAME[$i]}` is defined in the file `${BASH_SOURCE[$i]}` and called from `${BASH_SOURCE[$i+1]}` .

BASH_SUBSHELL

Incremented by one within each subshell or subshell environment when the shell begins executing in that environment. The initial value is 0. If **BASH_SUBSHELL** is unset, it loses its special properties, even if it is subsequently reset.

BASH_VERSINFO

A readonly array variable whose members hold version information for this instance of **bash**. The values assigned to the array members are as follows:

BASH_VERSINFO[0]	The major version number (the <i>release</i>).
BASH_VERSINFO[1]	The minor version number (the <i>version</i>).
BASH_VERSINFO[2]	The patch level.
BASH_VERSINFO[3]	The build version.
BASH_VERSINFO[4]	The release status (e.g., <i>beta</i>).
BASH_VERSINFO[5]	The value of MACHTYPE .

BASH_VERSION

Expands to a string describing the version of this instance of **bash**.

COMP_CWORD

An index into `${COMP_WORDS}` of the word containing the current cursor position. This variable is available only in shell functions invoked by the programmable completion facilities (see **Programmable Completion** below).

COMP_KEY

The key (or final key of a key sequence) used to invoke the current completion function.

COMP_LINE

The current command line. This variable is available only in shell functions and external commands invoked by the programmable completion facilities (see **Programmable Completion** below).

COMP_POINT

The index of the current cursor position relative to the beginning of the current command. If the current cursor position is at the end of the current command, the value of this variable is equal to `${#COMP_LINE}` . This variable is available only in shell functions and external commands invoked by the programmable completion facilities (see **Programmable Completion** below).

COMP_TYPE

Set to an integer value corresponding to the type of completion attempted that caused a completion function to be called: `TAB`, for normal completion, `?`, for listing completions after successive tabs, `!`, for listing alternatives on partial word completion, `@`, to list completions if the word is not unmodified, or `%`, for menu completion. This variable is available only in shell functions and external commands invoked by the programmable completion facilities (see **Programmable Completion** below).

COMP_WORDBREAKS

The set of characters that the **readline** library treats as word separators when performing word completion. If **COMP_WORDBREAKS** is unset, it loses its special properties, even if it is subsequently reset.

COMP_WORDS

An array variable (see **Arrays** below) consisting of the individual words in the current command line. The line is split into words as **readline** would split it, using **COMP_WORDBREAKS** as described above. This variable is available only in shell functions invoked by the programmable completion facilities (see **Programmable Completion** below).

COPROC

An array variable (see **Arrays** below) created to hold the file descriptors for output from and input to an unnamed coprocess (see **Coprocesses** above).

DIRSTACK

An array variable (see **Arrays** below) containing the current contents of the directory stack. Directories appear in the stack in the order they are displayed by the **dirs** builtin. Assigning to members of this array variable may be used to modify directories already in the stack, but the **pushd** and **popd** builtins must be used to add and remove directories. Assignment to this variable will not change the current directory. If **DIRSTACK** is unset, it loses its special properties, even if it is subsequently reset.

EPOCHREALTIME

Each time this parameter is referenced, it expands to the number of seconds since the Unix Epoch (see *time(3)*) as a floating point value with micro-second granularity. Assignments to **EPOCHREALTIME** are ignored. If **EPOCHREALTIME** is unset, it loses its special properties, even if it is subsequently reset.

EPOCHSECONDS

Each time this parameter is referenced, it expands to the number of seconds since the Unix Epoch (see *time(3)*). Assignments to **EPOCHSECONDS** are ignored. If **EPOCHSECONDS** is unset, it loses its special properties, even if it is subsequently reset.

EUID Expands to the effective user ID of the current user, initialized at shell startup. This variable is readonly.

FUNCNAME

An array variable containing the names of all shell functions currently in the execution call stack. The element with index 0 is the name of any currently-executing shell function. The bottom-most element (the one with the highest index) is "main". This variable exists only when a shell function is executing. Assignments to **FUNCNAME** have no effect. If **FUNCNAME** is unset, it loses its special properties, even if it is subsequently reset.

This variable can be used with **BASH_LINENO** and **BASH_SOURCE**. Each element of **FUNCNAME** has corresponding elements in **BASH_LINENO** and **BASH_SOURCE** to describe the call stack. For instance, **FUNCNAME[*i*]** was called from the file **BASH_SOURCE[*i*+1]** at line number **BASH_LINENO[*i*]**. The **caller** builtin displays the current call stack using this information.

GROUPS

An array variable containing the list of groups of which the current user is a member. Assignments to **GROUPS** have no effect. If **GROUPS** is unset, it loses its special properties, even if it is subsequently reset.

HISTCMD

The history number, or index in the history list, of the current command. Assignments to **HISTCMD** are ignored. If **HISTCMD** is unset, it loses its special properties, even if it is subsequently reset.

HOSTNAME

Automatically set to the name of the current host.

HOSTTYPE

Automatically set to a string that uniquely describes the type of machine on which **bash** is executing. The default is system-dependent.

LINENO

Each time this parameter is referenced, the shell substitutes a decimal number representing the current sequential line number (starting with 1) within a script or function. When not in a script or function, the value substituted is not guaranteed to be meaningful. If **LINENO** is unset, it loses its

special properties, even if it is subsequently reset.

MACHTYPE

Automatically set to a string that fully describes the system type on which **bash** is executing, in the standard GNU *cpu-company-system* format. The default is system-dependent.

MAPFILE

An array variable (see **Arrays** below) created to hold the text read by the **mapfile** builtin when no variable name is supplied.

OLDPWD

The previous working directory as set by the **cd** command.

OPTARG

The value of the last option argument processed by the **getopts** builtin command (see **SHELL BUILTIN COMMANDS** below).

OPTIND

The index of the next argument to be processed by the **getopts** builtin command (see **SHELL BUILTIN COMMANDS** below).

OSTYPE

Automatically set to a string that describes the operating system on which **bash** is executing. The default is system-dependent.

PIPESTATUS

An array variable (see **Arrays** below) containing a list of exit status values from the processes in the most-recently-executed foreground pipeline (which may contain only a single command).

PPID

The process ID of the shell's parent. This variable is readonly.

PWD

The current working directory as set by the **cd** command.

RANDOM

Each time this parameter is referenced, it expands to a random integer between 0 and 32767. Assigning a value to **RANDOM** initializes (seeds) the sequence of random numbers. If **RANDOM** is unset, it loses its special properties, even if it is subsequently reset.

READLINE_LINE

The contents of the **readline** line buffer, for use with **bind -x** (see **SHELL BUILTIN COMMANDS** below).

READLINE_MARK

The position of the mark (saved insertion point) in the **readline** line buffer, for use with **bind -x** (see **SHELL BUILTIN COMMANDS** below). The characters between the insertion point and the mark are often called the *region*.

READLINE_POINT

The position of the insertion point in the **readline** line buffer, for use with **bind -x** (see **SHELL BUILTIN COMMANDS** below).

REPLY

Set to the line of input read by the **read** builtin command when no arguments are supplied.

SECONDS

Each time this parameter is referenced, the number of seconds since shell invocation is returned. If a value is assigned to **SECONDS**, the value returned upon subsequent references is the number of seconds since the assignment plus the value assigned. The number of seconds at shell invocation and the current time is always determined by querying the system clock. If **SECONDS** is unset, it loses its special properties, even if it is subsequently reset.

SHELLOPTS

A colon-separated list of enabled shell options. Each word in the list is a valid argument for the **-o** option to the **set** builtin command (see **SHELL BUILTIN COMMANDS** below). The options appearing in **SHELLOPTS** are those reported as *on* by **set -o**. If this variable is in the environment when **bash** starts up, each shell option in the list will be enabled before reading any startup files. This variable is read-only.

SHLVL

Incremented by one each time an instance of **bash** is started.

SRANDOM

This variable expands to a 32-bit pseudo-random number each time it is referenced. The random number generator is not linear on systems that support `/dev/urandom` or `arc4random`, so each returned number has no relationship to the numbers preceding it. The random number generator cannot be seeded, so assignments to this variable have no effect. If **SRANDOM** is unset, it loses its special properties, even if it is subsequently reset.

UID Expands to the user ID of the current user, initialized at shell startup. This variable is readonly.

The following variables are used by the shell. In some cases, **bash** assigns a default value to a variable; these cases are noted below.

BASH_COMPAT

The value is used to set the shell's compatibility level. See **SHELL COMPATIBILITY MODE** below for a description of the various compatibility levels and their effects. The value may be a decimal number (e.g., 4.2) or an integer (e.g., 42) corresponding to the desired compatibility level. If **BASH_COMPAT** is unset or set to the empty string, the compatibility level is set to the default for the current version. If **ASH_COMPAT** is set to a value that is not one of the valid compatibility levels, the shell prints an error message and sets the compatibility level to the default for the current version. The valid values correspond to the compatibility levels described below under **BASHCOMPATIBILITYMODE**. For example, 4.2 and 42 are valid values that correspond to the **compat42** **shop** option and set the compatibility level to 42. The current version is also a valid value.

BASH_ENV

If this parameter is set when **bash** is executing a shell script, its value is interpreted as a filename containing commands to initialize the shell, as in `%bashrc`. The value of **BASH_ENV** is subjected to parameter expansion, command substitution, and arithmetic expansion before being interpreted as a filename. **PATH** is not used to search for the resultant filename.

BASH_XTRACEFD

If set to an integer corresponding to a valid file descriptor, **bash** will write the trace output generated when **set -x** is enabled to that file descriptor. The file descriptor is closed when **BASH_XTRACEFD** is unset or assigned a new value. Unsetting **BASH_XTRACEFD** or assigning it the empty string causes the trace output to be sent to the standard error. Note that setting **BASH_XTRACEFD** to 2 (the standard error file descriptor) and then unsetting it will result in the standard error being closed.

CDPATH

The search path for the **cd** command. This is a colon-separated list of directories in which the shell looks for destination directories specified by the **cd** command. A sample value is `".:~:/usr"`.

CHILD_MAX

Set the number of exited child status values for the shell to remember. Bash will not allow this value to be decreased below a POSIX-mandated minimum, and there is a maximum value (currently 8192) that this may not exceed. The minimum value is system-dependent.

COLUMNS

Used by the **select** compound command to determine the terminal width when printing selection lists. Automatically set if the **checkwinsize** option is enabled or in an interactive shell upon receipt of a **SIGWINCH**.

COMPREPLY

An array variable from which **bash** reads the possible completions generated by a shell function invoked by the programmable completion facility (see **Programmable Completion** below). Each array element contains one possible completion.

EMACS

If **bash** finds this variable in the environment when the shell starts with value `t`, it assumes that the shell is running in an Emacs shell buffer and disables line editing.

ENV Expanded and executed similarly to **BASH_ENV** (see **INVOCATION** above) when an interactive shell is invoked in *posix mode*.

EXECIGNORE

A colon-separated list of shell patterns (see **Pattern Matching**) defining the list of filenames to be ignored by command search using **PATH**. Files whose full pathnames match one of these patterns are not considered executable files for the purposes of completion and command execution via **PATH** lookup. This does not affect the behavior of the **[**, **test**, and **[[** commands. Full pathnames in the command hash table are not subject to **EXECIGNORE**. Use this variable to ignore shared library files that have the executable bit set, but are not executable files. The pattern matching honors the setting of the **extglob** shell option.

FCEDIT

The default editor for the **fc** builtin command.

FIGNORE

A colon-separated list of suffixes to ignore when performing filename completion (see **READLINE** below). A filename whose suffix matches one of the entries in **FIGNORE** is excluded from the list of matched filenames. A sample value is "`.o:~`". (Quoting is needed when assigning a value to this variable, which contains tildes).

FUNCNEST

If set to a numeric value greater than 0, defines a maximum function nesting level. Function invocations that exceed this nesting level will cause the current command to abort.

GLOBIGNORE

A colon-separated list of patterns defining the set of file names to be ignored by pathname expansion. If a file name matched by a pathname expansion pattern also matches one of the patterns in **GLOBIGNORE**, it is removed from the list of matches.

HISTCONTROL

A colon-separated list of values controlling how commands are saved on the history list. If the list of values includes *ignorespace*, lines which begin with a **space** character are not saved in the history list. A value of *ignoredups* causes lines matching the previous history entry to not be saved. A value of *ignoreboth* is shorthand for *ignorespace* and *ignoredups*. A value of *erasedups* causes all previous lines matching the current line to be removed from the history list before that line is saved. Any value not in the above list is ignored. If **HISTCONTROL** is unset, or does not include a valid value, all lines read by the shell parser are saved on the history list, subject to the value of **HISTIGNORE**. The second and subsequent lines of a multi-line compound command are not tested, and are added to the history regardless of the value of **HISTCONTROL**.

HISTFILE

The name of the file in which command history is saved (see **HISTORY** below). The default value is `~/.bash_history`. If unset, the command history is not saved when a shell exits.

HISTFILESIZE

The maximum number of lines contained in the history file. When this variable is assigned a value, the history file is truncated, if necessary, to contain no more than that number of lines by removing the oldest entries. The history file is also truncated to this size after writing it when a shell exits. If the value is 0, the history file is truncated to zero size. Non-numeric values and numeric values less than zero inhibit truncation. The shell sets the default value to the value of **HISTSIZE** after reading any startup files.

HISTIGNORE

A colon-separated list of patterns used to decide which command lines should be saved on the history list. Each pattern is anchored at the beginning of the line and must match the complete line (no implicit '*' is appended). Each pattern is tested against the line after the checks specified by **HISTCONTROL** are applied. In addition to the normal shell pattern matching characters, '&' matches the previous history line. '&' may be escaped using a backslash; the backslash is removed before attempting a match. The second and subsequent lines of a multi-line compound command are not tested, and are added to the history regardless of the value of **HISTIGNORE**. The pattern matching honors the setting of the **extglob** shell option.

HISTSIZE

The number of commands to remember in the command history (see **HISTORY** below). If the value is 0, commands are not saved in the history list. Numeric values less than zero result in

every command being saved on the history list (there is no limit). The shell sets the default value to 500 after reading any startup files.

HISTTIMEFORMAT

If this variable is set and not null, its value is used as a format string for *strftime*(3) to print the time stamp associated with each history entry displayed by the **history** builtin. If this variable is set, time stamps are written to the history file so they may be preserved across shell sessions. This uses the history comment character to distinguish timestamps from other history lines.

HOME

The home directory of the current user; the default argument for the **cd** builtin command. The value of this variable is also used when performing tilde expansion.

HOSTFILE

Contains the name of a file in the same format as */etc/hosts* that should be read when the shell needs to complete a hostname. The list of possible hostname completions may be changed while the shell is running; the next time hostname completion is attempted after the value is changed, **bash** adds the contents of the new file to the existing list. If **HOSTFILE** is set, but has no value, or does not name a readable file, **bash** attempts to read */etc/hosts* to obtain the list of possible hostname completions. When **HOSTFILE** is unset, the hostname list is cleared.

IFS The *Internal Field Separator* that is used for word splitting after expansion and to split lines into words with the **read** builtin command. The default value is “<space><tab><newline>”.

IGNOREEOF

Controls the action of an interactive shell on receipt of an **EOF** character as the sole input. If set, the value is the number of consecutive **EOF** characters which must be typed as the first characters on an input line before **bash** exits. If the variable exists but does not have a numeric value, or has no value, the default value is 10. If it does not exist, **EOF** signifies the end of input to the shell.

INPUTRC

The filename for the **readline** startup file, overriding the default of *~/.inputrc* (see **READLINE** below).

INSIDE_EMACS

If this variable appears in the environment when the shell starts, **bash** assumes that it is running inside an Emacs shell buffer and may disable line editing, depending on the value of **TERM**.

LANG Used to determine the locale category for any category not specifically selected with a variable starting with **LC_**.

LC_ALL

This variable overrides the value of **LANG** and any other **LC_** variable specifying a locale category.

LC_COLLATE

This variable determines the collation order used when sorting the results of pathname expansion, and determines the behavior of range expressions, equivalence classes, and collating sequences within pathname expansion and pattern matching.

LC_CTYPE

This variable determines the interpretation of characters and the behavior of character classes within pathname expansion and pattern matching.

LC_MESSAGES

This variable determines the locale used to translate double-quoted strings preceded by a \$.

LC_NUMERIC

This variable determines the locale category used for number formatting.

LC_TIME

This variable determines the locale category used for data and time formatting.

LINES Used by the **select** compound command to determine the column length for printing selection lists. Automatically set if the **checkwinsize** option is enabled or in an interactive shell upon receipt of a **SIGWINCH**.

MAIL If this parameter is set to a file or directory name and the **MAILPATH** variable is not set, **bash** informs the user of the arrival of mail in the specified file or Maildir-format directory.

MAILCHECK

Specifies how often (in seconds) **bash** checks for mail. The default is 60 seconds. When it is time to check for mail, the shell does so before displaying the primary prompt. If this variable is unset, or set to a value that is not a number greater than or equal to zero, the shell disables mail checking.

MAILPATH

A colon-separated list of filenames to be checked for mail. The message to be printed when mail arrives in a particular file may be specified by separating the filename from the message with a ‘?’.
When used in the text of the message, `$_` expands to the name of the current mailfile. Example:
`MAILPATH=/var/mail/bfox?"You have mail":~/shell-mail?"$_ has mail!"`
Bash can be configured to supply a default value for this variable (there is no value by default), but the location of the user mail files that it uses is system dependent (e.g., `/var/mail/$USER`).

OPTERR

If set to the value 1, **bash** displays error messages generated by the **getopts** builtin command (see **SHELL BUILTIN COMMANDS** below). **OPTERR** is initialized to 1 each time the shell is invoked or a shell script is executed.

PATH The search path for commands. It is a colon-separated list of directories in which the shell looks for commands (see **COMMAND EXECUTION** below). A zero-length (null) directory name in the value of **PATH** indicates the current directory. A null directory name may appear as two adjacent colons, or as an initial or trailing colon. The default path is system-dependent, and is set by the administrator who installs **bash**. A common value is `/usr/local/bin:/usr/local/sbin:/usr/bin:/usr/sbin:/bin:/sbin`.

POSIXLY_CORRECT

If this variable is in the environment when **bash** starts, the shell enters *posix mode* before reading the startup files, as if the `--posix` invocation option had been supplied. If it is set while the shell is running, **bash** enables *posix mode*, as if the command `set -o posix` had been executed. When the shell enters *posix mode*, it sets this variable if it was not already set.

PROMPT_COMMAND

If this variable is set, and is an array, the value of each set element is executed as a command prior to issuing each primary prompt. If this is set but not an array variable, its value is used as a command to execute instead.

PROMPT_DIRTRIM

If set to a number greater than zero, the value is used as the number of trailing directory components to retain when expanding the `\w` and `\W` prompt string escapes (see **PROMPTING** below). Characters removed are replaced with an ellipsis.

PS0 The value of this parameter is expanded (see **PROMPTING** below) and displayed by interactive shells after reading a command and before the command is executed.

PS1 The value of this parameter is expanded (see **PROMPTING** below) and used as the primary prompt string. The default value is `"\$-\$\"`.

PS2 The value of this parameter is expanded as with **PS1** and used as the secondary prompt string. The default is >.

PS3 The value of this parameter is used as the prompt for the **select** command (see **SHELL GRAMMAR** above).

PS4 The value of this parameter is expanded as with **PS1** and the value is printed before each command **bash** displays during an execution trace. The first character of the expanded value of **PS4** is replicated multiple times, as necessary, to indicate multiple levels of indirection. The default is `+`.

SHELL

This variable expands to the full pathname to the shell. If it is not set when the shell starts, **bash** assigns to it the full pathname of the current user's login shell.

TIMEFORMAT

The value of this parameter is used as a format string specifying how the timing information for pipelines prefixed with the **time** reserved word should be displayed. The `%` character introduces an escape sequence that is expanded to a time value or other information. The escape sequences and their meanings are as follows; the braces denote optional portions.

%%	A literal % .
%[p][I]R	The elapsed time in seconds.
%[p][I]U	The number of CPU seconds spent in user mode.
%[p][I]S	The number of CPU seconds spent in system mode.
%P	The CPU percentage, computed as (%U + %S) / %R .

The optional *p* is a digit specifying the *precision*, the number of fractional digits after a decimal point. A value of 0 causes no decimal point or fraction to be output. At most three places after the decimal point may be specified; values of *p* greater than 3 are changed to 3. If *p* is not specified, the value 3 is used.

The optional **I** specifies a longer format, including minutes, of the form *MMmSS.FFs*. The value of *p* determines whether or not the fraction is included.

If this variable is not set, **bash** acts as if it had the value **\$'\nreal\t%3lR\nuser\t%3lU\nsys\t%3lS'**. If the value is null, no timing information is displayed. A trailing newline is added when the format string is displayed.

TMOUT

If set to a value greater than zero, **TMOUT** is treated as the default timeout for the **read** builtin. The **select** command terminates if input does not arrive after **TMOUT** seconds when input is coming from a terminal. In an interactive shell, the value is interpreted as the number of seconds to wait for a line of input after issuing the primary prompt. **Bash** terminates after waiting for that number of seconds if a complete line of input does not arrive.

TMPDIR

If set, **bash** uses its value as the name of a directory in which **bash** creates temporary files for the shell's use.

auto_resume

This variable controls how the shell interacts with the user and job control. If this variable is set, single word simple commands without redirections are treated as candidates for resumption of an existing stopped job. There is no ambiguity allowed; if there is more than one job beginning with the string typed, the job most recently accessed is selected. The *name* of a stopped job, in this context, is the command line used to start it. If set to the value *exact*, the string supplied must match the name of a stopped job exactly; if set to *substring*, the string supplied needs to match a substring of the name of a stopped job. The *substring* value provides functionality analogous to the **%?** job identifier (see **JOB CONTROL** below). If set to any other value, the supplied string must be a prefix of a stopped job's name; this provides functionality analogous to the **%string** job identifier.

histchars

The two or three characters which control history expansion and tokenization (see **HISTORY EXPANSION** below). The first character is the *history expansion* character, the character which signals the start of a history expansion, normally ‘!’. The second character is the *quick substitution* character, which is used as shorthand for re-running the previous command entered, substituting one string for another in the command. The default is ‘^’. The optional third character is the character which indicates that the remainder of the line is a comment when found as the first character of a word, normally ‘#’. The history comment character causes history substitution to be skipped for the remaining words on the line. It does not necessarily cause the shell parser to treat the rest of the line as a comment.

Arrays

Bash provides one-dimensional indexed and associative array variables. Any variable may be used as an indexed array; the **declare** builtin will explicitly declare an array. There is no maximum limit on the size of an array, nor any requirement that members be indexed or assigned contiguously. Indexed arrays are referenced using integers (including arithmetic expressions) and are zero-based; associative arrays are referenced using arbitrary strings. Unless otherwise noted, indexed array indices must be non-negative integers.

An indexed array is created automatically if any variable is assigned to using the syntax *name[subscript]=value*. The *subscript* is treated as an arithmetic expression that must evaluate to a number. To

explicitly declare an indexed array, use **declare -a name** (see **SHELL BUILTIN COMMANDS** below). **declare -a name[subscript]** is also accepted; the *subscript* is ignored.

Associative arrays are created using **declare -A name**.

Attributes may be specified for an array variable using the **declare** and **readonly** builtins. Each attribute applies to all members of an array.

Arrays are assigned to using compound assignments of the form *name*=(*value1* ... *valuen*), where each *value* may be of the form [subscript]=*string*. Indexed array assignments do not require anything but *string*. Each *value* in the list is expanded using all the shell expansions described below under **EXPANSION**. When assigning to indexed arrays, if the optional brackets and subscript are supplied, that index is assigned to; otherwise the index of the element assigned is the last index assigned to by the statement plus one. Indexing starts at zero.

When assigning to an associative array, the words in a compound assignment may be either assignment statements, for which the subscript is required, or a list of words that is interpreted as a sequence of alternating keys and values: *name*=(*key1 value1 key2 value2 ...*). These are treated identically to *name*=[*key1*]=*value1* [*key2*]=*value2* ...). The first word in the list determines how the remaining words are interpreted; all assignments in a list must be of the same type. When using key/value pairs, the keys may not be missing or empty; a final missing value is treated like the empty string.

This syntax is also accepted by the **declare** builtin. Individual array elements may be assigned to using the *name*[subscript]=*value* syntax introduced above. When assigning to an indexed array, if *name* is subscripted by a negative number, that number is interpreted as relative to one greater than the maximum index of *name*, so negative indices count back from the end of the array, and an index of -1 references the last element.

Any element of an array may be referenced using \${*name*[subscript]}. The braces are required to avoid conflicts with pathname expansion. If *subscript* is @ or *, the word expands to all members of *name*. These subscripts differ only when the word appears within double quotes. If the word is double-quoted, \${*name*[*]} expands to a single word with the value of each array member separated by the first character of the **IFS** special variable, and \${*name*@[]} expands each element of *name* to a separate word. When there are no array members, \${*name*@[]}} expands to nothing. If the double-quoted expansion occurs within a word, the expansion of the first parameter is joined with the beginning part of the original word, and the expansion of the last parameter is joined with the last part of the original word. This is analogous to the expansion of the special parameters * and @ (see **Special Parameters** above). \${#*name*[subscript]} expands to the length of \${*name*[subscript]}. If *subscript* is * or @, the expansion is the number of elements in the array. If the *subscript* used to reference an element of an indexed array evaluates to a number less than zero, it is interpreted as relative to one greater than the maximum index of the array, so negative indices count back from the end of the array, and an index of -1 references the last element.

Referencing an array variable without a subscript is equivalent to referencing the array with a subscript of 0. Any reference to a variable using a valid subscript is legal, and **bash** will create an array if necessary.

An array variable is considered set if a subscript has been assigned a value. The null string is a valid value.

It is possible to obtain the keys (indices) of an array as well as the values. \${!*name*@[]}} and \${!*name*[*]} expand to the indices assigned in array variable *name*. The treatment when in double quotes is similar to the expansion of the special parameters @ and * within double quotes.

The **unset** builtin is used to destroy arrays. **unset** *name*[subscript] destroys the array element at index *subscript*, for both indexed and associative arrays. Negative subscripts to indexed arrays are interpreted as described above. Unsetting the last element of an array variable does not unset the variable. **unset** *name*, where *name* is an array, or **unset** *name*[subscript], where *subscript* is * or @, removes the entire array.

When using a variable name with a subscript as an argument to a command, such as with **unset**, without using the word expansion syntax described above, the argument is subject to pathname expansion. If pathname expansion is not desired, the argument should be quoted.

The **declare**, **local**, and **readonly** builtins each accept a -a option to specify an indexed array and a -A option to specify an associative array. If both options are supplied, -A takes precedence. The **read** builtin

accepts a **-a** option to assign a list of words read from the standard input to an array. The **set** and **declare e** builtins display array values in a way that allows them to be reused as assignments.

EXPANSION

Expansion is performed on the command line after it has been split into words. There are seven kinds of expansion performed: *brace expansion*, *tilde expansion*, *parameter and variable expansion*, *command substitution*, *arithmetic expansion*, *word splitting*, and *pathname expansion*.

The order of expansions is: brace expansion; tilde expansion, parameter and variable expansion, arithmetic expansion, and command substitution (done in a left-to-right fashion); word splitting; and pathname expansion.

On systems that can support it, there is an additional expansion available: *process substitution*. This is performed at the same time as tilde, parameter, variable, and arithmetic expansion and command substitution.

After these expansions are performed, quote characters present in the original word are removed unless they have been quoted themselves (*quote removal*).

Only brace expansion, word splitting, and pathname expansion can increase the number of words of the expansion; other expansions expand a single word to a single word. The only exceptions to this are the expansions of "\$@" and "\${name[@]}", and, in most cases, \$* and \${name[*]} as explained above (see **PARAMETERS**).

Brace Expansion

Brace expansion is a mechanism by which arbitrary strings may be generated. This mechanism is similar to *pathname expansion*, but the filenames generated need not exist. Patterns to be brace expanded take the form of an optional *preamble*, followed by either a series of comma-separated strings or a sequence expression between a pair of braces, followed by an optional *postscript*. The preamble is prefixed to each string contained within the braces, and the postscript is then appended to each resulting string, expanding left to right.

Brace expansions may be nested. The results of each expanded string are not sorted; left to right order is preserved. For example, a{d,c,b}e expands into ‘ade ace abe’.

A sequence expression takes the form {*x..y[..incr]*}, where *x* and *y* are either integers or single characters, and *incr*, an optional increment, is an integer. When integers are supplied, the expression expands to each number between *x* and *y*, inclusive. Supplied integers may be prefixed with 0 to force each term to have the same width. When either *x* or *y* begins with a zero, the shell attempts to force all generated terms to contain the same number of digits, zero-padding where necessary. When characters are supplied, the expression expands to each character lexicographically between *x* and *y*, inclusive, using the default C locale. Note that both *x* and *y* must be of the same type. When the increment is supplied, it is used as the difference between each term. The default increment is 1 or -1 as appropriate.

Brace expansion is performed before any other expansions, and any characters special to other expansions are preserved in the result. It is strictly textual. **Bash** does not apply any syntactic interpretation to the context of the expansion or the text between the braces.

A correctly-formed brace expansion must contain unquoted opening and closing braces, and at least one unquoted comma or a valid sequence expression. Any incorrectly formed brace expansion is left unchanged. A { or , may be quoted with a backslash to prevent its being considered part of a brace expression. To avoid conflicts with parameter expansion, the string \${ is not considered eligible for brace expansion, and inhibits brace expansion until the closing }.

This construct is typically used as shorthand when the common prefix of the strings to be generated is longer than in the above example:

```
mkdir /usr/local/src/bash/{old,new,dist,bugs}
or
chown root /usr/{ucb/{ex,edit},lib/{ex?.?*,how_ex}}
```

Brace expansion introduces a slight incompatibility with historical versions of **sh**. **sh** does not treat opening or closing braces specially when they appear as part of a word, and preserves them in the output. **Bash**

removes braces from words as a consequence of brace expansion. For example, a word entered to **sh** as *file{1,2}* appears identically in the output. The same word is output as *file1 file2* after expansion by **bash**. If strict compatibility with **sh** is desired, start **bash** with the **+B** option or disable brace expansion with the **+B** option to the **set** command (see **SHELL BUILTIN COMMANDS** below).

Tilde Expansion

If a word begins with an unquoted tilde character (~), all of the characters preceding the first unquoted slash (or all characters, if there is no unquoted slash) are considered a *tilde-prefix*. If none of the characters in the tilde-prefix are quoted, the characters in the tilde-prefix following the tilde are treated as a possible *login name*. If this login name is the null string, the tilde is replaced with the value of the shell parameter **HOME**. If **HOME** is unset, the home directory of the user executing the shell is substituted instead. Otherwise, the tilde-prefix is replaced with the home directory associated with the specified login name.

If the tilde-prefix is a ~+, the value of the shell variable **PWD** replaces the tilde-prefix. If the tilde-prefix is a ~-, the value of the shell variable **OLDPWD**, if it is set, is substituted. If the characters following the tilde in the tilde-prefix consist of a number *N*, optionally prefixed by a + or a -, the tilde-prefix is replaced with the corresponding element from the directory stack, as it would be displayed by the **dirs** builtin invoked with the tilde-prefix as an argument. If the characters following the tilde in the tilde-prefix consist of a number without a leading + or -, + is assumed.

If the login name is invalid, or the tilde expansion fails, the word is unchanged.

Each variable assignment is checked for unquoted tilde-prefixes immediately following a : or the first =. In these cases, tilde expansion is also performed. Consequently, one may use filenames with tildes in assignments to **PATH**, **MAILPATH**, and **CDPATH**, and the shell assigns the expanded value.

Bash also performs tilde expansion on words satisfying the conditions of variable assignments (as described above under **PARAMETERS**) when they appear as arguments to simple commands. Bash does not do this, except for the *declaration* commands listed above, when in *posix mode*.

Parameter Expansion

The \$' character introduces parameter expansion, command substitution, or arithmetic expansion. The parameter name or symbol to be expanded may be enclosed in braces, which are optional but serve to protect the variable to be expanded from characters immediately following it which could be interpreted as part of the name.

When braces are used, the matching ending brace is the first '}' not escaped by a backslash or within a quoted string, and not within an embedded arithmetic expansion, command substitution, or parameter expansion.

\${parameter}

The value of *parameter* is substituted. The braces are required when *parameter* is a positional parameter with more than one digit, or when *parameter* is followed by a character which is not to be interpreted as part of its name. The *parameter* is a shell parameter as described above **PARAMETERS** or an array reference (**Arrays**).

If the first character of *parameter* is an exclamation point (!), and *parameter* is not a *nameref*, it introduces a level of indirection. **Bash** uses the value formed by expanding the rest of *parameter* as the new *parameter*; this is then expanded and that value is used in the rest of the expansion, rather than the expansion of the original *parameter*. This is known as *indirect expansion*. The value is subject to tilde expansion, parameter expansion, command substitution, and arithmetic expansion. If *parameter* is a *nameref*, this expands to the name of the parameter referenced by *parameter* instead of performing the complete indirect expansion. The exceptions to this are the expansions of \${!prefix*} and \${!name[@]} described below. The exclamation point must immediately follow the left brace in order to introduce indirection.

In each of the cases below, *word* is subject to tilde expansion, parameter expansion, command substitution, and arithmetic expansion.

When not performing substring expansion, using the forms documented below (e.g., :-), **bash** tests for a parameter that is unset or null. Omitting the colon results in a test only for a parameter that is unset.

`${parameter:-word}`

Use Default Values. If *parameter* is unset or null, the expansion of *word* is substituted. Otherwise, the value of *parameter* is substituted.

`${parameter:=word}`

Assign Default Values. If *parameter* is unset or null, the expansion of *word* is assigned to *parameter*. The value of *parameter* is then substituted. Positional parameters and special parameters may not be assigned to in this way.

`${parameter:?word}`

Display Error if Null or Unset. If *parameter* is null or unset, the expansion of *word* (or a message to that effect if *word* is not present) is written to the standard error and the shell, if it is not interactive, exits. Otherwise, the value of *parameter* is substituted.

`${parameter:+word}`

Use Alternate Value. If *parameter* is null or unset, nothing is substituted, otherwise the expansion of *word* is substituted.

`${parameter:offset}`

`${parameter:offset:length}`

Substring Expansion. Expands to up to *length* characters of the value of *parameter* starting at the character specified by *offset*. If *parameter* is @, an indexed array subscripted by @ or *, or an associative array name, the results differ as described below. If *length* is omitted, expands to the substring of the value of *parameter* starting at the character specified by *offset* and extending to the end of the value. *length* and *offset* are arithmetic expressions (see **ARITHMETIC EVALUATION** below).

If *offset* evaluates to a number less than zero, the value is used as an offset in characters from the end of the value of *parameter*. If *length* evaluates to a number less than zero, it is interpreted as an offset in characters from the end of the value of *parameter* rather than a number of characters, and the expansion is the characters between *offset* and that result. Note that a negative offset must be separated from the colon by at least one space to avoid being confused with the :- expansion.

If *parameter* is @, the result is *length* positional parameters beginning at *offset*. A negative *offset* is taken relative to one greater than the greatest positional parameter, so an offset of -1 evaluates to the last positional parameter. It is an expansion error if *length* evaluates to a number less than zero.

If *parameter* is an indexed array name subscripted by @ or *, the result is the *length* members of the array beginning with `${parameter[offset]}`. A negative *offset* is taken relative to one greater than the maximum index of the specified array. It is an expansion error if *length* evaluates to a number less than zero.

Substring expansion applied to an associative array produces undefined results.

Substring indexing is zero-based unless the positional parameters are used, in which case the indexing starts at 1 by default. If *offset* is 0, and the positional parameters are used, \$0 is prefixed to the list.

`${!prefix*}`

`${!prefix@}`

Names matching prefix. Expands to the names of variables whose names begin with *prefix*, separated by the first character of the IFS special variable. When @ is used and the expansion appears within double quotes, each variable name expands to a separate word.

`${!name[@]}`

`${!name[*]}`

List of array keys. If *name* is an array variable, expands to the list of array indices (keys) assigned in *name*. If *name* is not an array, expands to 0 if *name* is set and null otherwise. When @ is used and the expansion appears within double quotes, each key expands to a separate word.

`${#parameter}`

Parameter length. The length in characters of the value of *parameter* is substituted. If *parameter* is * or @, the value substituted is the number of positional parameters. If *parameter* is an array name subscripted by * or @, the value substituted is the number of elements in the array. If *parameter* is an indexed array name subscripted by a negative number, that number is interpreted as relative to one greater than the maximum index of *parameter*, so negative indices count back from the end of the array, and an index of -1 references the last element.

`${parameter##word}`
 `${parameter###word}`

Remove matching prefix pattern. The word *d* is expanded to produce a pattern just as in pathname expansion, and matched against the expanded value of *parameter* using the rules described under **Pattern Matching** below. If the pattern matches the beginning of the value of *parameter*, then the result of the expansion is the expanded value of *parameter* with the shortest matching pattern (the “#” case) or the longest matching pattern (the “##” case) deleted. If *parameter* is @ or *, the pattern removal operation is applied to each positional parameter in turn, and the expansion is the resultant list. If *parameter* is an array variable subscripted with @ or *, the pattern removal operation is applied to each member of the array in turn, and the expansion is the resultant list.

`${parameter%word}`
 `${parameter%%word}`

Remove matching suffix pattern. The word *d* is expanded to produce a pattern just as in pathname expansion, and matched against the expanded value of *parameter* using the rules described under **Pattern Matching** below. If the pattern matches a trailing portion of the expanded value of *parameter*, then the result of the expansion is the expanded value of *parameter* with the shortest matching pattern (the “%” case) or the longest matching pattern (the “%%” case) deleted. If *parameter* is @ or *, the pattern removal operation is applied to each positional parameter in turn, and the expansion is the resultant list. If *parameter* is an array variable subscripted with @ or *, the pattern removal operation is applied to each member of the array in turn, and the expansion is the resultant list.

`${parameter/pattern/string}`

Pattern substitution. The pattern is expanded to produce a pattern just as in pathname expansion, *Parameter* is expanded and the longest match of *pattern* against its value is replaced with *string*. The match is performed using the rules described under **Pattern Matching** below. If *pattern* begins with /, all matches of *pattern* are replaced with *string*. Normally only the first match is replaced. If *pattern* begins with #, it must match at the beginning of the expanded value of *parameter*. If *pattern* begins with %, it must match at the end of the expanded value of *parameter*. If *string* is null, matches of *pattern* are deleted and the / following *pattern* may be omitted. If the **nocasematch** shell option is enabled, the match is performed without regard to the case of alphabetic characters. If *parameter* is @ or *, the substitution operation is applied to each positional parameter in turn, and the expansion is the resultant list. If *parameter* is an array variable subscripted with @ or *, the substitution operation is applied to each member of the array in turn, and the expansion is the resultant list.

`${parameter^pattern}`
 `${parameter^^pattern}`
 `${parameter,,pattern}`
 `${parameter,,,pattern}`

Case modification. This expansion modifies the case of alphabetic characters in *parameter*. The *pattern* is expanded to produce a pattern just as in pathname expansion. Each character in the expanded value of *parameter* is tested against *pattern*, and, if it matches the pattern, its case is converted. The pattern should not attempt to match more than one character. The ^ operator converts lowercase letters matching *pattern* to uppercase; the , operator converts matching uppercase letters to lowercase. The ^^ and ,, expansions convert each matched character in the expanded value; the ^ and , expansions match and convert only the first character in the expanded value. If *pattern* is

omitted, it is treated like a ?, which matches every character. If *parameter* is @ or *, the case modification operation is applied to each positional parameter in turn, and the expansion is the resultant list. If *parameter* is an array variable subscripted with @ or *, the case modification operation is applied to each member of the array in turn, and the expansion is the resultant list.

`$(parameter@operator)`

Parameter transformation. The expansion is either a transformation of the value of *parameter* or information about *parameter* itself, depending on the value of *operator*. Each *operator* is a single letter:

- U** The expansion is a string that is the value of *parameter* with lowercase alphabetic characters converted to uppercase.
- u** The expansion is a string that is the value of *parameter* with the first character converted to uppercase, if it is alphabetic.
- L** The expansion is a string that is the value of *parameter* with uppercase alphabetic characters converted to lowercase.
- Q** The expansion is a string that is the value of *parameter* quoted in a format that can be reused as input.
- E** The expansion is a string that is the value of *parameter* with backslash escape sequences expanded as with the \$'...' quoting mechanism.
- P** The expansion is a string that is the result of expanding the value of *parameter* as if it were a prompt string (see **PROMPTING** below).
- A** The expansion is a string in the form of an assignment statement or **declare** command that, if evaluated, will recreate *parameter* with its attributes and value.
- K** Produces a possibly-quoted version of the value of *parameter*, except that it prints the values of indexed and associative arrays as a sequence of quoted key-value pairs (see **Arrays** above).
- a** The expansion is a string consisting of flag values representing *parameter*'s attributes.

If *parameter* is @ or *, the operation is applied to each positional parameter in turn, and the expansion is the resultant list. If *parameter* is an array variable subscripted with @ or *, the operation is applied to each member of the array in turn, and the expansion is the resultant list.

The result of the expansion is subject to word splitting and pathname expansion as described below.

Command Substitution

Command substitution allows the output of a command to replace the command name. There are two forms:

`$(command)`

or

``command``

Bash performs the expansion by executing *command* in a subshell environment and replacing the command substitution with the standard output of the command, with any trailing newlines deleted. Embedded newlines are not deleted, but they may be removed during word splitting. The command substitution `$(cat file)` can be replaced by the equivalent but faster `$(<file)`.

When the old-style backquote form of substitution is used, backslash retains its literal meaning except when followed by \$, ` , or \. The first backquote not preceded by a backslash terminates the command substitution. When using the `$(command)` form, all characters between the parentheses make up the command; none are treated specially.

Command substitutions may be nested. To nest when using the backquoted form, escape the inner backquotes with backslashes.

If the substitution appears within double quotes, word splitting and pathname expansion are not performed on the results.

Arithmetic Expansion

Arithmetic expansion allows the evaluation of an arithmetic expression and the substitution of the result. The format for arithmetic expansion is:

`$((expression))`

The old format `$[expression]` is deprecated and will be removed in upcoming versions of bash.

The *expression* is treated as if it were within double quotes, but a double quote inside the parentheses is not treated specially. All tokens in the expression undergo parameter and variable expansion, command substitution, and quote removal. The result is treated as the arithmetic expression to be evaluated. Arithmetic expansions may be nested.

The evaluation is performed according to the rules listed below under **ARITHMETIC EVALUATION**. If *expression* is invalid, **bash** prints a message indicating failure and no substitution occurs.

Process Substitution

Process substitution allows a process's input or output to be referred to using a filename. It takes the form of `<(list)` or `>(list)`. The *processlist* is run asynchronously, and its input or output appears as a filename. This filename is passed as an argument to the current command as the result of the expansion. If the `>(list)` form is used, writing to the file will provide input for *list*. If the `<(list)` form is used, the file passed as an argument should be read to obtain the output of *list*. Process substitution is supported on systems that support named pipes (*FIFOs*) or the `/dev/fd` method of naming open files.

When available, process substitution is performed simultaneously with parameter and variable expansion, command substitution, and arithmetic expansion.

Word Splitting

The shell scans the results of parameter expansion, command substitution, and arithmetic expansion that did not occur within double quotes for *word splitting*.

The shell treats each character of **IFS** as a delimiter, and splits the results of the other expansions into words using these characters as field terminators. If **IFS** is unset, or its value is exactly `<space><tab><newline>`, the default, then sequences of `<space>`, `<tab>`, and `<newline>` at the beginning and end of the results of the previous expansions are ignored, and any sequence of **IFS** characters not at the beginning or end serves to delimit words. If **IFS** has a value other than the default, then sequences of the whitespace characters **space**, **tab**, and **newline** are ignored at the beginning and end of the word, as long as the whitespace character is in the value of **IFS** (an **IFS** whitespace character). Any character in **IFS** that is not **IFS** whitespace, along with any adjacent **IFS** whitespace characters, delimits a field. A sequence of **IFS** whitespace characters is also treated as a delimiter. If the value of **IFS** is null, no word splitting occurs.

Explicit null arguments ("'" or '') are retained and passed to commands as empty strings. Unquoted implicit null arguments, resulting from the expansion of parameters that have no values, are removed. If a parameter with no value is expanded within double quotes, a null argument results and is retained and passed to a command as an empty string. When a quoted null argument appears as part of a word whose expansion is non-null, the null argument is removed. That is, the word `-d ''` becomes `-d` after word splitting and null argument removal.

Note that if no expansion occurs, no splitting is performed.

Pathname Expansion

After word splitting, unless the **-f** option has been set, **bash** scans each word for the characters *****, **?**, and **[**. If one of these characters appears, and is not quoted, then the word is regarded as a *pattern*, and replaced with an alphabetically sorted list of filenames matching the pattern (see **Pattern Matching** below). If no matching filenames are found, and the shell option **nullglob** is not enabled, the word is left unchanged. If the **nullglob** option is set, and no matches are found, the word is removed. If the **failglob** shell option is set, and no matches are found, an error message is printed and the command is not executed. If the shell option **nocaseglob** is enabled, the match is performed without regard to the case of alphabetic characters. Note that when using range expressions like `[a-z]` (see below), letters of the other case may be included, depending on the setting of **LC_COLLATE**. When a pattern is used for pathname expansion, the character `"."` at the start of a name or immediately following a slash must be matched explicitly, unless the shell

option **dotglob** is set. The filenames “.” and “..” must always be matched explicitly, even if **dotglob** is set. In other cases, the ‘‘.’’ character is not treated specially. When matching a pathname, the slash character must always be matched explicitly by a slash in the pattern, but in other matching contexts it can be matched by a special pattern character as described below under **Pattern Matching**. See the description of **shopt** below under **SHELL BUILTIN COMMANDS** for a description of the **nocaseglob**, **nullglob**, **failglob**, and **dotglob** shell options.

The **GLOBIGNORE** shell variable may be used to restrict the set of file names matching a *pattern*. If **GLOBIGNORE** is set, each matching file name that also matches one of the patterns in **GLOBIGNORE** is removed from the list of matches. If the **nocaseglob** option is set, the matching against the patterns in **GLOBIGNORE** is performed without regard to case. The filenames “.” and “..” are always ignored when **GLOBIGNORE** is set and not null. However, setting **GLOBIGNORE** to a non-null value has the effect of enabling the **dotglob** shell option, so all other filenames beginning with a “.” will match. To get the old behavior of ignoring filenames beginning with a “.”, make “.*” one of the patterns in **GLOBIGNORE**. The **dotglob** option is disabled when **GLOBIGNORE** is unset. The pattern matching honors the setting of the **extglob** shell option.

Pattern Matching

Any character that appears in a pattern, other than the special pattern characters described below, matches itself. The NUL character may not occur in a pattern. A backslash escapes the following character; the escaping backslash is discarded when matching. The special pattern characters must be quoted if they are to be matched literally.

The special pattern characters have the following meanings:

- * Matches any string, including the null string. When the **globstar** shell option is enabled, and * is used in a pathname expansion context, two adjacent *'s used as a single pattern will match all files and zero or more directories and subdirectories. If followed by a /, two adjacent *'s will match only directories and subdirectories.
- ? Matches any single character.
- [...] Matches any one of the enclosed characters. A pair of characters separated by a hyphen denotes a *range expression*; any character that falls between those two characters, inclusive, using the current locale's collating sequence and character set, is matched. If the first character following the [is a ! or a ^ then any character not enclosed is matched. The sorting order of characters in range expressions is determined by the current locale and the values of the **LC_COLLATE** or **LC_ALL** shell variables, if set. To obtain the traditional interpretation of range expressions, where [a-d] is equivalent to [abcd], set value of the **LC_ALL** shell variable to C, or enable the **globasciiranges** shell option. A – may be matched by including it as the first or last character in the set. A] may be matched by including it as the first character in the set.

Within [and], *character classes* can be specified using the syntax [:*class*:], where *class* is one of the following classes defined in the POSIX standard:

alnum alpha ascii blank cntrl digit graph lower print punct space upper word xdigit

A character class matches any character belonging to that class. The **word** character class matches letters, digits, and the character _.

Within [and], an *equivalence class* can be specified using the syntax [=c=], which matches all characters with the same collation weight (as defined by the current locale) as the character *c*.

Within [and], the syntax [.*symbol*.] matches the collating symbol *symbol*.

If the **extglob** shell option is enabled using the **shopt** builtin, several extended pattern matching operators are recognized. In the following description, a *pattern-list* is a list of one or more patterns separated by a |. Composite patterns may be formed using one or more of the following sub-patterns:

?(pattern-list)	Matches zero or one occurrence of the given patterns
*(pattern-list)	Matches zero or more occurrences of the given patterns
+(pattern-list)	Matches one or more occurrences of the given patterns
@(pattern-list)	Matches one of the given patterns
!(pattern-list)	Matches anything except one of the given patterns

Complicated extended pattern matching against long strings is slow, especially when the patterns contain alternations and the strings contain multiple matches. Using separate matches against shorter strings, or using arrays of strings instead of a single long string, may be faster.

Quote Removal

After the preceding expansions, all unquoted occurrences of the characters \, ', and " that did not result from one of the above expansions are removed.

REDIRECTION

Before a command is executed, its input and output may be *redirected* using a special notation interpreted by the shell. Redirection allows commands' file handles to be duplicated, opened, closed, made to refer to different files, and can change the files the command reads from and writes to. Redirection may also be used to modify file handles in the current shell execution environment. The following redirection operators may precede or appear anywhere within a *simple command* or may follow a *command*. Redirections are processed in the order they appear, from left to right.

Each redirection that may be preceded by a file descriptor number may instead be preceded by a word of the form {*varname*}. In this case, for each redirection operator except >&- and <&-, the shell will allocate a file descriptor greater than or equal to 10 and assign it to *varname*. If >&- or <&- is preceded by {*varname*}, the value of *varname* defines the file descriptor to close. If {*varname*} is supplied, the redirection persists beyond the scope of the command, allowing the shell programmer to manage the file descriptor himself.

In the following descriptions, if the file descriptor number is omitted, and the first character of the redirection operator is <, the redirection refers to the standard input (file descriptor 0). If the first character of the redirection operator is >, the redirection refers to the standard output (file descriptor 1).

The word following the redirection operator in the following descriptions, unless otherwise noted, is subjected to brace expansion, tilde expansion, parameter and variable expansion, command substitution, arithmetic expansion, quote removal, pathname expansion, and word splitting. If it expands to more than one word, **bash** reports an error.

Note that the order of redirections is significant. For example, the command

```
ls > dirlist 2>&1
```

directs both standard output and standard error to the file *dirlist*, while the command

```
ls 2>&1 > dirlist
```

directs only the standard output to file *dirlist*, because the standard error was duplicated from the standard output before the standard output was redirected to *dirlist*.

Bash handles several filenames specially when they are used in redirections, as described in the following table. If the operating system on which**bash** is running provides these special files, bash will use them; otherwise it will emulate them internally with the behavior described below.

/dev/fd/fd

If *fd* is a valid integer, file descriptor *fd* is duplicated.

/dev/stdin

File descriptor 0 is duplicated.

/dev/stdout

File descriptor 1 is duplicated.

/dev/stderr

File descriptor 2 is duplicated.

/dev/tcp/host/port

If *host* is a valid hostname or Internet address, and *port* is an integer port number or service name, **bash** attempts to open the corresponding TCP socket.

/dev/udp/host/port

If *host* is a valid hostname or Internet address, and *port* is an integer port number or service name, **bash** attempts to open the corresponding UDP socket.

A failure to open or create a file causes the redirection to fail.

Redirections using file descriptors greater than 9 should be used with care, as they may conflict with file descriptors the shell uses internally.

Note that the **exec** builtin command can make redirections take effect in the current shell.

Redirecting Input

Redirection of input causes the file whose name results from the expansion of *word* to be opened for reading on file descriptor *n*, or the standard input (file descriptor 0) if *n* is not specified.

The general format for redirecting input is:

[n]<word

Redirecting Output

Redirection of output causes the file whose name results from the expansion of *word* to be opened for writing on file descriptor *n*, or the standard output (file descriptor 1) if *n* is not specified. If the file does not exist it is created; if it does exist it is truncated to zero size.

The general format for redirecting output is:

[n]>word

If the redirection operator is **>**, and the **noclobber** option to the **set** builtin has been enabled, the redirection will fail if the file whose name results from the expansion of *word* exists and is a regular file. If the redirection operator is **>|**, or the redirection operator is **>** and the **noclobber** option to the **set** builtin command is not enabled, the redirection is attempted even if the file named by *word* exists.

Appending Redirected Output

Redirection of output in this fashion causes the file whose name results from the expansion of *word* to be opened for appending on file descriptor *n*, or the standard output (file descriptor 1) if *n* is not specified. If the file does not exist it is created.

The general format for appending output is:

[n]>>word

Redirecting Standard Output and Standard Error

This construct allows both the standard output (file descriptor 1) and the standard error output (file descriptor 2) to be redirected to the file whose name is the expansion of *word*.

There are two formats for redirecting standard output and standard error:

&>word

and

>&word

Of the two forms, the first is preferred. This is semantically equivalent to

>word 2>&1

When using the second form, *word* may not expand to a number or **-**. If it does, other redirection operators

apply (see **Duplicating File Descriptors** below) for compatibility reasons.

Appending Standard Output and Standard Error

This construct allows both the standard output (file descriptor 1) and the standard error output (file descriptor 2) to be appended to the file whose name is the expansion of *word*.

The format for appending standard output and standard error is:

&>>word

This is semantically equivalent to

>>word 2>&1

(see **Duplicating File Descriptors** below).

Here Documents

This type of redirection instructs the shell to read input from the current source until a line containing only *delimiter* (with no trailing blanks) is seen. All of the lines read up to that point are then used as the standard input (or file descriptor *n* if *n* is specified) for a command.

The format of here-documents is:

[*n*]<<[−]word
here-document
delimiter

No parameter and variable expansion, command substitution, arithmetic expansion, or pathname expansion is performed on *word*. If any part of *word* is quoted, the *delimiter* is the result of quote removal on *word*, and the lines in the here-document are not expanded. If *word* is unquoted, all lines of the here-document are subjected to parameter expansion, command substitution, and arithmetic expansion, the character sequence <newline> is ignored, and \ must be used to quote the characters \, \$, and `.

If the redirection operator is <<-, then all leading tab characters are stripped from input lines and the line containing *delimiter*. This allows here-documents within shell scripts to be indented in a natural fashion.

Here Strings

A variant of here documents, the format is:

[*n*]<<<*word*

The *word* undergoes tilde expansion, parameter and variable expansion, command substitution, arithmetic expansion, and quote removal. Pathname expansion and word splitting are not performed. The result is supplied as a single string, with a newline appended, to the command on its standard input (or file descriptor *n* if *n* is specified).

Duplicating File Descriptors

The redirection operator

[*n*]<&*word*

is used to duplicate input file descriptors. If *word* expands to one or more digits, the file descriptor denoted by *n* is made to be a copy of that file descriptor. If the digits in *word* do not specify a file descriptor open for input, a redirection error occurs. If *word* evaluates to −, file descriptor *n* is closed. If *n* is not specified, the standard input (file descriptor 0) is used.

The operator

[*n*]>&*word*

is used similarly to duplicate output file descriptors. If *n* is not specified, the standard output (file descriptor 1) is used. If the digits in *word* do not specify a file descriptor open for output, a redirection error occurs. If *word* evaluates to −, file descriptor *n* is closed. As a special case, if *n* is omitted, and *word* does not expand to one or more digits or −, the standard output and standard error are redirected as described previously.

Moving File Descriptors

The redirection operator

`[n]<&digit-`

moves the file descriptor *digit* to file descriptor *n*, or the standard input (file descriptor 0) if *n* is not specified. *digit* is closed after being duplicated to *n*.

Similarly, the redirection operator

`[n]>&digit-`

moves the file descriptor *digit* to file descriptor *n*, or the standard output (file descriptor 1) if *n* is not specified.

Opening File Descriptors for Reading and Writing

The redirection operator

`[n]<>word`

causes the file whose name is the expansion of *word* to be opened for both reading and writing on file descriptor *n*, or on file descriptor 0 if *n* is not specified. If the file does not exist, it is created.

ALIASES

Aliases allow a string to be substituted for a word when it is used as the first word of a simple command. The shell maintains a list of aliases that may be set and unset with the **alias** and **unalias** builtin commands (see **SHELL BUILTIN COMMANDS** below). The first word of each simple command, if unquoted, is checked to see if it has an alias. If so, that word is replaced by the text of the alias. The characters /, \$, `, and = and any of the shell *metacharacters* or quoting characters listed above may not appear in an alias name. The replacement text may contain any valid shell input, including shell metacharacters. The first word of the replacement text is tested for aliases, but a word that is identical to an alias being expanded is not expanded a second time. This means that one may alias **ls** to **ls -F**, for instance, and **bash** does not try to recursively expand the replacement text. If the last character of the alias value is a *blank*, then the next command word following the alias is also checked for alias expansion.

Aliases are created and listed with the **alias** command, and removed with the **unalias** command.

There is no mechanism for using arguments in the replacement text. If arguments are needed, a shell function should be used (see **FUNCTIONS** below).

Aliases are not expanded when the shell is not interactive, unless the **expand_aliases** shell option is set using **shopt** (see the description of **shopt** under **SHELL BUILTIN COMMANDS** below).

The rules concerning the definition and use of aliases are somewhat confusing. **Bash** always reads at least one complete line of input, and all lines that make up a compound command, before executing any of the commands on that line or the compound command. Aliases are expanded when a command is read, not when it is executed. Therefore, an alias definition appearing on the same line as another command does not take effect until the next line of input is read. The commands following the alias definition on that line are not affected by the new alias. This behavior is also an issue when functions are executed. Aliases are expanded when a function definition is read, not when the function is executed, because a function definition is itself a command. As a consequence, aliases defined in a function are not available until after that function is executed. To be safe, always put alias definitions on a separate line, and do not use **alias** in compound commands.

For almost every purpose, aliases are superseded by shell functions.

FUNCTIONS

A shell function, defined as described above under **SHELL GRAMMAR**, stores a series of commands for later execution. When the name of a shell function is used as a simple command name, the list of commands associated with that function name is executed. Functions are executed in the context of the current shell; no new process is created to interpret them (contrast this with the execution of a shell script). When a function is executed, the arguments to the function become the positional parameters during its execution. The special parameter # is updated to reflect the change. Special parameter 0 is unchanged. The first

element of the **FUNCNAME** variable is set to the name of the function while the function is executing.

All other aspects of the shell execution environment are identical between a function and its caller with these exceptions: the **DEBUG** and **RETURN** traps (see the description of the **trap** builtin under **SHELL BUILTIN COMMANDS** below) are not inherited unless the function has been given the **trace** attribute (see the description of the **declare** builtin below) or the **-o functrace** shell option has been enabled with the **set** builtin (in which case all functions inherit the **DEBUG** and **RETURN** traps), and the **ERR** trap is not inherited unless the **-o errtrace** shell option has been enabled.

Variables local to the function may be declared with the **local** builtin command. Ordinarily, variables and their values are shared between the function and its caller. If a variable is declared **local**, the variable's visible scope is restricted to that function and its children (including the functions it calls). Local variables "shadow" variables with the same name declared at previous scopes. For instance, a local variable declared in a function hides a global variable of the same name: references and assignments refer to the local variable, leaving the global variable unmodified. When the function returns, the global variable is once again visible.

The shell uses *dynamic scoping* to control a variable's visibility within functions. With dynamic scoping, visible variables and their values are a result of the sequence of function calls that caused execution to reach the current function. The value of a variable that a function sees depends on its value within its caller, if any, whether that caller is the "global" scope or another shell function. This is also the value that a local variable declaration "shadows", and the value that is restored when the function returns.

For example, if a variable *var* is declared as local in function *func1*, and *func1* calls another function *func2*, references to *var* made from within *func2* will resolve to the local variable *var* from *func1*, shadowing any global variable named *var*.

The **unset** builtin also acts using the same dynamic scope: if a variable is local to the current scope, **unset** will unset it; otherwise the **unset** will refer to the variable found in any calling scope as described above. If a variable at the current local scope is unset, it will remain so until it is reset in that scope or until the function returns. Once the function returns, any instance of the variable at a previous scope will become visible. If the **unset** acts on a variable at a previous scope, any instance of a variable with that name that had been shadowed will become visible.

The **FUNCNEST** variable, if set to a numeric value greater than 0, defines a maximum function nesting level. Function invocations that exceed the limit cause the entire command to abort.

If the builtin command **return** is executed in a function, the function completes and execution resumes with the next command after the function call. Any command associated with the **RETURN** trap is executed before execution resumes. When a function completes, the values of the positional parameters and the special parameter **#** are restored to the values they had prior to the function's execution.

Function names and definitions may be listed with the **-f** option to the **declare** or **typeset** builtin commands. The **-F** option to **declare** or **typeset** will list the function names only (and optionally the source file and line number, if the **extdebug** shell option is enabled). Functions may be exported so that subshells automatically have them defined with the **-f** option to the **export** builtin. A function definition may be deleted using the **-f** option to the **unset** builtin.

Functions may be recursive. The **FUNCNEST** variable may be used to limit the depth of the function call stack and restrict the number of function invocations. By default, no limit is imposed on the number of recursive calls.

ARITHMETIC EVALUATION

The shell allows arithmetic expressions to be evaluated, under certain circumstances (see the **let** and **declare** builtin commands, the **((** compound command, and **Arithmetic Expansion**). Evaluation is done in fixed-width integers with no check for overflow, though division by 0 is trapped and flagged as an error. The operators and their precedence, associativity, and values are the same as in the C language. The following list of operators is grouped into levels of equal-precedence operators. The levels are listed in order of decreasing precedence.

```

id++ id--           variable post-increment and post-decrement
- +      unary minus and plus
++id --id       variable pre-increment and pre-decrement
! ~      logical and bitwise negation
**      exponentiation
* / %   multiplication, division, remainder
+ -     addition, subtraction
<< >>  left and right bitwise shifts
<= >= < >    comparison
== !=   equality and inequality
&      bitwise AND
^      bitwise exclusive OR
|      bitwise OR
&&    logical AND
||      logical OR
expr?expr:expr  conditional operator
= *= /= %= += -= <<= >>= &= ^= |==
               assignment
expr1,expr2  comma

```

Shell variables are allowed as operands; parameter expansion is performed before the expression is evaluated. Within an expression, shell variables may also be referenced by name without using the parameter expansion syntax. A shell variable that is null or unset evaluates to 0 when referenced by name without using the parameter expansion syntax. The value of a variable is evaluated as an arithmetic expression when it is referenced, or when a variable which has been given the *integer* attribute using **declare -i** is assigned a value. A null value evaluates to 0. A shell variable need not have its *integer* attribute turned on to be used in an expression.

Integer constants follow the C language definition, without suffixes or character constants. Constants with a leading 0 are interpreted as octal numbers. A leading 0x or 0X denotes hexadecimal. Otherwise, numbers take the form [*base*#]*n*, where the optional *base* is a decimal number between 2 and 64 representing the arithmetic base, and *n* is a number in that base. If *base*# is omitted, then base 10 is used. When specifying *n*, if a non-digit is required, the digits greater than 9 are represented by the lowercase letters, the uppercase letters, @, and _, in that order. If *base* is less than or equal to 36, lowercase and uppercase letters may be used interchangeably to represent numbers between 10 and 35.

Operators are evaluated in order of precedence. Sub-expressions in parentheses are evaluated first and may override the precedence rules above.

CONDITIONAL EXPRESSIONS

Conditional expressions are used by the [[compound command and the **test** and [builtin commands to test file attributes and perform string and arithmetic comparisons. The **test** and [commands determine their behavior based on the number of arguments; see the descriptions of those commands for any other command-specific actions.

Expressions are formed from the following unary or binary primaries. **Bash** handles several filenames specially when they are used in expressions. If the operating system on which **bash** is running provides these special files, **bash** will use them; otherwise it will emulate them internally with this behavior: If any *file* argument to one of the primaries is of the form */dev/fd/n*, then file descriptor *n* is checked. If the *file* argument to one of the primaries is one of */dev/stdin*, */dev/stdout*, or */dev/stderr*, file descriptor 0, 1, or 2, respectively, is checked.

Unless otherwise specified, primaries that operate on files follow symbolic links and operate on the target

of the link, rather than the link itself.

When used with [[, the < and > operators sort lexicographically using the current locale. The **test** command sorts using ASCII ordering.

- a** *file* True if *file* exists.
- b** *file* True if *file* exists and is a block special file.
- c** *file* True if *file* exists and is a character special file.
- d** *file* True if *file* exists and is a directory.
- e** *file* True if *file* exists.
- f** *file* True if *file* exists and is a regular file.
- g** *file* True if *file* exists and is set-group-id.
- h** *file* True if *file* exists and is a symbolic link.
- k** *file* True if *file* exists and its “sticky” bit is set.
- p** *file* True if *file* exists and is a named pipe (FIFO).
- r** *file* True if *file* exists and is readable.
- s** *file* True if *file* exists and has a size greater than zero.
- t** *fd* True if file descriptor *fd* is open and refers to a terminal.
- u** *file* True if *file* exists and its set-user-id bit is set.
- w** *file* True if *file* exists and is writable.
- x** *file* True if *file* exists and is executable.
- G** *file* True if *file* exists and is owned by the effective group id.
- L** *file* True if *file* exists and is a symbolic link.
- N** *file* True if *file* exists and has been modified since it was last read.
- O** *file* True if *file* exists and is owned by the effective user id.
- S** *file* True if *file* exists and is a socket.
- file1* -ef *file2*** True if *file1* and *file2* refer to the same device and inode numbers.
- file1* -nt *file2*** True if *file1* is newer (according to modification date) than *file2*, or if *file1* exists and *file2* does not.
- file1* -ot *file2*** True if *file1* is older than *file2*, or if *file2* exists and *file1* does not.
- o** *optname* True if the shell option *optname* is enabled. See the list of options under the description of the **-o** option to the **set** builtin below.
- v** *varname* True if the shell variable *varname* is set (has been assigned a value).
- R** *varname* True if the shell variable *varname* is set and is a name reference.
- z** *string* True if the length of *string* is zero.
- string***
- n** *string* True if the length of *string* is non-zero.
- string1* == *string2***
- string1* = *string2*** True if the strings are equal. = should be used with the **test** command for POSIX conformance. When used with the [[command, this performs pattern matching as described above (**Compound Commands**)).
- string1* != *string2*** True if the strings are not equal.
- string1* < *string2*** True if *string1* sorts before *string2* lexicographically.

string1 > string2

True if *string1* sorts after *string2* lexicographically.

arg1 OP arg2

OP is one of **-eq**, **-ne**, **-lt**, **-le**, **-gt**, or **-ge**. These arithmetic binary operators return true if *arg1* is equal to, not equal to, less than, less than or equal to, greater than, or greater than or equal to *arg2*, respectively. *Arg1* and *arg2* may be positive or negative integers. When used with the [[command, *Arg1* and *Arg2* are evaluated as arithmetic expressions (see **ARITHMETIC EVALUATION** above).

SIMPLE COMMAND EXPANSION

When a simple command is executed, the shell performs the following expansions, assignments, and redirections, from left to right, in the following order.

1. The words that the parser has marked as variable assignments (those preceding the command name) and redirections are saved for later processing.
2. The words that are not variable assignments or redirections are expanded. If any words remain after expansion, the first word is taken to be the name of the command and the remaining words are the arguments.
3. Redirections are performed as described above under **REDIRECTION**.
4. The text after the = in each variable assignment undergoes tilde expansion, parameter expansion, command substitution, arithmetic expansion, and quote removal before being assigned to the variable.

If no command name results, the variable assignments affect the current shell environment. Otherwise, the variables are added to the environment of the executed command and do not affect the current shell environment. If any of the assignments attempts to assign a value to a readonly variable, an error occurs, and the command exits with a non-zero status.

If no command name results, redirections are performed, but do not affect the current shell environment. A redirection error causes the command to exit with a non-zero status.

If there is a command name left after expansion, execution proceeds as described below. Otherwise, the command exits. If one of the expansions contained a command substitution, the exit status of the command is the exit status of the last command substitution performed. If there were no command substitutions, the command exits with a status of zero.

COMMAND EXECUTION

After a command has been split into words, if it results in a simple command and an optional list of arguments, the following actions are taken.

If the command name contains no slashes, the shell attempts to locate it. If there exists a shell function by that name, that function is invoked as described above in **FUNCTIONS**. If the name does not match a function, the shell searches for it in the list of shell builtins. If a match is found, that builtin is invoked.

If the name is neither a shell function nor a builtin, and contains no slashes, **bash** searches each element of the **PATH** for a directory containing an executable file by that name. **Bash** uses a hash table to remember the full pathnames of executable files (see **hash** under **SHELL BUILTIN COMMANDS** below). A full search of the directories in **PATH** is performed only if the command is not found in the hash table. If the search is unsuccessful, the shell searches for a defined shell function named **command_not_found_handle**. If that function exists, it is invoked in a separate execution environment with the original command and the original command's arguments as its arguments, and the function's exit status becomes the exit status of that subshell. If that function is not defined, the shell prints an error message and returns an exit status of 127.

If the search is successful, or if the command name contains one or more slashes, the shell executes the named program in a separate execution environment. Argument 0 is set to the name given, and the remaining arguments to the command are set to the arguments given, if any.

If this execution fails because the file is not in executable format, and the file is not a directory, it is

assumed to be a *shell script*, a file containing shell commands. A subshell is spawned to execute it. This subshell reinitializes itself, so that the effect is as if a new shell had been invoked to handle the script, with the exception that the locations of commands remembered by the parent (see **hash** below under **SHELL BUILTIN COMMANDS**) are retained by the child.

If the program is a file beginning with **#!**, the remainder of the first line specifies an interpreter for the program. The shell executes the specified interpreter on operating systems that do not handle this executable format themselves. The arguments to the interpreter consist of a single optional argument following the interpreter name on the first line of the program, followed by the name of the program, followed by the command arguments, if any.

COMMAND EXECUTION ENVIRONMENT

The shell has an *execution environment*, which consists of the following:

- open files inherited by the shell at invocation, as modified by redirections supplied to the **exec** builtin
- the current working directory as set by **cd**, **pushd**, or **popd**, or inherited by the shell at invocation
- the file creation mode mask as set by **umask** or inherited from the shell's parent
- current traps set by **trap**
- shell parameters that are set by variable assignment or with **set** or inherited from the shell's parent in the environment
- shell functions defined during execution or inherited from the shell's parent in the environment
- options enabled at invocation (either by default or with command-line arguments) or by **set**
- options enabled by **shopt**
- shell aliases defined with **alias**
- various process IDs, including those of background jobs, the value of **\$\$**, and the value of **PPID**

When a simple command other than a builtin or shell function is to be executed, it is invoked in a separate execution environment that consists of the following. Unless otherwise noted, the values are inherited from the shell.

- the shell's open files, plus any modifications and additions specified by redirections to the command
- the current working directory
- the file creation mode mask
- shell variables and functions marked for export, along with variables exported for the command, passed in the environment
- traps caught by the shell are reset to the values inherited from the shell's parent, and traps ignored by the shell are ignored

A command invoked in this separate environment cannot affect the shell's execution environment.

Command substitution, commands grouped with parentheses, and asynchronous commands are invoked in a subshell environment that is a duplicate of the shell environment, except that traps caught by the shell are reset to the values that the shell inherited from its parent at invocation. Builtin commands that are invoked as part of a pipeline are also executed in a subshell environment. Changes made to the subshell environment cannot affect the shell's execution environment.

Subshells spawned to execute command substitutions inherit the value of the **-e** option from the parent shell. When not in *posix mode*, **bash** clears the **-e** option in such subshells.

If a command is followed by a **&** and job control is not active, the default standard input for the command is the empty file **/dev/null**. Otherwise, the invoked command inherits the file descriptors of the calling shell as modified by redirections.

ENVIRONMENT

When a program is invoked it is given an array of strings called the *environment*. This is a list of *name=value* pairs, of the form *name=value*.

The shell provides several ways to manipulate the environment. On invocation, the shell scans its own environment and creates a parameter for each name found, automatically marking it for *export* to child processes. Executed commands inherit the environment. The **export** and **declare -x** commands allow parameters and functions to be added to and deleted from the environment. If the value of a parameter in the environment is modified, the new value becomes part of the environment, replacing the old. The environment inherited by any executed command consists of the shell's initial environment, whose values may be modified in the shell, less any pairs removed by the **unset** command, plus any additions via the **export** and **declare -x** commands.

The environment for any *simple command* or function may be augmented temporarily by prefixing it with parameter assignments, as described above in **PARAMETERS**. These assignment statements affect only the environment seen by that command.

If the **-k** option is set (see the **set** builtin command below), then *all* parameter assignments are placed in the environment for a command, not just those that precede the command name.

When **bash** invokes an external command, the variable **_** is set to the full filename of the command and passed to that command in its environment.

EXIT STATUS

The exit status of an executed command is the value returned by the *waitpid* system call or equivalent function. Exit statuses fall between 0 and 255, though, as explained below, the shell may use values above 125 specially. Exit statuses from shell builtins and compound commands are also limited to this range. Under certain circumstances, the shell will use special values to indicate specific failure modes.

For the shell's purposes, a command which exits with a zero exit status has succeeded. An exit status of zero indicates success. A non-zero exit status indicates failure. When a command terminates on a fatal signal *N*, **bash** uses the value of 128+*N* as the exit status.

If a command is not found, the child process created to execute it returns a status of 127. If a command is found but is not executable, the return status is 126.

If a command fails because of an error during expansion or redirection, the exit status is greater than zero.

Shell builtin commands return a status of 0 (*true*) if successful, and non-zero (*false*) if an error occurs while they execute. All builtins return an exit status of 2 to indicate incorrect usage, generally invalid options or missing arguments.

Bash itself returns the exit status of the last command executed, unless a syntax error occurs, in which case it exits with a non-zero value. See also the **exit** builtin command below.

SIGNALS

When **bash** is interactive, in the absence of any traps, it ignores **SIGTERM** (so that **kill 0** does not kill an interactive shell), and **SIGINT** is caught and handled (so that the **wait** builtin is interruptible). In all cases, **bash** ignores **SIGQUIT**. If job control is in effect, **bash** ignores **SIGTTIN**, **SIGTTOU**, and **SIGTSTP**.

Non-builtin commands run by **bash** have signal handlers set to the values inherited by the shell from its parent. When job control is not in effect, asynchronous commands ignore **SIGINT** and **SIGQUIT** in addition to these inherited handlers. Commands run as a result of command substitution ignore the keyboard-generated job control signals **SIGTTIN**, **SIGTTOU**, and **SIGTSTP**.

The shell exits by default upon receipt of a **SIGHUP**. Before exiting, an interactive shell resends the **SIGHUP** to all jobs, running or stopped. Stopped jobs are sent **SIGCONT** to ensure that they receive the **SIGHUP**. To prevent the shell from sending the signal to a particular job, it should be removed from the jobs table with the **disown** builtin (see **SHELL BUILTIN COMMANDS** below) or marked to not receive **SIGHUP** using **disown -h**.

If the **huponexit** shell option has been set with **shopt**, **bash** sends a **SIGHUP** to all jobs when an interactive login shell exits.

If **bash** is waiting for a command to complete and receives a signal for which a trap has been set, the trap will not be executed until the command completes. When **bash** is waiting for an asynchronous command via the **wait** builtin, the reception of a signal for which a trap has been set will cause the **wait** builtin to return immediately with an exit status greater than 128, immediately after which the trap is executed.

JOB CONTROL

Job control refers to the ability to selectively stop (*suspend*) the execution of processes and continue (*resume*) their execution at a later point. A user typically employs this facility via an interactive interface supplied jointly by the operating system kernel's terminal driver and **bash**.

The shell associates a *job* with each pipeline. It keeps a table of currently executing jobs, which may be listed with the **jobs** command. When **bash** starts a job asynchronously (in the *background*), it prints a line that looks like:

```
[1] 25647
```

indicating that this job is job number 1 and that the process ID of the last process in the pipeline associated with this job is 25647. All of the processes in a single pipeline are members of the same job. **Bash** uses the *job* abstraction as the basis for job control.

To facilitate the implementation of the user interface to job control, the operating system maintains the notion of a *current terminal process group ID*. Members of this process group (processes whose process group ID is equal to the current terminal process group ID) receive keyboard-generated signals such as **SIGINT**. These processes are said to be in the *foreground*. *Background* processes are those whose process group ID differs from the terminal's; such processes are immune to keyboard-generated signals. Only foreground processes are allowed to read from or, if the user so specifies with **stty tostop**, write to the terminal. Background processes which attempt to read from (write to when **stty tostop** is in effect) the terminal are sent a **SIGTTIN** (**SIGTTOU**) signal by the kernel's terminal driver, which, unless caught, suspends the process.

If the operating system on which **bash** is running supports job control, **bash** contains facilities to use it. Typing the *suspend* character (typically **^Z**, Control-Z) while a process is running causes that process to be stopped and returns control to **bash**. Typing the *delayed suspend* character (typically **^Y**, Control-Y) causes the process to be stopped when it attempts to read input from the terminal, and control to be returned to **bash**. The user may then manipulate the state of this job, using the **bg** command to continue it in the background, the **fg** command to continue it in the foreground, or the **kill** command to kill it. A **^Z** takes effect immediately, and has the additional side effect of causing pending output and typeahead to be discarded.

There are a number of ways to refer to a job in the shell. The character **%** introduces a job specification (*jobspec*). Job number *n* may be referred to as **%n**. A job may also be referred to using a prefix of the name used to start it, or using a substring that appears in its command line. For example, **%ce** refers to a stopped job whose command name begins with **ce**. If a prefix matches more than one job, **bash** reports an error. Using **%?ce**, on the other hand, refers to any job containing the string **ce** in its command line. If the substring matches more than one job, **bash** reports an error. The symbols **%%** and **%+** refer to the shell's notion of the *current job*, which is the last job stopped while it was in the foreground or started in the background. The *previous job* may be referenced using **%-**. If there is only a single job, **%+** and **%-** can both be used to refer to that job. In output pertaining to jobs (e.g., the output of the **jobs** command), the current job is always flagged with a **+**, and the previous job with a **-**. A single **%** (with no accompanying job specification) also refers to the current job.

Simply naming a job can be used to bring it into the foreground: **%1** is a synonym for "**fg %1**", bringing job 1 from the background into the foreground. Similarly, "**%1 &**" resumes job 1 in the background, equivalent to "**bg %1**".

The shell learns immediately whenever a job changes state. Normally, **bash** waits until it is about to print a prompt before reporting changes in a job's status so as to not interrupt any other output. If the **-b** option to the **set** builtin command is enabled, **bash** reports such changes immediately. Any trap on **SIGCHLD** is executed for each child that exits.

If an attempt to exit **bash** is made while jobs are stopped (or, if the **checkjobs** shell option has been enabled using the **shopt** builtin, running), the shell prints a warning message, and, if the **checkjobs** option is enabled, lists the jobs and their statuses. The **jobs** command may then be used to inspect their status. If a second attempt to exit is made without an intervening command, the shell does not print another warning, and any stopped jobs are terminated.

When the shell is waiting for a job or process using the **wait** builtin, and job control is enabled, **wait** will return when the job changes state. The **-f** option causes **wait** to wait until the job or process terminates before returning.

PROMPTING

When executing interactively, **bash** displays the primary prompt **PS1** when it is ready to read a command, and the secondary prompt **PS2** when it needs more input to complete a command. **Bash** displays **PS0** after it reads a command but before executing it. **Bash** displays **PS4** as described above before tracing each command when the **-x** option is enabled. **Bash** allows these prompt strings to be customized by inserting a number of backslash-escaped special characters that are decoded as follows:

\a	an ASCII bell character (07)
\d	the date in "Weekday Month Date" format (e.g., "Tue May 26")
\D{format}	the <i>format</i> is passed to <i>strftime(3)</i> and the result is inserted into the prompt string; an empty <i>format</i> results in a locale-specific time representation. The braces are required
\e	an ASCII escape character (033)
\h	the hostname up to the first ‘:’
\H	the hostname
\j	the number of jobs currently managed by the shell
\l	the basename of the shell’s terminal device name
\n	newline
\r	carriage return
\s	the name of the shell, the basename of \$0 (the portion following the final slash)
\t	the current time in 24-hour HH:MM:SS format
\T	the current time in 12-hour HH:MM:SS format
\@	the current time in 12-hour am/pm format
\A	the current time in 24-hour HH:MM format
\u	the username of the current user
\v	the version of bash (e.g., 2.00)
\V	the release of bash , version + patch level (e.g., 2.00.0)
\w	the current working directory, with \$HOME abbreviated with a tilde (uses the value of the PROMPT_DIRTRIM variable)
\W	the basename of the current working directory, with \$HOME abbreviated with a tilde
\!	the history number of this command
\#	the command number of this command
\\$	if the effective UID is 0, a #, otherwise a \$
\nnn	the character corresponding to the octal number <i>nnn</i>
\\\	a backslash
\[begin a sequence of non-printing characters, which could be used to embed a terminal control sequence into the prompt
\]	end a sequence of non-printing characters

The command number and the history number are usually different: the history number of a command is its position in the history list, which may include commands restored from the history file (see **HISTORY** below), while the command number is the position in the sequence of commands executed during the current shell session. After the string is decoded, it is expanded via parameter expansion, command substitution, arithmetic expansion, and quote removal, subject to the value of the **promptvars** shell option (see the description of the **shopt** command under **SHELL BUILTIN COMMANDS** below). This can have unwanted side effects if escaped portions of the string appear within command substitution or contain characters special to word expansion.

READLINE

This is the library that handles reading input when using an interactive shell, unless the **--noediting** option is given at shell invocation. Line editing is also used when using the **-e** option to the **read** builtin. By default, the line editing commands are similar to those of Emacs. A vi-style line editing interface is also available. Line editing can be enabled at any time using the **-o emacs** or **-o vi** options to the **set** builtin (see **SHELL BUILTIN COMMANDS** below). To turn off line editing after the shell is running, use the **+o emacs** or **+o vi** options to the **set** builtin.

Readline Notation

In this section, the Emacs-style notation is used to denote keystrokes. Control keys are denoted by C-key, e.g., C-n means Control-N. Similarly, *meta* keys are denoted by M-key, so M-x means Meta-X. (On keyboards without a *meta* key, M-x means ESC x, i.e., press the Escape key then the x key. This makes ESC the *meta prefix*. The combination M-C-x means ESC-Control-x, or press the Escape key then hold the Control key while pressing the x key.)

Readline commands may be given numeric *arguments*, which normally act as a repeat count. Sometimes, however, it is the sign of the argument that is significant. Passing a negative argument to a command that acts in the forward direction (e.g., **kill-line**) causes that command to act in a backward direction. Commands whose behavior with arguments deviates from this are noted below.

When a command is described as *killing* text, the text deleted is saved for possible future retrieval (*yanking*). The killed text is saved in a *kill ring*. Consecutive kills cause the text to be accumulated into one unit, which can be yanked all at once. Commands which do not kill text separate the chunks of text on the kill ring.

Readline Initialization

Readline is customized by putting commands in an initialization file (the *inputrc* file). The name of this file is taken from the value of the **INPUTRC** variable. If that variable is unset, the default is *%inputrc*. If that file does not exist or cannot be read, the ultimate default is */etc/inputrc*. When a program which uses the readline library starts up, the initialization file is read, and the key bindings and variables are set. There are only a few basic constructs allowed in the readline initialization file. Blank lines are ignored. Lines beginning with a # are comments. Lines beginning with a \$ indicate conditional constructs. Other lines denote key bindings and variable settings.

The default key-bindings may be changed with an *inputrc* file. Other programs that use this library may add their own commands and bindings.

For example, placing

M-Control-u: universal-argument

or

C-Meta-u: universal-argument

into the *inputrc* would make M-C-u execute the readline command *universal-argument*.

The following symbolic character names are recognized: *RUBOUT*, *DEL*, *ESC*, *LFD*, *NEWLINE*, *RET*, *RETURN*, *SPC*, *SPACE*, and *TAB*.

In addition to command names, readline allows keys to be bound to a string that is inserted when the key is pressed (a *macro*).

Readline Key Bindings

The syntax for controlling key bindings in the *inputrc* file is simple. All that is required is the name of the command or the text of a macro and a key sequence to which it should be bound. The name may be specified in one of two ways: as a symbolic key name, possibly with *Meta-* or *Control-* prefixes, or as a key sequence.

When using the form **keyname:function-name** or **macro**, *keyname* is the name of a key spelled out in English. For example:

Control-u: universal-argument

Meta-Rubout: backward-kill-word

Control-o: "> output"

In the above example, *C-u* is bound to the function **universal-argument**, *M-DEL* is bound to the function **backward-kill-word**, and *C-o* is bound to run the macro expressed on the right hand side (that is, to insert the text > output into the line).

In the second form, "**keyseq**":*function-name* or *macro*, **keyseq** differs from **keyname** above in that strings denoting an entire key sequence may be specified by placing the sequence within double quotes. Some GNU Emacs style key escapes can be used, as in the following example, but the symbolic character names are not recognized.

```
"\C-u": universal-argument
"\C-x\C-r": re-read-init-file
"\e[11~": "Function Key 1"
```

In this example, *C-u* is again bound to the function **universal-argument**. *C-x C-r* is bound to the function **re-read-init-file**, and *ESC / 11 ~* is bound to insert the text Function Key 1.

The full set of GNU Emacs style escape sequences is

\C-	control prefix
\M-	meta prefix
\e	an escape character
\	backslash
\"	literal "
\'	literal '

In addition to the GNU Emacs style escape sequences, a second set of backslash escapes is available:

\a	alert (bell)
\b	backspace
\d	delete
\f	form feed
\n	newline
\r	carriage return
\t	horizontal tab
\v	vertical tab
\nnn	the eight-bit character whose value is the octal value <i>nnn</i> (one to three digits)
\xHH	the eight-bit character whose value is the hexadecimal value <i>HH</i> (one or two hex digits)

When entering the text of a macro, single or double quotes must be used to indicate a macro definition. Unquoted text is assumed to be a function name. In the macro body, the backslash escapes described above are expanded. Backslash will quote any other character in the macro text, including " and '.

Bash allows the current readline key bindings to be displayed or modified with the **bind** builtin command. The editing mode may be switched during interactive use by using the **-o** option to the **set** builtin command (see **SHELL BUILTIN COMMANDS** below).

Readline Variables

Readline has variables that can be used to further customize its behavior. A variable may be set in the *inputrc* file with a statement of the form

```
set variable-name value
```

or using the **bind** builtin command (see **SHELL BUILTIN COMMANDS** below).

Except where noted, readline variables can take the values **On** or **Off** (without regard to case). Unrecognized variable names are ignored. When a variable value is read, empty or null values, "on" (case-insensitive), and "1" are equivalent to **On**. All other values are equivalent to **Off**. The variables and their default values are:

bell-style (audible)

Controls what happens when readline wants to ring the terminal bell. If set to **none**, readline never rings the bell. If set to **visible**, readline uses a visible bell if one is available. If set to **audible**,

readline attempts to ring the terminal's bell.

bind-tty-special-chars (On)

If set to **On**, readline attempts to bind the control characters treated specially by the kernel's terminal driver to their readline equivalents.

blink-matching-paren (Off)

If set to **On**, readline attempts to briefly move the cursor to an opening parenthesis when a closing parenthesis is inserted.

colored-completion-prefix (Off)

If set to **On**, when listing completions, readline displays the common prefix of the set of possible completions using a different color. The color definitions are taken from the value of the **LS_COLORS** environment variable.

colored-stats (Off)

If set to **On**, readline displays possible completions using different colors to indicate their file type. The color definitions are taken from the value of the **LS_COLORS** environment variable.

comment-begin ("#")

The string that is inserted when the readline **insert-comment** command is executed. This command is bound to **M-#** in emacs mode and to **#** in vi command mode.

completion-display-width (-1)

The number of screen columns used to display possible matches when performing completion. The value is ignored if it is less than 0 or greater than the terminal screen width. A value of 0 will cause matches to be displayed one per line. The default value is -1.

completion-ignore-case (Off)

If set to **On**, readline performs filename matching and completion in a case-insensitive fashion.

completion-map-case (Off)

If set to **On**, and **completion-ignore-case** is enabled, readline treats hyphens (-) and underscores (_) as equivalent when performing case-insensitive filename matching and completion.

completion-prefix-display-length (0)

The length in characters of the common prefix of a list of possible completions that is displayed without modification. When set to a value greater than zero, common prefixes longer than this value are replaced with an ellipsis when displaying possible completions.

completion-query-items (100)

This determines when the user is queried about viewing the number of possible completions generated by the **possible-completions** command. It may be set to any integer value greater than or equal to zero. If the number of possible completions is greater than or equal to the value of this variable, readline will ask whether or not the user wishes to view them; otherwise they are simply listed on the terminal.

convert-meta (On)

If set to **On**, readline will convert characters with the eighth bit set to an ASCII key sequence by stripping the eighth bit and prefixing an escape character (in effect, using escape as the *meta prefix*). The default is *On*, but readline will set it to *Off* if the locale contains eight-bit characters.

disable-completion (Off)

If set to **On**, readline will inhibit word completion. Completion characters will be inserted into the line as if they had been mapped to **self-insert**.

echo-control-characters (On)

When set to **On**, on operating systems that indicate they support it, readline echoes a character corresponding to a signal generated from the keyboard.

editing-mode (emacs)

Controls whether readline begins with a set of key bindings similar to *Emacs* or *vi*. **editing-mode** can be set to either **emacs** or **vi**.

emacs-mode-string (@)

If the *show-mode-in-prompt* variable is enabled, this string is displayed immediately before the last line of the primary prompt when emacs editing mode is active. The value is expanded like a key binding, so the standard set of meta- and control prefixes and backslash escape sequences is available. Use the \1 and \2 escapes to begin and end sequences of non-printing characters, which

can be used to embed a terminal control sequence into the mode string.

enable-bracketed-paste (On)

When set to **On**, readline will configure the terminal in a way that will enable it to insert each paste into the editing buffer as a single string of characters, instead of treating each character as if it had been read from the keyboard. This can prevent pasted characters from being interpreted as editing commands.

enable-keypad (Off)

When set to **On**, readline will try to enable the application keypad when it is called. Some systems need this to enable the arrow keys.

enable-meta-key (On)

When set to **On**, readline will try to enable any meta modifier key the terminal claims to support when it is called. On many terminals, the meta key is used to send eight-bit characters.

expand-tilde (Off)

If set to **On**, tilde expansion is performed when readline attempts word completion.

history-preserve-point (Off)

If set to **On**, the history code attempts to place point at the same location on each history line retrieved with **previous-history** or **next-history**.

history-size (unset)

Set the maximum number of history entries saved in the history list. If set to zero, any existing history entries are deleted and no new entries are saved. If set to a value less than zero, the number of history entries is not limited. By default, the number of history entries is set to the value of the **HISTSIZE** shell variable. If an attempt is made to set **history-size** to a non-numeric value, the maximum number of history entries will be set to 500.

horizontal-scroll-mode (Off)

When set to **On**, makes readline use a single line for display, scrolling the input horizontally on a single screen line when it becomes longer than the screen width rather than wrapping to a new line. This setting is automatically enabled for terminals of height 1.

input-meta (Off)

If set to **On**, readline will enable eight-bit input (that is, it will not strip the eighth bit from the characters it reads), regardless of what the terminal claims it can support. The name **meta-flag** is a synonym for this variable. The default is *Off*, but readline will set it to *On* if the locale contains eight-bit characters.

isearch-terminators (“C-[C-J]”)

The string of characters that should terminate an incremental search without subsequently executing the character as a command. If this variable has not been given a value, the characters *ESC* and *C-J* will terminate an incremental search.

keymap (emacs)

Set the current readline keymap. The set of valid keymap names is *emacs*, *emacs-standard*, *emacs-meta*, *emacs-ctlx*, *vi*, *vi-command*, and *vi-insert*. *vi* is equivalent to *vi-command*; *emacs* is equivalent to *emacs-standard*. The default value is *emacs*; the value of **editing-mode** also affects the default keymap.

keyseq-timeout (500)

Specifies the duration readline will wait for a character when reading an ambiguous key sequence (one that can form a complete key sequence using the input read so far, or can take additional input to complete a longer key sequence). If no input is received within the timeout, readline will use the shorter but complete key sequence. The value is specified in milliseconds, so a value of 1000 means that readline will wait one second for additional input. If this variable is set to a value less than or equal to zero, or to a non-numeric value, readline will wait until another key is pressed to decide which key sequence to complete.

mark-directories (On)

If set to **On**, completed directory names have a slash appended.

mark-modified-lines (Off)

If set to **On**, history lines that have been modified are displayed with a preceding asterisk (*).

mark-symlinked-directories (Off)

If set to **On**, completed names which are symbolic links to directories have a slash appended (subject to the value of **mark-directories**).

match-hidden-files (On)

This variable, when set to **On**, causes readline to match files whose names begin with a ‘.’ (hidden files) when performing filename completion. If set to **Off**, the leading ‘.’ must be supplied by the user in the filename to be completed.

menu-complete-display-prefix (Off)

If set to **On**, menu completion displays the common prefix of the list of possible completions (which may be empty) before cycling through the list.

output-meta (Off)

If set to **On**, readline will display characters with the eighth bit set directly rather than as a meta-prefixed escape sequence. The default is *Off*, but readline will set it to *On* if the locale contains eight-bit characters.

page-completions (On)

If set to **On**, readline uses an internal *more*-like pager to display a screenful of possible completions at a time.

print-completions-horizontally (Off)

If set to **On**, readline will display completions with matches sorted horizontally in alphabetical order, rather than down the screen.

revert-all-at-newline (Off)

If set to **On**, readline will undo all changes to history lines before returning when **accept-line** is executed. By default, history lines may be modified and retain individual undo lists across calls to **readline**.

show-all-if-ambiguous (Off)

This alters the default behavior of the completion functions. If set to **On**, words which have more than one possible completion cause the matches to be listed immediately instead of ringing the bell.

show-all-if-unmodified (Off)

This alters the default behavior of the completion functions in a fashion similar to **show-all-if-ambiguous**. If set to **On**, words which have more than one possible completion without any possible partial completion (the possible completions don't share a common prefix) cause the matches to be listed immediately instead of ringing the bell.

show-mode-in-prompt (Off)

If set to **On**, add a string to the beginning of the prompt indicating the editing mode: emacs, vi command, or vi insertion. The mode strings are user-settable (e.g., *emacs-mode-string*).

skip-completed-text (Off)

If set to **On**, this alters the default completion behavior when inserting a single match into the line. It's only active when performing completion in the middle of a word. If enabled, readline does not insert characters from the completion that match characters after point in the word being completed, so portions of the word following the cursor are not duplicated.

vi-cmd-mode-string ((cmd))

If the *show-mode-in-prompt* variable is enabled, this string is displayed immediately before the last line of the primary prompt when vi editing mode is active and in command mode. The value is expanded like a key binding, so the standard set of meta- and control prefixes and backslash escape sequences is available. Use the `\1` and `\2` escapes to begin and end sequences of non-printing characters, which can be used to embed a terminal control sequence into the mode string.

vi-ins-mode-string ((ins))

If the *show-mode-in-prompt* variable is enabled, this string is displayed immediately before the last line of the primary prompt when vi editing mode is active and in insertion mode. The value is expanded like a key binding, so the standard set of meta- and control prefixes and backslash escape sequences is available. Use the `\1` and `\2` escapes to begin and end sequences of non-printing characters, which can be used to embed a terminal control sequence into the mode string.

visible-stats (Off)

If set to **On**, a character denoting a file's type as reported by *stat(2)* is appended to the filename when listing possible completions.

Readline Conditional Constructs

Readline implements a facility similar in spirit to the conditional compilation features of the C preprocessor which allows key bindings and variable settings to be performed as the result of tests. There are four parser directives used.

\$if The **\$if** construct allows bindings to be made based on the editing mode, the terminal being used, or the application using readline. The text of the test, after any comparison operator, extends to the end of the line; unless otherwise noted, no characters are required to isolate it.

mode The **mode=** form of the **\$if** directive is used to test whether readline is in emacs or vi mode. This may be used in conjunction with the **set k eymap** command, for instance, to set bindings in the *emacs-standard* and *emacs-ctlx* keymaps only if readline is starting out in emacs mode.

term The **term=** form may be used to include terminal-specific key bindings, perhaps to bind the key sequences output by the terminal's function keys. The word on the right side of the **=** is tested against both the full name of the terminal and the portion of the terminal name before the first **-**. This allows *sun* to match both *sun* and *sun-cmd*, for instance.

version

The **version** test may be used to perform comparisons against specific readline versions. The **version** expands to the current readline version. The set of comparison operators includes **=**, **==**, **!=**, **<=**, **>=**, **<**, and **>**. The version number supplied on the right side of the operator consists of a major version number, an optional decimal point, and an optional minor version (e.g., **7.1**). If the minor version is omitted, it is assumed to be **0**. The operator may be separated from the string **version** and from the version number argument by whitespace.

application

The **application** construct is used to include application-specific settings. Each program using the readline library sets the *application name*, and an initialization file can test for a particular value. This could be used to bind key sequences to functions useful for a specific program. For instance, the following command adds a key sequence that quotes the current or previous word in **bash**:

```
$if Bash
# Quote the current or previous word
"\C-xq": "\eb\"ef\""
$endif
```

variable

The **variable** construct provides simple equality tests for readline variables and values. The permitted comparison operators are **=**, **==**, and **!=**. The variable name must be separated from the comparison operator by whitespace; the operator may be separated from the value on the right hand side by whitespace. Both string and boolean variables may be tested. Boolean variables must be tested against the values *on* and *off*.

\$endif This command, as seen in the previous example, terminates an **\$if** command.

\$else Commands in this branch of the **\$if** directive are executed if the test fails.

\$include

This directive takes a single filename as an argument and reads commands and bindings from that file. For example, the following directive would read */etc/inputrc*:

```
$include /etc/inputrc
```

Searching

Readline provides commands for searching through the command history (see **HISTORY** below) for lines containing a specified string. There are two search modes: *incremental* and *non-incremental*.

Incremental searches begin before the user has finished typing the search string. As each character of the search string is typed, readline displays the next entry from the history matching the string typed so far. An incremental search requires only as many characters as needed to find the desired history entry. The characters present in the value of the **isearch-terminators** variable are used to terminate an incremental search. If that variable has not been assigned a value the Escape and Control-J characters will terminate an incremental search. Control-G will abort an incremental search and restore the original line. When the search is terminated, the history entry containing the search string becomes the current line.

To find other matching entries in the history list, type Control-S or Control-R as appropriate. This will search backward or forward in the history for the next entry matching the search string typed so far. Any other key sequence bound to a readline command will terminate the search and execute that command. For instance, a *newline* will terminate the search and accept the line, thereby executing the command from the history list.

Readline remembers the last incremental search string. If two Control-Rs are typed without any intervening characters defining a new search string, any remembered search string is used.

Non-incremental searches read the entire search string before starting to search for matching history lines. The search string may be typed by the user or be part of the contents of the current line.

Readline Command Names

The following is a list of the names of the commands and the default key sequences to which they are bound. Command names without an accompanying key sequence are unbound by default. In the following descriptions, *point* refers to the current cursor position, and *mark* refers to a cursor position saved by the **set-mark** command. The text between the point and mark is referred to as the *region*.

Commands for Moving

beginning-of-line (C-a)

Move to the start of the current line.

end-of-line (C-e)

Move to the end of the line.

forward-char (C-f)

Move forward a character.

backward-char (C-b)

Move back a character.

forward-word (M-f)

Move forward to the end of the next word. Words are composed of alphanumeric characters (letters and digits).

backward-word (M-b)

Move back to the start of the current or previous word. Words are composed of alphanumeric characters (letters and digits).

shell-forward-word

Move forward to the end of the next word. Words are delimited by non-quoted shell metacharacters.

shell-backward-word

Move back to the start of the current or previous word. Words are delimited by non-quoted shell metacharacters.

previous-screen-line

Attempt to move point to the same physical screen column on the previous physical screen line. This will not have the desired effect if the current Readline line does not take up more than one physical line or if point is not greater than the length of the prompt plus the screen width.

next-screen-line

Attempt to move point to the same physical screen column on the next physical screen line. This will not have the desired effect if the current Readline line does not take up more than one physical

line or if the length of the current Readline line is not greater than the length of the prompt plus the screen width.

clear–display (M–C–I)

Clear the screen and, if possible, the terminal's scrollback buffer, then redraw the current line, leaving the current line at the top of the screen.

clear–screen (C–I)

Clear the screen, then redraw the current line, leaving the current line at the top of the screen.

With an argument, refresh the current line without clearing the screen.

redraw–current–line

Refresh the current line.

Commands for Manipulating the History

accept–line (Newline, Return)

Accept the line regardless of where the cursor is. If this line is non-empty, add it to the history list according to the state of the **HISTCONTROL** variable. If the line is a modified history line, then restore the history line to its original state.

previous–history (C–p)

Fetch the previous command from the history list, moving back in the list.

next–history (C–n)

Fetch the next command from the history list, moving forward in the list.

beginning–of–history (M–<)

Move to the first line in the history.

end–of–history (M–>)

Move to the end of the input history, i.e., the line currently being entered.

reverse–search–history (C–r)

Search backward starting at the current line and moving 'up' through the history as necessary. This is an incremental search.

forward–search–history (C–s)

Search forward starting at the current line and moving 'down' through the history as necessary. This is an incremental search.

non–incremental–reverse–search–history (M–p)

Search backward through the history starting at the current line using a non-incremental search for a string supplied by the user.

non–incremental–forward–search–history (M–n)

Search forward through the history using a non-incremental search for a string supplied by the user.

history–search–forward

Search forward through the history for the string of characters between the start of the current line and the point. This is a non-incremental search.

history–search–backward

Search backward through the history for the string of characters between the start of the current line and the point. This is a non-incremental search.

history–substring–search–backward

Search backward through the history for the string of characters between the start of the current line and the current cursor position (the *point*). The search string may match anywhere in a history line. This is a non-incremental search.

history–substring–search–forward

Search forward through the history for the string of characters between the start of the current line and the point. The search string may match anywhere in a history line. This is a non-incremental search.

yank–nth–arg (M–C–y)

Insert the first argument to the previous command (usually the second word on the previous line) at point. With an argument *n*, insert the *n*th word from the previous command (the words in the previous command begin with word 0). A negative argument inserts the *n*th word from the end of the previous command. Once the argument *n* is computed, the argument is extracted as if the "!"

history expansion had been specified.

yank–last–arg (M–., M–_)

Insert the last argument to the previous command (the last word of the previous history entry).

With a numeric argument, behave exactly like **yank–nth–arg**. Successive calls to **yank–last–arg** move back through the history list, inserting the last word (or the word specified by the argument to the first call) of each line in turn. Any numeric argument supplied to these successive calls determines the direction to move through the history. A negative argument switches the direction through the history (back or forward). The history expansion facilities are used to extract the last word, as if the "\$!" history expansion had been specified.

shell–expand–line (M–C–e)

Expand the line as the shell does. This performs alias and history expansion as well as all of the shell word expansions. See **HISTORY EXPANSION** below for a description of history expansion.

history–expand–line (M–^)

Perform history expansion on the current line. See **HISTORY EXPANSION** below for a description of history expansion.

magic–space

Perform history expansion on the current line and insert a space. See **HISTORY EXPANSION** below for a description of history expansion.

alias–expand–line

Perform alias expansion on the current line. See **ALIASES** above for a description of alias expansion.

history–and–alias–expand–line

Perform history and alias expansion on the current line.

insert–last–argument (M–., M–_)

A synonym for **yank–last–arg**.

operate–and–get–next (C–o)

Accept the current line for execution and fetch the next line relative to the current line from the history for editing. A numeric argument, if supplied, specifies the history entry to use instead of the current line.

edit–and–execute–command (C–x C–e)

Invoke an editor on the current command line, and execute the result as shell commands. **Bash** attempts to invoke **\$VISUAL**, **\$EDITOR**, and *emacs* as the editor, in that order.

Commands for Changing Text

end–of–file (usually C–d)

The character indicating end-of-file as set, for example, by **stty**. If this character is read when there are no characters on the line, and point is at the beginning of the line, Readline interprets it as the end of input and returns **EOF**.

delete–char (C–d)

Delete the character at point. If this function is bound to the same character as the **tt** **EOF** character, as **C–d** commonly is, see above for the effects.

backward–delete–char (Rubout)

Delete the character behind the cursor. When given a numeric argument, save the deleted text on the kill ring.

forward–backward–delete–char

Delete the character under the cursor, unless the cursor is at the end of the line, in which case the character behind the cursor is deleted.

quoted–insert (C–q, C–v)

Add the next character typed to the line verbatim. This is how to insert characters like **C–q**, for example.

tab–insert (C–v TAB)

Insert a tab character.

self–insert (a, b, A, 1, !, ...)

Insert the character typed.

transpose-chars (C-t)

Drag the character before point forward over the character at point, moving point forward as well. If point is at the end of the line, then this transposes the two characters before point. Negative arguments have no effect.

transpose-words (M-t)

Drag the word before point past the word after point, moving point over that word as well. If point is at the end of the line, this transposes the last two words on the line.

upcase-word (M-u)

Uppercase the current (or following) word. With a negative argument, uppercase the previous word, but do not move point.

downcase-word (M-l)

Lowercase the current (or following) word. With a negative argument, lowercase the previous word, but do not move point.

capitalize-word (M-c)

Capitalize the current (or following) word. With a negative argument, capitalize the previous word, but do not move point.

overwrite-mode

Toggle overwrite mode. With an explicit positive numeric argument, switches to overwrite mode. With an explicit non-positive numeric argument, switches to insert mode. This command affects only **emacs** mode; **vi** mode does overwrite differently. Each call to `readline()` starts in insert mode. In overwrite mode, characters bound to **self-insert** replace the text at point rather than pushing the text to the right. Characters bound to **backward-delete-char** replace the character before point with a space. By default, this command is unbound.

Killing and Yanking**kill-line (C-k)**

Kill the text from point to the end of the line.

backward-kill-line (C-x Rubout)

Kill backward to the beginning of the line.

unix-line-discard (C-u)

Kill backward from point to the beginning of the line. The killed text is saved on the kill-ring.

kill-whole-line

Kill all characters on the current line, no matter where point is.

kill-word (M-d)

Kill from point to the end of the current word, or if between words, to the end of the next word.

Word boundaries are the same as those used by **forward-word**.

backward-kill-word (M-Rubout)

Kill the word behind point. Word boundaries are the same as those used by **backward-word**.

shell-kill-word

Kill from point to the end of the current word, or if between words, to the end of the next word.

Word boundaries are the same as those used by **shell-forward-word**.

shell-backward-kill-word

Kill the word behind point. Word boundaries are the same as those used by **shell-backward-word**.

unix-word-rubout (C-w)

Kill the word behind point, using white space as a word boundary. The killed text is saved on the kill-ring.

unix-filename-rubout

Kill the word behind point, using white space and the slash character as the word boundaries. The killed text is saved on the kill-ring.

delete-horizontal-space (M-|)

Delete all spaces and tabs around point.

kill-region

Kill the text in the current region.

copy-region-as-kill

Copy the text in the region to the kill buffer.

copy-backward-word

Copy the word before point to the kill buffer. The word boundaries are the same as **backward-word**.

copy-forward-word

Copy the word following point to the kill buffer. The word boundaries are the same as **forward-word**.

yank (C-y)

Yank the top of the kill ring into the buffer at point.

yank-pop (M-y)

Rotate the kill ring, and yank the new top. Only works following **yank** or **yank-pop**.

Numeric Arguments**digit-argument (M-0, M-1, ..., M--)**

Add this digit to the argument already accumulating, or start a new argument. M-- starts a negative argument.

universal-argument

This is another way to specify an argument. If this command is followed by one or more digits, optionally with a leading minus sign, those digits define the argument. If the command is followed by digits, executing **universal-argument** again ends the numeric argument, but is otherwise ignored. As a special case, if this command is immediately followed by a character that is neither a digit nor minus sign, the argument count for the next command is multiplied by four. The argument count is initially one, so executing this function the first time makes the argument count four, a second time makes the argument count sixteen, and so on.

Completing**complete (TAB)**

Attempt to perform completion on the text before point. **Bash** attempts completion treating the text as a variable (if the text begins with \$), username (if the text begins with ~), hostname (if the text begins with @), or command (including aliases and functions) in turn. If none of these produces a match, filename completion is attempted.

possible-completions (M-?)

List the possible completions of the text before point.

insert-completions (M-*)

Insert all completions of the text before point that would have been generated by **possible-completions**.

menu-complete

Similar to **complete**, but replaces the word to be completed with a single match from the list of possible completions. Repeated execution of **menu-complete** steps through the list of possible completions, inserting each match in turn. At the end of the list of completions, the bell is rung (subject to the setting of **bell-style**) and the original text is restored. An argument of *n* moves *n* positions forward in the list of matches; a negative argument may be used to move backward through the list. This command is intended to be bound to **TAB**, but is unbound by default.

menu-complete-backward

Identical to **menu-complete**, but moves backward through the list of possible completions, as if **menu-complete** had been given a negative argument. This command is unbound by default.

delete-char-or-list

Deletes the character under the cursor if not at the beginning or end of the line (like **delete-char**). If at the end of the line, behaves identically to **possible-completions**. This command is unbound by default.

complete-filename (M-/)

Attempt filename completion on the text before point.

possible-filename-completions (C-x /)

List the possible completions of the text before point, treating it as a filename.

complete-username (M-~)

Attempt completion on the text before point, treating it as a username.

possible-username-completions (C-x ~)

List the possible completions of the text before point, treating it as a username.

complete-variable (M-\$)

Attempt completion on the text before point, treating it as a shell variable.

possible-variable-completions (C-x \$)

List the possible completions of the text before point, treating it as a shell variable.

complete-hostname (M-@)

Attempt completion on the text before point, treating it as a hostname.

possible-hostname-completions (C-x @)

List the possible completions of the text before point, treating it as a hostname.

complete-command (M-!)

Attempt completion on the text before point, treating it as a command name. Command completion attempts to match the text against aliases, reserved words, shell functions, shell builtins, and finally executable filenames, in that order.

possible-command-completions (C-x !)

List the possible completions of the text before point, treating it as a command name.

dynamic-complete-history (M-TAB)

Attempt completion on the text before point, comparing the text against lines from the history list for possible completion matches.

dabbrev-expand

Attempt menu completion on the text before point, comparing the text against lines from the history list for possible completion matches.

complete-into-braces (M-{)

Perform filename completion and insert the list of possible completions enclosed within braces so the list is available to the shell (see **Brace Expansion** above).

Keyboard Macros**start-kbd-macro (C-x ()**

Begin saving the characters typed into the current keyboard macro.

end-kbd-macro (C-x))

Stop saving the characters typed into the current keyboard macro and store the definition.

call-last-kbd-macro (C-x e)

Re-execute the last keyboard macro defined, by making the characters in the macro appear as if typed at the keyboard.

print-last-kbd-macro ()

Print the last keyboard macro defined in a format suitable for the *inputrc* file.

Miscellaneous**re-read-init-file (C-x C-r)**

Read in the contents of the *inputrc* file, and incorporate any bindings or variable assignments found there.

abort (C-g)

Abort the current editing command and ring the terminal's bell (subject to the setting of **bell-style**).

do-lowercase-version (M-A, M-B, M-x, ...)

If the metabified character *x* is uppercase, run the command that is bound to the corresponding metabified lowercase character. The behavior is undefined if *x* is already lowercase.

prefix-meta (ESC)

Metabify the next character typed. **ESC f** is equivalent to **Meta-f**.

undo (C-, C-x C-u)

Incremental undo, separately remembered for each line.

revert-line (M-r)

Undo all changes made to this line. This is like executing the **undo** command enough times to return the line to its initial state.

tilde-expand (M-&)

Perform tilde expansion on the current word.

set-mark (C-@, M-<space>)

Set the mark to the point. If a numeric argument is supplied, the mark is set to that position.

exchange-point-and-mark (C-x C-x)

Swap the point with the mark. The current cursor position is set to the saved position, and the old cursor position is saved as the mark.

character-search (C-])

A character is read and point is moved to the next occurrence of that character. A negative count searches for previous occurrences.

character-search-backward (M-C-])

A character is read and point is moved to the previous occurrence of that character. A negative count searches for subsequent occurrences.

skip-csi-sequence

Read enough characters to consume a multi-key sequence such as those defined for keys like Home and End. Such sequences begin with a Control Sequence Indicator (CSI), usually ESC-[. If this sequence is bound to "\|", keys producing such sequences will have no effect unless explicitly bound to a readline command, instead of inserting stray characters into the editing buffer. This is unbound by default, but usually bound to ESC-[.

insert-comment (M-#)

Without a numeric argument, the value of the readline **comment-begin** variable is inserted at the beginning of the current line. If a numeric argument is supplied, this command acts as a toggle: if the characters at the beginning of the line do not match the value of **comment-begin**, the value is inserted, otherwise the characters in **comment-begin** are deleted from the beginning of the line. In either case, the line is accepted as if a newline had been typed. The default value of **comment-begin** causes this command to make the current line a shell comment. If a numeric argument causes the comment character to be removed, the line will be executed by the shell.

glob-complete-word (M-g)

The word before point is treated as a pattern for pathname expansion, with an asterisk implicitly appended. This pattern is used to generate a list of matching filenames for possible completions.

glob-expand-word (C-x *)

The word before point is treated as a pattern for pathname expansion, and the list of matching filenames is inserted, replacing the word. If a numeric argument is supplied, an asterisk is appended before pathname expansion.

glob-list-expansions (C-x g)

The list of expansions that would have been generated by **glob-expand-word** is displayed, and the line is redrawn. If a numeric argument is supplied, an asterisk is appended before pathname expansion.

dump-functions

Print all of the functions and their key bindings to the readline output stream. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an *inputrc* file.

dump-variables

Print all of the settable readline variables and their values to the readline output stream. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an *inputrc* file.

dump-macros

Print all of the readline key sequences bound to macros and the strings they output. If a numeric argument is supplied, the output is formatted in such a way that it can be made part of an *inputrc* file.

display-shell-version (C-x C-v)

Display version information about the current instance of **bash**.

Programmable Completion

When word completion is attempted for an argument to a command for which a completion specification (*compspec*) has been defined using the **complete** builtin (see **SHELL BUILTIN COMMANDS** below), the

programmable completion facilities are invoked.

First, the command name is identified. If the command word is the empty string (completion attempted at the beginning of an empty line), any compspec defined with the **-E** option to **complete** is used. If a compspec has been defined for that command, the compspec is used to generate the list of possible completions for the word. If the command word is a full pathname, a compspec for the full pathname is searched for first. If no compspec is found for the full pathname, an attempt is made to find a compspec for the portion following the final slash. If those searches do not result in a compspec, any compspec defined with the **-D** option to **complete** is used as the default. If there is no default compspec, **bash** attempts alias expansion on the command word as a final resort, and attempts to find a compspec for the command word from any successful expansion.

Once a compspec has been found, it is used to generate the list of matching words. If a compspec is not found, the default **bash** completion as described above under **Completing** is performed.

First, the actions specified by the compspec are used. Only matches which are prefixed by the word being completed are returned. When the **-f** or **-d** option is used for filename or directory name completion, the shell variable **IGNORE** is used to filter the matches.

Any completions specified by a pathname expansion pattern to the **-G** option are generated next. The words generated by the pattern need not match the word being completed. The **GLOBIGNORE** shell variable is not used to filter the matches, but the **IGNORE** variable is used.

Next, the string specified as the argument to the **-W** option is considered. The string is first split using the characters in the **IFS** special variable as delimiters. Shell quoting is honored. Each word is then expanded using brace expansion, tilde expansion, parameter and variable expansion, command substitution, and arithmetic expansion, as described above under **EXPANSION**. The results are split using the rules described above under **Word Splitting**. The results of the expansion are prefix-matched against the word being completed, and the matching words become the possible completions.

After these matches have been generated, any shell function or command specified with the **-F** and **-C** options is invoked. When the command or function is invoked, the **COMP_LINE**, **COMP_POINT**, **COMP_KEY**, and **COMP_TYPE** variables are assigned values as described above under **Shell Variables**. If a shell function is being invoked, the **COMP_WORDS** and **COMP_CWORD** variables are also set. When the function or command is invoked, the first argument (**\$1**) is the name of the command whose arguments are being completed, the second argument (**\$2**) is the word being completed, and the third argument (**\$3**) is the word preceding the word being completed on the current command line. No filtering of the generated completions against the word being completed is performed; the function or command has complete freedom in generating the matches.

Any function specified with **-F** is invoked first. The function may use any of the shell facilities, including the **compgen** builtin described below, to generate the matches. It must put the possible completions in the **COMPREPLY** array variable, one per array element.

Next, any command specified with the **-C** option is invoked in an environment equivalent to command substitution. It should print a list of completions, one per line, to the standard output. Backslash may be used to escape a newline, if necessary.

After all of the possible completions are generated, any filter specified with the **-X** option is applied to the list. The filter is a pattern as used for pathname expansion; a **&** in the pattern is replaced with the text of the word being completed. A literal **&** may be escaped with a backslash; the backslash is removed before attempting a match. Any completion that matches the pattern will be removed from the list. A leading **!** negates the pattern; in this case any completion not matching the pattern will be removed. If the **nocase-match** shell option is enabled, the match is performed without regard to the case of alphabetic characters.

Finally, any prefix and suffix specified with the **-P** and **-S** options are added to each member of the completion list, and the result is returned to the readline completion code as the list of possible completions.

If the previously-applied actions do not generate any matches, and the **-o dirnames** option was supplied to **complete** when the compspec was defined, directory name completion is attempted.

If the **-o plusdirs** option was supplied to **complete** when the compspec was defined, directory name

completion is attempted and any matches are added to the results of the other actions.

By default, if a compspec is found, whatever it generates is returned to the completion code as the full set of possible completions. The default **bash** completions are not attempted, and the readline default of file-name completion is disabled. If the **-o bashdefault** option was supplied to **complete** when the compspec was defined, the **bash** default completions are attempted if the compspec generates no matches. If the **-o default** option was supplied to **complete** when the compspec was defined, readline's default completion will be performed if the compspec (and, if attempted, the default **bash** completions) generate no matches.

When a compspec indicates that directory name completion is desired, the programmable completion functions force readline to append a slash to completed names which are symbolic links to directories, subject to the value of the **mark-directories** readline variable, regardless of the setting of the **mark-sym-linked-directories** readline variable.

There is some support for dynamically modifying completions. This is most useful when used in combination with a default completion specified with **complete -D**. It's possible for shell functions executed as completion handlers to indicate that completion should be retried by returning an exit status of 124. If a shell function returns 124, and changes the compspec associated with the command on which completion is being attempted (supplied as the first argument when the function is executed), programmable completion restarts from the beginning, with an attempt to find a new compspec for that command. This allows a set of completions to be built dynamically as completion is attempted, rather than being loaded all at once.

For instance, assuming that there is a library of compspecs, each kept in a file corresponding to the name of the command, the following default completion function would load completions dynamically:

```
_completion_loader()
{
    . "/etc/bash_completion.d/$1.sh" >/dev/null 2>&1 && return 124
}
complete -D -F _completion_loader -o bashdefault -o default
```

HISTORY

When the **-o history** option to the **set** builtin is enabled, the shell provides access to the *command history*, the list of commands previously typed. The value of the **HISTSIZE** variable is used as the number of commands to save in a history list. The text of the last **HISTSIZE** commands (default 500) is saved. The shell stores each command in the history list prior to parameter and variable expansion (see **EXPANSION** above) but after history expansion is performed, subject to the values of the shell variables **HISTIGNORE** and **HISTCONTROL**.

On startup, the history is initialized from the file named by the variable **HISTFILE** (default `~/.bash_history`). The file named by the value of **HISTFILE** is truncated, if necessary, to contain no more than the number of lines specified by the value of **HISTFILESIZE**. If **HISTFILESIZE** is unset, or set to null, a non-numeric value, or a numeric value less than zero, the history file is not truncated. When the history file is read, lines beginning with the history comment character followed immediately by a digit are interpreted as timestamps for the following history line. These timestamps are optionally displayed depending on the value of the **HISTTIMEFORMAT** variable. When a shell with history enabled exits, the last **\$HISTSIZE** lines are copied from the history list to **\$HISTFILE**. If the **histappend** shell option is enabled (see the description of **shopt** under **SHELL BUILTIN COMMANDS** below), the lines are appended to the history file, otherwise the history file is overwritten. If **HISTFILE** is unset, or if the history file is unwritable, the history is not saved. If the **HISTTIMEFORMAT** variable is set, time stamps are written to the history file, marked with the history comment character, so they may be preserved across shell sessions. This uses the history comment character to distinguish timestamps from other history lines. After saving the history, the history file is truncated to contain no more than **HISTFILESIZE** lines. If **HISTFILESIZE** is unset, or set to null, a non-numeric value, or a numeric value less than zero, the history file is not truncated.

The builtin command **fc** (see **SHELL BUILTIN COMMANDS** below) may be used to list or edit and re-execute a portion of the history list. The **history** builtin may be used to display or modify the history list and manipulate the history file. When using command-line editing, search commands are available in each

editing mode that provide access to the history list.

The shell allows control over which commands are saved on the history list. The **HISTCONTROL** and **HISTIGNORE** variables may be set to cause the shell to save only a subset of the commands entered. The **cmdhist** shell option, if enabled, causes the shell to attempt to save each line of a multi-line command in the same history entry, adding semicolons where necessary to preserve syntactic correctness. The **lithist** shell option causes the shell to save the command with embedded newlines instead of semicolons. See the description of the **shopt** builtin below under **SHELL BUILTIN COMMANDS** for information on setting and unsetting shell options.

HISTORY EXPANSION

The shell supports a history expansion feature that is similar to the history expansion in **csh**. This section describes what syntax features are available. This feature is enabled by default for interactive shells, and can be disabled using the **+H** option to the **set** builtin command (see **SHELL BUILTIN COMMANDS** below). Non-interactive shells do not perform history expansion by default.

History expansions introduce words from the history list into the input stream, making it easy to repeat commands, insert the arguments to a previous command into the current input line, or fix errors in previous commands quickly.

History expansion is performed immediately after a complete line is read, before the shell breaks it into words, and is performed on each line individually without taking quoting on previous lines into account. It takes place in two parts. The first is to determine which line from the history list to use during substitution. The second is to select portions of that line for inclusion into the current one. The line selected from the history is the *event*, and the portions of that line that are acted upon are *words*. Various *modifiers* are available to manipulate the selected words. The line is broken into words in the same fashion as when reading input, so that several *metacharacter*-separated words surrounded by quotes are considered one word. History expansions are introduced by the appearance of the history expansion character, which is **!** by default. Only backslash (****) and single quotes can quote the history expansion character, but the history expansion character is also treated as quoted if it immediately precedes the closing double quote in a double-quoted string.

Several characters inhibit history expansion if found immediately following the history expansion character, even if it is unquoted: space, tab, newline, carriage return, and **=**. If the **extglob** shell option is enabled, **(** will also inhibit expansion.

Several shell options settable with the **shopt** builtin may be used to tailor the behavior of history expansion. If the **histverify** shell option is enabled (see the description of the **shopt** builtin below), and **readline** is being used, history substitutions are not immediately passed to the shell parser. Instead, the expanded line is reloaded into the **readline** editing buffer for further modification. If **readline** is being used, and the **histreedit** shell option is enabled, a failed history substitution will be reloaded into the **readline** editing buffer for correction. The **-p** option to the **history** builtin command may be used to see what a history expansion will do before using it. The **-s** option to the **history** builtin may be used to add commands to the end of the history list without actually executing them, so that they are available for subsequent recall.

The shell allows control of the various characters used by the history expansion mechanism (see the description of **histchars** above under **Shell Variables**). The shell uses the history comment character to mark history timestamps when writing the history file.

Event Designators

An event designator is a reference to a command line entry in the history list. Unless the reference is absolute, events are relative to the current position in the history list.

- !** Start a history substitution, except when followed by a **blank**, newline, carriage return, **=** or **(** (when the **extglob** shell option is enabled using the **shopt** builtin).
- !n** Refer to command line *n*.
- !-n** Refer to the current command minus *n*.
- !!** Refer to the previous command. This is a synonym for '**!-1**'.
- !string** Refer to the most recent command preceding the current position in the history list starting with *string*.

!?*string[?]*

Refer to the most recent command preceding the current position in the history list containing *string*. The trailing? may be omitted if *string* is followed immediately by a newline. If *string* is missing, the string from the most recent search is used; it is an error if there is no previous search string.

~*string1***^***string2***^**

Quick substitution. Repeat the previous command, replacing *string1* with *string2*. Equivalent to “`!!:s~string1~string2~`” (see **Modifiers** below).

!#

The entire command line typed so far.

Word Designators

Word designators are used to select desired words from the event. A: separates the event specification from the word designator. It may be omitted if the word designator begins with a ^, \$, *, -, or %. Words are numbered from the beginning of the line, with the first word being denoted by 0 (zero). Words are inserted into the current line separated by single spaces.

0 (zero)

The zeroth word. For the shell, this is the command word.

n

The *n*th word.

^

The first argument. That is, word 1.

\$

The last word. This is usually the last argument, but will expand to the zeroth word if there is only one word in the line.

%

The first word matched by the most recent ‘?*string*?’ search, if the search string begins with a character that is part of a word.

x-y

A range of words; ‘-y’ abbreviates ‘0-y’.

All of the words but the zeroth. This is a synonym for ‘1-\$’. It is not an error to use* if there is just one word in the event; the empty string is returned in that case.

x*

Abbreviates *x-\$*.

x-

Abbreviates *x-\$* like **x***, but omits the last word. If **x** is missing, it defaults to 0.

If a word designator is supplied without an event specification, the previous command is used as the event.

Modifiers

After the optional word designator, there may appear a sequence of one or more of the following modifiers, each preceded by a ‘:’. These modify, or edit, the word or words selected from the history event.

h

Remove a trailing filename component, leaving only the head.

t

Remove all leading filename components, leaving the tail.

r

Remove a trailing suffix of the form .xxx, leaving the basename.

e

Remove all but the trailing suffix.

p

Print the new command but do not execute it.

q

Quote the substituted words, escaping further substitutions.

x

Quote the substituted words as with **q**, but break into words at **blanks** and newlines. The **q** and **x** modifiers are mutually exclusive; the last one supplied is used.

s*old*/*new***/**

Substitute *new* for the first occurrence of *old* in the event line. Any character may be used as the delimiter in place of /. The final delimiter is optional if it is the last character of the event line. The delimiter may be quoted in *old* and *new* with a single backslash. If & appears in *new*, it is replaced by *old*. A single backslash will quote the &. If *old* is null, it is set to the last *old* substituted, or, if no previous history substitutions took place, the last *string* in a !?*string*[?] search. If *new* is null, each matching *old* is deleted.

&

Repeat the previous substitution.

g

Cause changes to be applied over the entire event line. This is used in conjunction with ‘:s’ (e.g., ‘:gs/*old*/*new*/’) or ‘:&’. If used with ‘:s’, any delimiter can be used in place of /, and the final delimiter is optional if it is the last character of the event line. An **a** may be used as a synonym for **g**.

G

Apply the following ‘s’ or ‘&’ modifier once to each word in the event line.

SHELL BUILTIN COMMANDS

Unless otherwise noted, each builtin command documented in this section as accepting options preceded by `-` accepts `--` to signify the end of the options. The `:`, `true`, `false`, and `test/[` builtins do not accept options and do not treat `--` specially. The `exit`, `logout`, `r eturn`, `b reak`, `c ontinue`, `l et`, and `s hift` builtins accept and process arguments beginning with `-` without requiring `--`. Other builtins that accept arguments but are not specified as accepting options interpret arguments beginning with `-` as invalid options and require `--` to prevent this interpretation.

: [arguments]

No effect; the command does nothing beyond expanding *arguments* and performing any specified redirections. The return status is zero.

. filename [arguments]

source filename [arguments]

Read and execute commands from *filename* in the current shell environment and return the exit status of the last command executed from *filename*. If *filename* does not contain a slash, filenames in **PATH** are used to find the directory containing *filename*. The file searched for in **PATH** need not be executable. When **bash** is not in *posix mode*, the current directory is searched if no file is found in **PATH**. If the **sourcepath** option to the **shopt** builtin command is turned off, the **PATH** is not searched. If any *arguments* are supplied, they become the positional parameters when *filename* is executed. Otherwise the positional parameters are unchanged. If the **-T** option is enabled, **source** inherits any trap on **DEBUG**; if it is not, any **DEBUG** trap string is saved and restored around the call to **source**, and **source** unsets the **DEBUG** trap while it executes. If **-T** is not set, and the sourced file changes the **DEBUG** trap, the new value is retained when **source** completes. The return status is the status of the last command exited within the script (0 if no commands are executed), and false if *filename* is not found or cannot be read.

alias [-p] [name[=value] ...]

Alias with no arguments or with the **-p** option prints the list of aliases in the form **alias name=value** on standard output. When arguments are supplied, an alias is defined for each *name* whose *value* is given. A trailing space *invalue* causes the next word to be checked for alias substitution when the alias is expanded. For each *name* in the argument list for which no *value* is supplied, the name and value of the alias is printed. **Alias** returns true unless a *name* is given for which no alias has been defined.

bg [jobspec ...]

Resume each suspended job *jobspec* in the background, as if it had been started with **&**. If *jobspec* is not present, the shell's notion of the *current job* is used. **bg** *jobspec* returns 0 unless run when job control is disabled or, when run with job control enabled, any specified *jobspec* was not found or was started without job control.

bind [-m keymap] [-lpsvPSVX]

bind [-m keymap] [-q function] [-u function] [-r keyseq]

bind [-m keymap] -f filename

bind [-m keymap] -x keyseq:shell-command

bind [-m keymap] keyseq:function-name

bind [-m keymap] keyseq:readline-command

Display current **readline** key and function bindings, bind a key sequence to a **readline** function or macro, or set a **readline** variable. Each non-option argument is a command as it would appear in *.inputrc*, but each binding or command must be passed as a separate argument; e.g., `'"\C-x\C-r":re-read-init-file'`. Options, if supplied, have the following meanings:

-m keymap

Use *keymap* as the keymap to be affected by the subsequent bindings. Acceptable *keymap* names are *emacs*, *emacs-standard*, *emacs-meta*, *emacs-ctlx*, *vi*, *vi-move*, *vi-command*, and *vi-insert*. *vi* is equivalent to *vi-command* (*vi-move* is also a synonym); *emacs* is equivalent to *emacs-standard*.

- l** List the names of all **readline** functions.
- p** Display **readline** function names and bindings in such a way that they can be re-read.
- P** List current **readline** function names and bindings.
- s** Display **readline** key sequences bound to macros and the strings they output in such a way that they can be re-read.
- S** Display **readline** key sequences bound to macros and the strings they output.
- v** Display **readline** variable names and values in such a way that they can be re-read.
- V** List current **readline** variable names and values.
- f** *filename*
Read key bindings from *filename*.
- q** *function*
Query about which keys invoke the named *function*.
- u** *function*
Unbind all keys bound to the named *function*.
- r** *keyseq*
Remove any current binding for *keyseq*.
- x** *keyseq:shell-command*
Cause *shell-command* to be executed whenever *keyseq* is entered. When *shell-command* is executed, the shell sets the **READLINE_LINE** variable to the contents of the **readline** line buffer and the **READLINE_POINT** and **READLINE_MARK** variables to the current location of the insertion point and the saved insertion point (the mark), respectively. If the executed command changes the value of any of **READLINE_LINE**, **READLINE_POINT**, or **READLINE_MARK**, those new values will be reflected in the editing state.
- X** List all key sequences bound to shell commands and the associated commands in a format that can be reused as input.

The return value is 0 unless an unrecognized option is given or an error occurred.

break [*n*]

Exit from within a **for**, **while**, **until**, or **select** loop. If *n* is specified, break *n* levels. *n* must be ≥ 1 . If *n* is greater than the number of enclosing loops, all enclosing loops are exited. The return value is 0 unless *n* is not greater than or equal to 1.

builtin *shell-builtin* [*arguments*]

Execute the specified shell builtin, passing it *arguments*, and return its exit status. This is useful when defining a function whose name is the same as a shell builtin, retaining the functionality of the builtin within the function. The **cd** builtin is commonly redefined this way. The return status is false if *shell-builtin* is not a shell builtin command.

caller [*expr*]

Returns the context of any active subroutine call (a shell function or a script executed with the **.** or **source** builtins). Without *expr*, **caller** displays the line number and source filename of the current subroutine call. If a non-negative integer is supplied as *expr*, **caller** displays the line number, subroutine name, and source file corresponding to that position in the current execution call stack. This extra information may be used, for example, to print a stack trace. The current frame is frame 0. The return value is 0 unless the shell is not executing a subroutine call or *expr* does not correspond to a valid position in the call stack.

cd [−**L**|[−**P** [−**e**]] [−@]] [*dir*]

Change the current directory to *dir*. If *dir* is not supplied, the value of the **HOME** shell variable is the default. Any additional arguments following *dir* are ignored. The variable **CDPATH** defines the search path for the directory containing *dir*: each directory name in **CDPATH** is searched for *dir*. Alternative directory names in **CDPATH** are separated by a colon (:). A null directory name in **CDPATH** is the same as the current directory, i.e., “.”. If *dir* begins with a slash (/), then **CDPATH** is not used. The **-P** option causes **cd** to use the physical directory structure by resolving symbolic links while traversing *dir* and before processing instances of .. in *dir* (see also the **-P**

option to the **set** builtin command); the **-L** option forces symbolic links to be followed by resolving the link after processing instances of .. in *dir*. If.. appears in *dir*, it is processed by removing the immediately previous pathname component from *dir*, back to a slash or the beginning of *dir*. If the **-e** option is supplied with **-P**, and the current working directory cannot be successfully determined after a successful directory change, **cd** will return an unsuccessful status. On systems that support it, the **-@** option presents the extended attributes associated with a file as a directory. An argument of – is converted to **\$OLDPWD** before the directory change is attempted. If a non-empty directory name from **CDPATH** is used, or if – is the first argument, and the directory change is successful, the absolute pathname of the new working directory is written to the standard output. The return value is true if the directory was successfully changed; false otherwise.

command [**-pVv**] *command* [*arg* ...]

Run *command* with *args* suppressing the normal shell function lookup. Only builtin commands or commands found in the **PATH** are executed. If the **-p** option is given, the search for *command* is performed using a default value for **PATH** that is guaranteed to find all of the standard utilities. If either the **-V** or **-v** option is supplied, a description of *command* is printed. The **-v** option causes a single word indicating the command or filename used to invoke *command* to be displayed; the **-V** option produces a more verbose description. If the **-V** or **-v** option is supplied, the exit status is 0 if *command* was found, and 1 if not. If neither option is supplied and an error occurred or *command* cannot be found, the exit status is 127. Otherwise, the exit status of the **command** builtin is the exit status of *command*.

compgen [*option*] [*word*]

Generate possible completion matches for *word* according to the *options*, which may be any option accepted by the **complete** builtin with the exception of **-p** and **-r**, and write the matches to the standard output. When using the **-F** or **-C** options, the various shell variables set by the programmable completion facilities, while available, will not have useful values.

The matches will be generated in the same way as if the programmable completion code had generated them directly from a completion specification with the same flags. If *word* is specified, only those completions matching *word* will be displayed.

The return value is true unless an invalid option is supplied, or no matches were generated.

complete [**-abcdefgjksuv**] [**-o** *comp-option*] [**-DEI**] [**-A** *action*] [**-G** *globpat*] [**-W** *wordlist*]
[**-F** *function*] [**-C** *command*] [**-X** *filterpat*] [**-P** *prefix*] [**-S** *suffix*] *name* [*name* ...]

complete **-pr** [**-DEI**] [*name* ...]

Specify how arguments to each *name* should be completed. If the **-p** option is supplied, or if no options are supplied, existing completion specifications are printed in a way that allows them to be reused as input. The **-r** option removes a completion specification for each *name*, or, if no *names* are supplied, all completion specifications. The **-D** option indicates that other supplied options and actions should apply to the “default” command completion; that is, completion attempted on a command for which no completion has previously been defined. The **-E** option indicates that other supplied options and actions should apply to “empty” command completion; that is, completion attempted on a blank line. The **-I** option indicates that other supplied options and actions should apply to completion on the initial non-assignment word on the line, or after a command delimiter such as ; or |, which is usually command name completion. If multiple options are supplied, the **-D** option takes precedence over **-E**, and both take precedence over **-I**. If any of **-D**, **-E**, or **-I** are supplied, any other *name* arguments are ignored; these completions only apply to the case specified by the option.

The process of applying these completion specifications when word completion is attempted is described above under **Programmable Completion**.

Other options, if specified, have the following meanings. The arguments to the **-G**, **-W**, and **-X** options (and, if necessary, the **-P** and **-S** options) should be quoted to protect them from

expansion before the **complete** builtin is invoked.

-o comp-option

The *comp-option* controls several aspects of the compspec's behavior beyond the simple generation of completions. *comp-option* may be one of:

bashdefault

Perform the rest of the default **bash** completions if the compspec generates no matches.

default Use readline's default filename completion if the compspec generates no matches.

dirnames

Perform directory name completion if the compspec generates no matches.

filenames

Tell readline that the compspec generates filenames, so it can perform any file-name-specific processing (like adding a slash to directory names, quoting special characters, or suppressing trailing spaces). Intended to be used with shell functions.

noquote Tell readline not to quote the completed words if they are filenames (quoting filenames is the default).

nosort Tell readline not to sort the list of possible completions alphabetically.

nospace Tell readline not to append a space (the default) to words completed at the end of the line.

plusdirs After any matches defined by the compspec are generated, directory name completion is attempted and any matches are added to the results of the other actions.

-A action

The *action* may be one of the following to generate a list of possible completions:

alias Alias names. May also be specified as **-a**.

arrayvar

Array variable names.

binding Readline key binding names.

builtin Names of shell builtin commands. May also be specified as **-b**.

command

Command names. May also be specified as **-c**.

directory

Directory names. May also be specified as **-d**.

disabled

Names of disabled shell builtins.

enabled Names of enabled shell builtins.

export Names of exported shell variables. May also be specified as **-e**.

file File names. May also be specified as **-f**.

function

Names of shell functions.

group Group names. May also be specified as **-g**.

helptopic

Help topics as accepted by the **help** builtin.

hostname

Hostnames, as taken from the file specified by the **HOSTFILE** shell variable.

job Job names, if job control is active. May also be specified as **-j**.

keyword

Shell reserved words. May also be specified as **-k**.

running Names of running jobs, if job control is active.

service Service names. May also be specified as **-s**.

setopt Valid arguments for the **-o** option to the **set** builtin.

shopt Shell option names as accepted by the **shopt** builtin.

signal Signal names.

stopped Names of stopped jobs, if job control is active.

user User names. May also be specified as **-u**.

variable Names of all shell variables. May also be specified as **-v**.

-C *command*

command is executed in a subshell environment, and its output is used as the possible completions.

-F *function*

The shell function *function* is executed in the current shell environment. When the function is executed, the first argument (**\$1**) is the name of the command whose arguments are being completed, the second argument (**\$2**) is the word being completed, and the third argument (**\$3**) is the word preceding the word being completed on the current command line. When it finishes, the possible completions are retrieved from the value of the **COMPREPLY** array variable.

-G *globpat*

The pathname expansion pattern *globpat* is expanded to generate the possible completions.

-P *prefix*

prefix is added at the beginning of each possible completion after all other options have been applied.

-S *suffix* *suffix* is appended to each possible completion after all other options have been applied.

-W *wordlist*

The *wordlist* is split using the characters in the **IFS** special variable as delimiters, and each resultant word is expanded. Shell quoting is honored within *wordlist*, in order to provide a mechanism for the words to contain shell metacharacters or characters in the value of **IFS**. The possible completions are the members of the resultant list which match the word being completed.

-X *filterpat*

filterpat is a pattern as used for pathname expansion. It is applied to the list of possible completions generated by the preceding options and arguments, and each completion matching *filterpat* is removed from the list. A leading ! in *filterpat* negates the pattern; in this case, any completion not matching *filterpat* is removed.

The return value is true unless an invalid option is supplied, an option other than **-p** or **-r** is supplied without a *name* argument, an attempt is made to remove a completion specification for a *name* for which no specification exists, or an error occurs adding a completion specification.

compopt [**-o** *option*] [**-DEI**] [**+o** *option*] [*name*]

Modify completion options for each *name* according to the *options*, or for the currently-executing completion if no *names* are supplied. If no *options* are given, display the completion options for each *name* or the current completion. The possible values of *option* are those valid for the **complete** builtin described above. The **-D** option indicates that other supplied options should apply to the “default” command completion; that is, completion attempted on a command for which no completion has previously been defined. The **-E** option indicates that other supplied options should apply to “empty” command completion; that is, completion attempted on a blank line. The **-I** option indicates that other supplied options should apply to completion on the initial non-assignment word on the line, or after a command delimiter such as ; or |, which is usually command name completion.

The return value is true unless an invalid option is supplied, an attempt is made to modify the options for a *name* for which no completion specification exists, or an output error occurs.

continue [*n*]

Resume the next iteration of the enclosing **for**, **while**, **until**, or **select** loop. If *n* is specified, resume at the *n*th enclosing loop. *n* must be ≥ 1 . If *n* is greater than the number of enclosing loops,

the last enclosing loop (the “top-level” loop) is resumed. The return value is 0 unless *n* is not greater than or equal to 1.

declare [**-aAfFgiIlnrux**] [**-p**] [*name[=value]* ...]
typeset [**-aAfFgiIlnrux**] [**-p**] [*name[=value]* ...]

Declare variables and/or give them attributes. If *nonames* are given then display the values of variables. The **-p** option will display the attributes and values of each *name*. When **-p** is used with *name* arguments, additional options, other than **-f** and **-F**, are ignored. When **-p** is supplied without *name* arguments, it will display the attributes and values of all variables having the attributes specified by the additional options. If no other options are supplied with **-p**, **declare** will display the attributes and values of all shell variables. The **-f** option will restrict the display to shell functions. The **-F** option inhibits the display of function definitions; only the function name and attributes are printed. If the **extdebug** shell option is enabled using **shopt**, the source file name and line number where each *name* is defined are displayed as well. The **-F** option implies **-f**. The **-g** option forces variables to be created or modified at the global scope, even when **declare** is executed in a shell function. It is ignored in all other cases. The **-I** option causes local variables to inherit the attributes (except the *nameref* attribute) and value of any existing variable with the same *name* at a surrounding scope. If there is no existing variable, the local variable is initially unset. The following options can be used to restrict output to variables with the specified attribute or to give variables attributes:

- a** Each *name* is an indexed array variable (see **Arrays** above).
- A** Each *name* is an associative array variable (see **Arrays** above).
- f** Use function names only.
- i** The variable is treated as an integer; arithmetic evaluation (see **ARITHMETIC EVALUATION** above) is performed when the variable is assigned a value.
- l** When the variable is assigned a value, all upper-case characters are converted to lower-case. The upper-case attribute is disabled.
- n** Give each *name* the *nameref* attribute, making it a name reference to another variable. That other variable is defined by the value of *name*. All references, assignments, and attribute modifications to *name*, except those using or changing the **-n** attribute itself, are performed on the variable referenced by *name*’s value. The *nameref* attribute cannot be applied to array variables.
- r** Make *names* readonly. These names cannot then be assigned values by subsequent assignment statements or unset.
- t** Give each *name* the *trace* attribute. Traced functions inherit the **DEBUG** and **RETURN** traps from the calling shell. The *trace* attribute has no special meaning for variables.
- u** When the variable is assigned a value, all lower-case characters are converted to upper-case. The lower-case attribute is disabled.
- x** Mark *names* for export to subsequent commands via the environment.

Using ‘+’ instead of ‘-’ turns off the attribute instead, with the exceptions that **+a** and **+A** may not be used to destroy array variables and **+r** will not remove the readonly attribute. When used in a function, **declare** and **typeset** make each *name* local, as with the **local** command, unless the **-g** option is supplied. If a variable name is followed by *=value*, the value of the variable is set to *value*. When using **-a** or **-A** and the compound assignment syntax to create array variables, additional attributes do not take effect until subsequent assignments. The return value is 0 unless an invalid option is encountered, an attempt is made to define a function using **-f** *foo=bar*, an attempt is made to assign a value to a readonly variable, an attempt is made to assign a value to an array variable without using the compound assignment syntax (see **Arrays** above), one of the *names* is not a valid shell variable name, an attempt is made to turn off readonly status for a readonly variable, an attempt is made to turn off array status for an array variable, or an attempt is made to display a non-existent function with **-f**.

dirs [**-clpv**] [**+n**] [**-n**]

Without options, displays the list of currently remembered directories. The default display is on a single line with directory names separated by spaces. Directories are added to the list with the

pushd command; the **popd** command removes entries from the list. The current directory is always the first directory in the stack.

- c** Clears the directory stack by deleting all of the entries.
- l** Produces a listing using full pathnames; the default listing format uses a tilde to denote the home directory.
- p** Print the directory stack with one entry per line.
- v** Print the directory stack with one entry per line, prefixing each entry with its index in the stack.
- +n** Displays the *n*th entry counting from the left of the list shown by **dirs** when invoked without options, starting with zero.
- n** Displays the *n*th entry counting from the right of the list shown by **dirs** when invoked without options, starting with zero.

The return value is 0 unless an invalid option is supplied or *n* indexes beyond the end of the directory stack.

disown [**-ar**] [**-h**] [*jobspec* ... | *pid* ...]

Without options, remove each *jobspec* from the table of active jobs. If *jobspec* is not present, and neither the **-a** nor the **-r** option is supplied, the *current job* is used. If the **-h** option is given, each *jobspec* is not removed from the table, but is marked so that **SIGHUP** is not sent to the job if the shell receives a **SIGHUP**. If no *jobspec* is supplied, the **-a** option means to remove or mark all jobs; the **-r** option without a *jobspec* argument restricts operation to running jobs. The return value is 0 unless a *jobspec* does not specify a valid job.

echo [**-neE**] [*arg* ...]

Output the *args*, separated by spaces, followed by a newline. The return status is 0 unless a write error occurs. If **-n** is specified, the trailing newline is suppressed. If the **-e** option is given, interpretation of the following backslash-escaped characters is enabled. The **-E** option disables the interpretation of these escape characters, even on systems where they are interpreted by default. The **xpg_echo** shell option may be used to dynamically determine whether or not **echo** expands these escape characters by default. **echo** does not interpret -- to mean the end of options. **echo** interprets the following escape sequences:

- \a** alert (bell)
- \b** backspace
- \c** suppress further output
- \e**
- \E** an escape character
- \f** form feed
- \n** new line
- \r** carriage return
- \t** horizontal tab
- \v** vertical tab
- ** backslash
- \0nnn** the eight-bit character whose value is the octal value *nnn* (zero to three octal digits)
- \xHH** the eight-bit character whose value is the hexadecimal value *HH* (one or two hex digits)
- \uHHHH** the Unicode (ISO/IEC 10646) character whose value is the hexadecimal value *HHHH* (one to four hex digits)
- \UHHHHHHHHH** the Unicode (ISO/IEC 10646) character whose value is the hexadecimal value *HHHH-HHH* (one to eight hex digits)

enable [**-a**] [**-dnps**] [**-f** *filename*] [*name* ...]

Enable and disable builtin shell commands. Disabling a builtin allows a disk command which has the same name as a shell builtin to be executed without specifying a full pathname, even though the shell normally searches for builtins before disk commands. If **-n** is used, each *name* is disabled; otherwise, *names* are enabled. For example, to use the **test** binary found via the **PATH**

instead of the shell builtin version, run `enable -n test`. The **-f** option means to load the new builtin command *name* from shared object *filename*, on systems that support dynamic loading. The **-d** option will delete a builtin previously loaded with **-f**. If no *name* arguments are given, or if the **-p** option is supplied, a list of shell builtins is printed. With no other option arguments, the list consists of all enabled shell builtins. If **-n** is supplied, only disabled builtins are printed. If **-a** is supplied, the list printed includes all builtins, with an indication of whether or not each is enabled. If **-s** is supplied, the output is restricted to the POSIX *special* builtins. The return value is 0 unless a *name* is not a shell builtin or there is an error loading a new builtin from a shared object.

eval [*arg* ...]

The *args* are read and concatenated together into a single command. This command is then read and executed by the shell, and its exit status is returned as the value of **eval**. If there are no *args*, or only null arguments, **eval** returns 0.

exec [**-cl**] [**-a** *name*] [*command* [*arguments*]]

If *command* is specified, it replaces the shell. No new process is created. The *arguments* become the arguments to *command*. If the **-l** option is supplied, the shell places a dash at the beginning of the zeroth argument passed to *command*. This is what *login(1)* does. The **-c** option causes *command* to be executed with an empty environment. If **-a** is supplied, the shell passes *name* as the zeroth argument to the executed command. If *command* cannot be executed for some reason, a non-interactive shell exits, unless the **execfail** shell option is enabled. In that case, it returns failure. An interactive shell returns failure if the file cannot be executed. A subshell exits unconditionally if **exec** fails. If *command* is not specified, any redirections take effect in the current shell, and the return status is 0. If there is a redirection error, the return status is 1.

exit [*n*] Cause the shell to exit with a status of *n*. If *n* is omitted, the exit status is that of the last command executed. A trap on **EXIT** is executed before the shell terminates.

export [**-fn**] [*name*[=*word*]] ...
export **-p**

The supplied *names* are marked for automatic export to the environment of subsequently executed commands. If the **-f** option is given, the *names* refer to functions. If no *names* are given, or if the **-p** option is supplied, a list of names of all exported variables is printed. The **-n** option causes the export property to be removed from each *name*. If a variable name is followed by **=word**, the value of the variable is set to *word*. **export** returns an exit status of 0 unless an invalid option is encountered, one of the *names* is not a valid shell variable name, or **-f** is supplied with a *name* that is not a function.

fc [**-e** *ename*] [**-lnr**] [*first*] [*last*]
fc **-s** [*pat=rep*] [*cmd*]

The first form selects a range of commands from *first* to *last* from the history list and displays or edits and re-executes them. *First* and *last* may be specified as a string (to locate the last command beginning with that string) or as a number (an index into the history list, where a negative number is used as an offset from the current command number). When listing, a *first* or *last* of 0 is equivalent to **-1** and **-0** is equivalent to the current command (usually the **fc** command); otherwise 0 is equivalent to **-1** and **-0** is invalid. If *last* is not specified, it is set to the current command for listing (so that **fc -1 -10** prints the last 10 commands) and to *first* otherwise. If *first* is not specified, it is set to the previous command for editing and **-16** for listing.

The **-n** option suppresses the command numbers when listing. The **-r** option reverses the order of the commands. If the **-l** option is given, the commands are listed on standard output. Otherwise, the editor given by *ename* is invoked on a file containing those commands. If *ename* is not given, the value of the **FCEDIT** variable is used, and the value of **EDITOR** if **FCEDIT** is not set. If neither variable is set, **vi** is used. When editing is complete, the edited commands are echoed and executed.

In the second form, *command* is re-executed after each instance of *pat* is replaced by *rep*.

Command is interpreted the same as *first* above. A useful alias to use with this is `r='fc -s'`, so that typing `r cc` runs the last command beginning with `cc` and typing `r` re-executes the last command.

If the first form is used, the return value is 0 unless an invalid option is encountered or *first* or *last* specify history lines out of range. If the `-e` option is supplied, the return value is the value of the last command executed or failure if an error occurs with the temporary file of commands. If the second form is used, the return status is that of the command re-executed, unless *cmd* does not specify a valid history line, in which case `fc` returns failure.

fg [jobspec]

Resume *jobspec* in the foreground, and make it the current job. If *jobspec* is not present, the shell's notion of the *current job* is used. The return value is that of the command placed into the foreground, or failure if run when job control is disabled or, when run with job control enabled, if *jobspec* does not specify a valid job or *jobspec* specifies a job that was started without job control.

getopts optstring name [arg ...]

getopts is used by shell procedures to parse positional parameters. *optstring* contains the option characters to be recognized; if a character is followed by a colon, the option is expected to have an argument, which should be separated from it by white space. The colon and question mark characters may not be used as option characters. Each time it is invoked, **getopts** places the next option in the shell variable *name*, initializing *name* if it does not exist, and the index of the next argument to be processed into the variable **OPTIND**. **OPTIND** is initialized to 1 each time the shell or a shell script is invoked. When an option requires an argument, **getopts** places that argument into the variable **OPTARG**. The shell does not reset **OPTIND** automatically; it must be manually reset between multiple calls to **getopts** within the same shell invocation if a new set of parameters is to be used.

When the end of options is encountered, **getopts** exits with a return value greater than zero. **OPTIND** is set to the index of the first non-option argument, and *name* is set to `?`.

getopts normally parses the positional parameters, but if more arguments are supplied as *arg* values, **getopts** parses those instead.

getopts can report errors in two ways. If the first character of *optstring* is a colon, *silent* error reporting is used. In normal operation, diagnostic messages are printed when invalid options or missing option arguments are encountered. If the variable **OPTERR** is set to 0, no error messages will be displayed, even if the first character of *optstring* is not a colon.

If an invalid option is seen, **getopts** places `?` into *name* and, if not silent, prints an error message and unsets **OPTARG**. If **getopts** is silent, the option character found is placed in **OPTARG** and no diagnostic message is printed.

If a required argument is not found, and **getopts** is not silent, a question mark (`?`) is placed in *name*, **OPTARG** is unset, and a diagnostic message is printed. If **getopts** is silent, then a colon (`:`) is placed in *name* and **OPTARG** is set to the option character found.

getopts returns true if an option, specified or unspecified, is found. It returns false if the end of options is encountered or an error occurs.

hash [-lr] [-p filename] [-dt] [name]

Each time **hash** is invoked, the full pathname of the command *name* is determined by searching the directories in **\$PATH** and remembered. Any previously-remembered pathname is discarded. If the `-p` option is supplied, no path search is performed, and *filename* is used as the full filename of the command. The `-r` option causes the shell to forget all remembered locations. The `-d` option causes the shell to forget the remembered location of each *name*. If the `-t` option is supplied,

the full pathname to which each *name* corresponds is printed. If multiple *name* arguments are supplied with **-t**, the *name* is printed before the hashed full pathname. The **-I** option causes output to be displayed in a format that may be reused as input. If no arguments are given, or if only **-I** is supplied, information about remembered commands is printed. The return status is true unless a *name* is not found or an invalid option is supplied.

help [**-dms**] [*pattern*]

Display helpful information about builtin commands. If *pattern* is specified, **help** gives detailed help on all commands matching *pattern*; otherwise help for all the builtins and shell control structures is printed.

- d** Display a short description of each *pattern*
- m** Display the description of each *pattern* in a manpage-like format
- s** Display only a short usage synopsis for each *pattern*

The return status is 0 unless no command matches *pattern*.

history [*n*]
history -c
history -d *offset*
history -d *start-end*
history -anrw [*filename*]
history -p *arg* [*arg* ...]
history -s *arg* [*arg* ...]

With no options, display the command history list with line numbers. Lines listed with a * have been modified. An argument of *n* lists only the last *n* lines. If the shell variable **HISTTIMEFORMAT** is set and not null, it is used as a format string for *strftime*(3) to display the time stamp associated with each displayed history entry. No intervening blank is printed between the formatted time stamp and the history line. If *filename* is supplied, it is used as the name of the history file; if not, the value of **HISTFILE** is used. Options, if supplied, have the following meanings:

- c** Clear the history list by deleting all the entries.

-d *offset*

Delete the history entry at position *offset*. If *offset* is negative, it is interpreted as relative to one greater than the last history position, so negative indices count back from the end of the history, and an index of -1 refers to the current **history -d** command.

-d *start-end*

Delete the history entries between positions *start* and *end*, inclusive. Positive and negative values for *start* and *end* are interpreted as described above.

- a** Append the “new” history lines to the history file. These are history lines entered since the beginning of the current **bash** session, but not already appended to the history file.

- n** Read the history lines not already read from the history file into the current history list. These are lines appended to the history file since the beginning of the current **bash** session.

- r** Read the contents of the history file and append them to the current history list.

- w** Write the current history list to the history file, overwriting the history file’s contents.

- p** Perform history substitution on the following *args* and display the result on the standard output. Does not store the results in the history list. Each *arg* must be quoted to disable normal history expansion.

- s** Store the *args* in the history list as a single entry. The last command in the history list is removed before the *args* are added.

If the **HISTTIMEFORMAT** variable is set, the time stamp information associated with each history entry is written to the history file, marked with the history comment character. When the history file is read, lines beginning with the history comment character followed immediately by a digit are interpreted as timestamps for the following history entry. The return value is 0 unless an invalid option is encountered, an error occurs while reading or writing the history file, an invalid *offset* is supplied as an argument to **-d**, or the history expansion supplied as an argument to **-p** fails.

jobs [**-l****n****p****r**] [*jobspec* ...]
jobs **-x** *command* [*args* ...]

The first form lists the active jobs. The options have the following meanings:

- l** List process IDs in addition to the normal information.
- n** Display information only about jobs that have changed status since the user was last notified of their status.
- p** List only the process ID of the job's process group leader.
- r** Display only running jobs.
- s** Display only stopped jobs.

If *jobspec* is given, output is restricted to information about that job. The return status is 0 unless an invalid option is encountered or an invalid *jobspec* is supplied.

If the **-x** option is supplied, **jobs** replaces any *jobspec* found in *command* or *args* with the corresponding process group ID, and executes *command* passing it *args*, returning its exit status.

kill [**-s** *sigspec* | **-n** *signum* | **-sig***sigspec*] [*pid* | *jobspec*] ...
kill **-l**|**-L** [*sigspec* | *exit_status*]

Send the signal named by *sigspec* or *signum* to the processes named by *pid* or *jobspec*. *sigspec* is either a case-insensitive signal name such as **SIGKILL** (with or without the **SIG** prefix) or a signal number; *signum* is a signal number. If *sigspec* is not present, then **SIGTERM** is assumed. An argument of **-l** lists the signal names. If any arguments are supplied when **-l** is given, the names of the signals corresponding to the arguments are listed, and the return status is 0. The *exit_status* argument to **-L** is a number specifying either a signal number or the exit status of a process terminated by a signal. The **-L** option is equivalent to **-l**. **kill** returns true if at least one signal was successfully sent, or false if an error occurs or an invalid option is encountered.

let *arg* [*arg* ...]

Each *arg* is an arithmetic expression to be evaluated (see **ARITHMETIC EVALUATION** above). If the last *arg* evaluates to 0, **let** returns 1; 0 is returned otherwise.

local [*option*] [*name*=*value*] ... | -]

For each argument, a local variable named *name* is created, and assigned *value*. The *option* can be any of the options accepted by **declare**. When **local** is used within a function, it causes the variable *name* to have a visible scope restricted to that function and its children. If *name* is -, the set of shell options is made local to the function in which **local** is invoked: shell options changed using the **set** builtin inside the function are restored to their original values when the function returns. The restore is effected as if a series of **set** commands were executed to restore the values that were in place before the function. With no operands, **local** writes a list of local variables to the standard output. It is an error to use **local** when not within a function. The return status is 0 unless **local** is used outside a function, an invalid *name* is supplied, or *name* is a readonly variable.

logout Exit a login shell.

mapfile [**-d** *delim*] [**-n** *count*] [**-O** *origin*] [**-s** *count*] [**-t**] [**-u** *fd*] [**-C** *callback*] [**-c** *quantum*] [*array*]
readarray [**-d** *delim*] [**-n** *count*] [**-O** *origin*] [**-s** *count*] [**-t**] [**-u** *fd*] [**-C** *callback*] [**-c** *quantum*] [*array*]

Read lines from the standard input into the indexed array variable *array*, or from file descriptor *fd* if the **-u** option is supplied. The variable **MAPFILE** is the default *array*. Options, if supplied, have the following meanings:

- d** The first character of *delim* is used to terminate each input line, rather than newline. If *delim* is the empty string, **mapfile** will terminate a line when it reads a NUL character.
- n** Copy at most *count* lines. If *count* is 0, all lines are copied.
- O** Begin assigning to *array* at index *origin*. The default index is 0.
- s** Discard the first *count* lines read.
- t** Remove a trailing *delim* (default newline) from each line read.
- u** Read lines from file descriptor *fd* instead of the standard input.
- C** Evaluate *callback* each time *quantum* lines are read. The **-c** option specifies *quantum*.
- c** Specify the number of lines read between each call to *callback*.

If **-C** is specified without **-c**, the default quantum is 5000. When *callback* is evaluated, it is supplied the index of the next array element to be assigned and the line to be assigned to that element as additional arguments. *callback* is evaluated after the line is read but before the array element is assigned.

If not supplied with an explicit origin, **mapfile** will clear *array* before assigning to it.

mapfile returns successfully unless an invalid option or option argument is supplied, *array* is invalid or unassignable, or if *array* is not an indexed array.

popd [**-n**] [**+n**] [**-n**]

Removes entries from the directory stack. With no arguments, removes the top directory from the stack, and performs a **cd** to the new top directory. Arguments, if supplied, have the following meanings:

- n** Suppresses the normal change of directory when removing directories from the stack, so that only the stack is manipulated.
- +n** Removes the *n*th entry counting from the left of the list shown by **dirs**, starting with zero. For example: **popd +0** removes the first directory, **popd +1** the second.
- n** Removes the *n*th entry counting from the right of the list shown by **dirs**, starting with zero. For example: **popd -0** removes the last directory, **popd -1** the next to last.

If the **popd** command is successful, a **dirs** is performed as well, and the return status is 0. **popd** returns false if an invalid option is encountered, the directory stack is empty, a non-existent directory stack entry is specified, or the directory change fails.

printf [**-v var**] *format* [*arguments*]

Write the formatted *arguments* to the standard output under the control of the *format*. The **-v** option causes the output to be assigned to the variable *var* rather than being printed to the standard output.

The *format* is a character string which contains three types of objects: plain characters, which are simply copied to standard output, character escape sequences, which are converted and copied to the standard output, and format specifications, each of which causes printing of the next successive *argument*. In addition to the standard *printf(1)* format specifications, **printf** interprets the following extensions:

- %b** causes **printf** to expand backslash escape sequences in the corresponding *argument* in the same way as **echo -e**.
- %q** causes **printf** to output the corresponding *argument* in a format that can be reused as shell input.

%(datefmt)T causes **printf** to output the date-time string resulting from using *datefmt* as a format string for *strftime(3)*. The corresponding *argument* is an integer representing the number of seconds since the epoch. Two special argument values may be used: **-1** represents the current time, and **-2** represents the time the shell was invoked. If no argument is specified, conversion behaves as if **-1** had been given. This is an exception to the usual **printf** behavior.

The **%b**, **%q**, and **%T** directives all use the field width and precision arguments from the format specification and write that many bytes from (or use that wide a field for) the expanded argument, which usually contains more characters than the original.

Arguments to non-string format specifiers are treated as C constants, except that a leading plus or minus sign is allowed, and if the leading character is a single or double quote, the value is the ASCII value of the following character.

The *format* is reused as necessary to consume all of the *arguments*. If the *format* requires more *arguments* than are supplied, the extra format specifications behave as if a zero value or null string, as appropriate, had been supplied. The return value is zero on success, non-zero on failure.

pushd [-n] [+n] [-n]
pushd [-n] [dir]

Adds a directory to the top of the directory stack, or rotates the stack, making the new top of the stack the current working directory. With no arguments, **pushd** exchanges the top two directories and returns 0, unless the directory stack is empty. Arguments, if supplied, have the following meanings:

- n Suppresses the normal change of directory when rotating or adding directories to the stack, so that only the stack is manipulated.
- +n Rotates the stack so that the *n*th directory (counting from the left of the list shown by **dirs**, starting with zero) is at the top.
- n Rotates the stack so that the *n*th directory (counting from the right of the list shown by **dirs**, starting with zero) is at the top.
- dir Adds *dir* to the directory stack at the top, making it the new current working directory as if it had been supplied as the argument to the **cd** builtin.

If the **pushd** command is successful, a **dirs** is performed as well. If the first form is used, **pushd** returns 0 unless the **cd** to *dir* fails. With the second form, **pushd** returns 0 unless the directory stack is empty, a non-existent directory stack element is specified, or the directory change to the specified new current directory fails.

pwd [-LP]

Print the absolute pathname of the current working directory. The pathname printed contains no symbolic links if the -P option is supplied or the -o **physical** option to the **set** builtin command is enabled. If the -L option is used, the pathname printed may contain symbolic links. The return status is 0 unless an error occurs while reading the name of the current directory or an invalid option is supplied.

read [-ers] [-a *aname*] [-d *delim*] [-i *text*] [-n *nchars*] [-N *nchars*] [-p *prompt*] [-t *timeout*] [-u *fd*] [*name ...*]

One line is read from the standard input, or from the file descriptor *fd* supplied as an argument to the -u option, split into words as described above under **Word Splitting**, and the first word is assigned to the first *name*, the second word to the second *name*, and so on. If there are more words than names, the remaining words and their intervening delimiters are assigned to the last *name*. If there are fewer words read from the input stream than names, the remaining names are assigned empty values. The characters in **IFS** are used to split the line into words using the same rules the shell uses for expansion (described above under **Word Splitting**). The backslash character (\) may be used to remove any special meaning for the next character read and for line continuation. Options, if supplied, have the following meanings:

-a *aname*

The words are assigned to sequential indices of the array variable *aname*, starting at 0. *aname* is unset before any new values are assigned. Other *name* arguments are ignored.

-d *delim*

The first character of *delim* is used to terminate the input line, rather than newline. If *delim* is the empty string, **read** will terminate a line when it reads a NUL character.

-e If the standard input is coming from a terminal, **readline** (see **READLINE** above) is used to obtain the line. Readline uses the current (or default, if line editing was not previously active) editing settings, but uses Readline's default filename completion.

-i *text* If **readline** is being used to read the line, *text* is placed into the editing buffer before editing begins.

-n *nchars*

read returns after reading *nchars* characters rather than waiting for a complete line of input, but honors a delimiter if fewer than *nchars* characters are read before the delimiter.

-N *nchars*

read returns after reading exactly *nchars* characters rather than waiting for a complete line of input, unless EOF is encountered or **read** times out. Delimiter characters encountered in the input are not treated specially and do not cause **read** to return until *nchars*

characters are read. The result is not split on the characters in **IFS**; the intent is that the variable is assigned exactly the characters read (with the exception of backslash; see the **-r** option below).

-p *prompt*

Display *prompt* on standard error, without a trailing newline, before attempting to read any input. The prompt is displayed only if input is coming from a terminal.

-r

Backslash does not act as an escape character. The backslash is considered to be part of the line. In particular, a backslash-newline pair may not then be used as a line continuation.

-s

Silent mode. If input is coming from a terminal, characters are not echoed.

-t *timeout*

Cause **read** to time out and return failure if a complete line of input (or a specified number of characters) is not read within *timeout* seconds. *timeout* may be a decimal number with a fractional portion following the decimal point. This option is only effective if **read** is reading input from a terminal, pipe, or other special file; it has no effect when reading from regular files. If **read** times out, **read** saves any partial input read into the specified variable *name*. If *timeout* is 0, **read** returns immediately, without trying to read any data. The exit status is 0 if input is available on the specified file descriptor, non-zero otherwise. The exit status is greater than 128 if the timeout is exceeded.

-u *fd*

Read input from file descriptor *fd*.

If no *names* are supplied, the line read, without the ending delimiter but otherwise unmodified, is assigned to the variable **REPLY**. The exit status is zero, unless end-of-file is encountered, **read** times out (in which case the status is greater than 128), a variable assignment error (such as assigning to a readonly variable) occurs, or an invalid file descriptor is supplied as the argument to **-u**.

readonly [**-aAf**] [**-p**] [*name[=word]* ...]

The given *names* are marked readonly; the values of these *names* may not be changed by subsequent assignment. If the **-f** option is supplied, the functions corresponding to the *names* are so marked. The **-a** option restricts the variables to indexed arrays; the **-A** option restricts the variables to associative arrays. If both options are supplied, **-A** takes precedence. If no *name* arguments are given, or if the **-p** option is supplied, a list of all readonly names is printed. The other options may be used to restrict the output to a subset of the set of readonly names. The **-p** option causes output to be displayed in a format that may be reused as input. If a variable name is followed by *=word*, the value of the variable is set to *word*. The return status is 0 unless an invalid option is encountered, one of the *names* is not a valid shell variable name, or **-f** is supplied with a *name* that is not a function.

return [*n*]

Causes a function to stop executing and return the value specified by *n* to its caller. If *n* is omitted, the return status is that of the last command executed in the function body. If **r** **eturn** is executed by a trap handler, the last command used to determine the status is the last command executed before the trap handler. If **r** **eturn** is executed during a **DEBUG** trap, the last command used to determine the status is the last command executed by the trap handler before **return** was invoked. If **return** is used outside a function, but during execution of a script by the **. (source)** command, it causes the shell to stop executing that script and return either *n* or the exit status of the last command executed within the script as the exit status of the script. If *n* is supplied, the return value is its least significant 8 bits. The return status is non-zero if **return** is supplied a non-numeric argument, or is used outside a function and not during execution of a script by **.** or **source**. Any command associated with the **RETURN** trap is executed before execution resumes after the function or script.

set [--**a****b****e****f****h****k****m****n****p****t****u****v****x****B****C****E****H****P****T**] [**-o** *option-name*] [*arg* ...]

set [+**a****b****e****f****h****k****m****n****p****t****u****v****x****B****C****E****H****P****T**] [**+o** *option-name*] [*arg* ...]

Without options, the name and value of each shell variable are displayed in a format that can be reused as input for setting or resetting the currently-set variables. Read-only variables cannot be

reset. In *Posix mode*, only shell variables are listed. The output is sorted according to the current locale. When options are specified, they set or unset shell attributes. Any arguments remaining after option processing are treated as values for the positional parameters and are assigned, in order, to **\$1**, **\$2**, ... **\$n**. Options, if specified, have the following meanings:

- a** Each variable or function that is created or modified is given the **export** attribute and marked for export to the environment of subsequent commands.
- b** Report the status of terminated background jobs immediately, rather than before the next primary prompt. This is effective only when job control is enabled.
- e** Exit immediately if a *pipeline* (which may consist of a single *simple command*), a *list*, or a *compound command* (see **SHELL GRAMMAR** above), exits with a non-zero status. The shell does not exit if the command that fails is part of the command list immediately following a **while** or **until** keyword, part of the test following the **if** or **elif** reserved words, part of any command executed in a **&&** or **||** list except the command following the final **&&** or **||**, any command in a pipeline but the last, or if the command's return value is being inverted with **!**. If a compound command other than a subshell returns a non-zero status because a command failed while **-e** was being ignored, the shell does not exit. A trap on **ERR**, if set, is executed before the shell exits. This option applies to the shell environment and each subshell environment separately (see **COMMAND EXECUTION ENVIRONMENT** above), and may cause subshells to exit before executing all the commands in the subshell.

If a compound command or shell function executes in a context where **-e** is being ignored, none of the commands executed within the compound command or function body will be affected by the **-e** setting, even if **-e** is set and a command returns a failure status. If a compound command or shell function sets **-e** while executing in a context where **-e** is ignored, that setting will not have any effect until the compound command or the command containing the function call completes.

- f** Disable pathname expansion.
- h** Remember the location of commands as they are looked up for execution. This is enabled by default.
- k** All arguments in the form of assignment statements are placed in the environment for a command, not just those that precede the command name.
- m** Monitor mode. Job control is enabled. This option is on by default for interactive shells on systems that support it (see **JOB CONTROL** above). All processes run in a separate process group. When a background job completes, the shell prints a line containing its exit status.
- n** Read commands but do not execute them. This may be used to check a shell script for syntax errors. This is ignored by interactive shells.

-o *option-name*

The *option-name* can be one of the following:

allexport

Same as **-a**.

braceexpand

Same as **-B**.

emacs Use an emacs-style command line editing interface. This is enabled by default when the shell is interactive, unless the shell is started with the **--noediting** option. This also affects the editing interface used for **read -e**.

errexit Same as **-e**.

errtrace Same as **-E**.

functrace

Same as **-T**.

hashall Same as **-h**.

histexpand

Same as **-H**.

history Enable command history, as described above under **HISTORY**. This option is on by default in interactive shells.

ignoreeof

The effect is as if the shell command `IGNOREEOF=10` had been executed (see **Shell Variables** above).

keyword

Same as **-k**.

monitor Same as **-m**.

noclobber

Same as **-C**.

noexec Same as **-n**.

noglob Same as **-f**.

nolog Currently ignored.

notify Same as **-b**.

nounset Same as **-u**.

onecmd Same as **-t**.

physical Same as **-P**.

pipefail If set, the return value of a pipeline is the value of the last (rightmost) command to exit with a non-zero status, or zero if all commands in the pipeline exit successfully. This option is disabled by default.

posix Change the behavior of **bash** where the default operation differs from the POSIX standard to match the standard (*posix mode*). See **SEE ALSO** below for a reference to a document that details how posix mode affects bash's behavior.

privileged

Same as **-p**.

verbose Same as **-v**.

vi Use a vi-style command line editing interface. This also affects the editing interface used for **read -e**.

xtrace Same as **-x**.

If **-o** is supplied with no *option-name*, the values of the current options are printed. If **+o** is supplied with no *option-name*, a series of **set** commands to recreate the current option settings is displayed on the standard output.

-p Turn on *privileged* mode. In this mode, the **\$ENV** and **\$BASH_ENV** files are not processed, shell functions are not inherited from the environment, and the **SHELLOPTS**, **BASHOPTS**, **CDPATH**, and **GLOBIGNORE** variables, if they appear in the environment, are ignored. If the shell is started with the effective user (group) id not equal to the real user (group) id, and the **-p** option is not supplied, these actions are taken and the effective user id is set to the real user id. If the **-p** option is supplied at startup, the effective user id is not reset. Turning this option off causes the effective user and group ids to be set to the real user and group ids.

-t Exit after reading and executing one command.

-u Treat unset variables and parameters other than the special parameters "@" and "*" as an error when performing parameter expansion. If expansion is attempted on an unset variable or parameter, the shell prints an error message, and, if not interactive, exits with a non-zero status.

-v Print shell input lines as they are read.

-x After expanding each *simple command*, **for** command, **case** command, **select** command, or arithmetic **for** command, display the expanded value of **PS4**, followed by the command and its expanded arguments or associated word list.

-B The shell performs brace expansion (see **Brace Expansion** above). This is on by default.

-C If set, **bash** does not overwrite an existing file with the **>**, **>&**, and **<>** redirection operators. This may be overridden when creating output files by using the redirection

- operator `>|` instead of `>`.
- E** If set, any trap on **ERR** is inherited by shell functions, command substitutions, and commands executed in a subshell environment. The **ERR** trap is normally not inherited in such cases.
- H** Enable ! style history substitution. This option is on by default when the shell is interactive.
- P** If set, the shell does not resolve symbolic links when executing commands such as **cd** that change the current working directory. It uses the physical directory structure instead. By default, **bash** follows the logical chain of directories when performing commands which change the current directory.
- T** If set, any traps on **DEBUG** and **RETURN** are inherited by shell functions, command substitutions, and commands executed in a subshell environment. The **DEB UG** and **RETURN** traps are normally not inherited in such cases.
- If no arguments follow this option, then the positional parameters are unset. Otherwise, the positional parameters are set to the *args*, even if some of them begin with a `-`.
- Signal the end of options, cause all remaining *args* to be assigned to the positional parameters. The **-x** and **-v** options are turned off. If there are *no args*, the positional parameters remain unchanged.

The options are off by default unless otherwise noted. Using + rather than – causes these options to be turned off. The options can also be specified as arguments to an invocation of the shell. The current set of options may be found in `$-`. The return status is always true unless an invalid option is encountered.

shift [*n*]

The positional parameters from *n+1* ... are renamed to **\$1** Parameters represented by the numbers `$#` down to `$#-n+1` are unset. *n* must be a non-negative number less than or equal to `$#`. If *n* is 0, no parameters are changed. If *n* is not given, it is assumed to be 1. If *n* is greater than `$#`, the positional parameters are not changed. The return status is greater than zero if *n* is greater than `$#` or less than zero; otherwise 0.

shopt [**-pqsu**] [**-o**] [*optname* ...]

Toggle the values of settings controlling optional shell behavior. The settings can be either those listed below, or, if the **-o** option is used, those available with the **-o** option to the **set** builtin command. With no options, or with the **-p** option, a list of all settable options is displayed, with an indication of whether or not each is set; if *optnames* are supplied, the output is restricted to those options. The **-p** option causes output to be displayed in a form that may be reused as input. Other options have the following meanings:

- s** Enable (set) each *optname*.
- u** Disable (unset) each *optname*.
- q** Suppresses normal output (quiet mode); the return status indicates whether the *optname* is set or unset. If multiple *optname* arguments are given with **-q**, the return status is zero if all *optnames* are enabled; non-zero otherwise.
- o** Restricts the values of *optname* to be those defined for the **-o** option to the **set** builtin.

If either **-s** or **-u** is used with no *optname* arguments, **shopt** shows only those options which are set or unset, respectively. Unless otherwise noted, the **shopt** options are disabled (unset) by default.

The return status when listing options is zero if all *optnames* are enabled, non-zero otherwise. When setting or unsetting options, the return status is zero unless an *optname* is not a valid shell option.

The list of **shopt** options is:

assoc_expand_once

If set, the shell suppresses multiple evaluation of associative array subscripts during arithmetic expression evaluation, while executing builtins that can perform variable assignments, and while executing builtins that perform array dereferencing.

autocd If set, a command name that is the name of a directory is executed as if it were the argument to the **cd** command. This option is only used by interactive shells.

cdable_vars

If set, an argument to the **cd** builtin command that is not a directory is assumed to be the name of a variable whose value is the directory to change to.

cdspell If set, minor errors in the spelling of a directory component in a **cd** command will be corrected. The errors checked for are transposed characters, a missing character, and one character too many. If a correction is found, the corrected filename is printed, and the command proceeds. This option is only used by interactive shells.

checkhash

If set, **bash** checks that a command found in the hash table exists before trying to execute it. If a hashed command no longer exists, a normal path search is performed.

checkjobs

If set, **bash** lists the status of any stopped and running jobs before exiting an interactive shell. If any jobs are running, this causes the exit to be deferred until a second exit is attempted without an intervening command (see **JOB CONTROL** above). The shell always postpones exiting if any jobs are stopped.

checkwinsize

If set, **bash** checks the window size after each external (non-builtin) command and, if necessary, updates the values of **INES** and **COLUMNS**. This option is enabled by default.

cmdhist If set, **bash** attempts to save all lines of a multiple-line command in the same history entry. This allows easy re-editing of multi-line commands. This option is enabled by default, but only has an effect if command history is enabled, as described above under **HISTORY**.

compat31

compat32

compat40

compat41

compat42

compat43

compat44

These control aspects of the shell's compatibility mode (see **SHELL COMPATIBILITY MODE** below).

complete_fullquote

If set, **bash** quotes all shell metacharacters in filenames and directory names when performing completion. If not set, **bash** removes metacharacters such as the dollar sign from the set of characters that will be quoted in completed filenames when these metacharacters appear in shell variable references in words to be completed. This means that dollar signs in variable names that expand to directories will not be quoted; however, any dollar signs appearing in filenames will not be quoted, either. This is active only when bash is using backslashes to quote completed filenames. This variable is set by default, which is the default bash behavior in versions through 4.2.

direxpand

If set, **bash** replaces directory names with the results of word expansion when performing filename completion. This changes the contents of the readline editing buffer. If not set, **bash** attempts to preserve what the user typed.

dirspell If set, **bash** attempts spelling correction on directory names during word completion if the directory name initially supplied does not exist.

dotglob If set, **bash** includes filenames beginning with a ‘.’ in the results of pathname expansion. The filenames “.” and “..” must always be matched explicitly, even if **dotglob** is set.

execfail If set, a non-interactive shell will not exit if it cannot execute the file specified as an argument to the **exec** builtin command. An interactive shell does not exit if **exec** fails.

expand_aliases

If set, aliases are expanded as described above under **ALIASES**. This option is enabled by default for interactive shells.

extdebug

If set at shell invocation, or in a shell startup file, arrange to execute the debugger profile before the shell starts, identical to the **--debugger** option. If set after invocation, behavior intended for use by debuggers is enabled:

1. The **-F** option to the **declare** builtin displays the source file name and line number corresponding to each function name supplied as an argument.
2. If the command run by the **DEBUG** trap returns a non-zero value, the next command is skipped and not executed.
3. If the command run by the **DEBUG** trap returns a value of 2, and the shell is executing in a subroutine (a shell function or a shell script executed by the **.** or **source** builtins), the shell simulates a call to **return**.
4. **BASH_ARGC** and **BASH_ARGV** are updated as described in their descriptions above.
5. Function tracing is enabled: command substitution, shell functions, and subshells invoked with (*command*) inherit the **DEBUG** and **RETURN** traps.
6. Error tracing is enabled: command substitution, shell functions, and subshells invoked with (*command*) inherit the **ERR** trap.

extglob If set, the extended pattern matching features described above under **Pathname Expansion** are enabled.

extquote

If set, `$'string'` and `$$"string"` quoting is performed within `$(parameter)` expansions enclosed in double quotes. This option is enabled by default.

failglob If set, patterns which fail to match filenames during pathname expansion result in an expansion error.

force_ignore

If set, the suffixes specified by the **IGNORE** shell variable cause words to be ignored when performing word completion even if the ignored words are the only possible completions. See **SHELL VARIABLES** above for a description of **IGNORE**. This option is enabled by default.

globasciiranges

If set, range expressions used in pattern matching bracket expressions (see **Pattern Matching** above) behave as if in the traditional C locale when performing comparisons. That is, the current locale's collating sequence is not taken into account, so **b** will not collate between **A** and **B**, and upper-case and lower-case ASCII characters will collate together.

globstar If set, the pattern ****** used in a pathname expansion context will match all files and zero or more directories and subdirectories. If the pattern is followed by a **/**, only directories and subdirectories match.

gnu_errfmt

If set, shell error messages are written in the standard GNU error message format.

histappend

If set, the history list is appended to the file named by the value of the **HISTFILE** variable when the shell exits, rather than overwriting the file.

histreedit

If set, and **readline** is being used, a user is given the opportunity to re-edit a failed history substitution.

histverify

If set, and **readline** is being used, the results of history substitution are not immediately passed to the shell parser. Instead, the resulting line is loaded into the **readline** editing buffer, allowing further modification.

hostcomplete

If set, and **readline** is being used, **bash** will attempt to perform hostname completion when a word containing a @ is being completed (see **Completing under READLINE** above). This is enabled by default.

huponexit

If set, **bash** will send **SIGHUP** to all jobs when an interactive login shell exits.

inherit_errexit

If set, command substitution inherits the value of the **errexit** option, instead of unsetting it in the subshell environment. This option is enabled when *posix mode* is enabled.

interactive_comments

If set, allow a word beginning with # to cause that word and all remaining characters on that line to be ignored in an interactive shell (see **COMMENTS** above). This option is enabled by default.

lastpipe If set, and job control is not active, the shell runs the last command of a pipeline not executed in the background in the current shell environment.

lithist If set, and the **cmdhist** option is enabled, multi-line commands are saved to the history with embedded newlines rather than using semicolon separators where possible.

localvar_inherit

If set, local variables inherit the value and attributes of a variable of the same name that exists at a previous scope before any new value is assigned. The **nameref** attribute is not inherited.

localvar_unset

If set, calling **unset** on local variables in previous function scopes marks them so subsequent lookups find them unset until that function returns. This is identical to the behavior of unsetting local variables at the current function scope.

login_shell

The shell sets this option if it is started as a login shell (see **INVOCATION** above). The value may not be changed.

mailwarn

If set, and a file that **bash** is checking for mail has been accessed since the last time it was checked, the message “The mail in *mailfile* has been read” is displayed.

no_empty_cmd_completion

If set, and **readline** is being used, **bash** will not attempt to search the **PATH** for possible completions when completion is attempted on an empty line.

nocaseglob

If set, **bash** matches filenames in a case-insensitive fashion when performing pathname expansion (see **Pathname Expansion** above).

nocasematch

If set, **bash** matches patterns in a case-insensitive fashion when performing matching while executing **case** or [[conditional commands, when performing pattern substitution word expansions, or when filtering possible completions as part of programmable completion.

nullglob

If set, **bash** allows patterns which match no files (see **Pathname Expansion** above) to expand to a null string, rather than themselves.

progcomp

If set, the programmable completion facilities (see **Programmable Completion** above) are enabled. This option is enabled by default.

progcomp_alias

If set, and programmable completion is enabled, **bash** treats a command name that doesn't have any completions as a possible alias and attempts alias expansion. If it has an alias, **bash** attempts programmable completion using the command word resulting from the expanded alias.

promptvars

If set, prompt strings undergo parameter expansion, command substitution, arithmetic expansion, and quote removal after being expanded as described in **PROMPTING** above. This option is enabled by default.

restricted_shell

The shell sets this option if it is started in restricted mode (see **RESTRICTED SHELL** below). The value may not be changed. This is not reset when the startup files are executed, allowing the startup files to discover whether or not a shell is restricted.

shift_verbose

If set, the **shift** builtin prints an error message when the shift count exceeds the number of positional parameters.

sourcepath

If set, the **source** (.) builtin uses the value of **PATH** to find the directory containing the file supplied as an argument. This option is enabled by default.

xpg_echo

If set, the **echo** builtin expands backslash-escape sequences by default.

suspend [-f]

Suspend the execution of this shell until it receives a **SIGCONT** signal. A login shell cannot be suspended; the **-f** option can be used to override this and force the suspension. The return status is 0 unless the shell is a login shell and **-f** is not supplied, or if job control is not enabled.

test expr

[*expr*] Return a status of 0 (true) or 1 (false) depending on the evaluation of the conditional expression *expr*. Each operator and operand must be a separate argument. Expressions are composed of the primaries described above under **CONDITIONAL EXPRESSIONS**. **test** does not accept an **y** options, nor does it accept and ignore an argument of **--** as signifying the end of options.

Expressions may be combined using the following operators, listed in decreasing order of precedence. The evaluation depends on the number of arguments; see below. Operator precedence is used when there are five or more arguments.

! *expr* True if *expr* is false.

(*expr*) Returns the value of *expr*. This may be used to override the normal precedence of operators.

expr1* -a *expr2

True if both *expr1* and *expr2* are true.

expr1* -o *expr2

True if either *expr1* or *expr2* is true.

test and [evaluate conditional expressions using a set of rules based on the number of arguments.

0 arguments

The expression is false.

1 argument

The expression is true if and only if the argument is not null.

2 arguments

If the first argument is **!**, the expression is true if and only if the second argument is null. If the first argument is one of the unary conditional operators listed above under **CONDITIONAL EXPRESSIONS**, the expression is true if the unary test is true. If the first argument is not a valid unary conditional operator, the expression is false.

3 arguments

The following conditions are applied in the order listed. If the second argument is one of the binary conditional operators listed above under **CONDITIONAL EXPRESSIONS**, the result of the expression is the result of the binary test using the first and third arguments as operands. The **-a** and **-o** operators are considered binary operators when there are three arguments. If the first argument is **!**, the value is the negation of the two-argument test using the second and third arguments. If the first argument is exactly **(** and the third argument is exactly **)**, the result is the one-argument test of the second argument. Otherwise, the expression is false.

4 arguments

If the first argument is **!**, the result is the negation of the three-argument expression composed of the remaining arguments. Otherwise, the expression is parsed and evaluated according to precedence using the rules listed above.

5 or more arguments

The expression is parsed and evaluated according to precedence using the rules listed above.

When used with **test** or **[**, the **<** and **>** operators sort lexicographically using ASCII ordering.

times Print the accumulated user and system times for the shell and for processes run from the shell. The return status is 0.

trap [-lp] [[arg] sigspec ...]

The command *arg* is to be read and executed when the shell receives signal(s) *sigspec*. If *arg* is absent (and there is a single *sigspec*) or **-**, each specified signal is reset to its original disposition (the value it had upon entrance to the shell). If *arg* is the null string the signal specified by each *sigspec* is ignored by the shell and by the commands it invokes. If *arg* is not present and **-p** has been supplied, then the trap commands associated with each *sigspec* are displayed. If no arguments are supplied or if only **-p** is given, **trap** prints the list of commands associated with each signal. The **-l** option causes the shell to print a list of signal names and their corresponding numbers. Each *sigspec* is either a signal name defined in *<signal.h>*, or a signal number. Signal names are case insensitive and the **SIG** prefix is optional.

If a *sigspec* is **EXIT** (0) the command *arg* is executed on exit from the shell. If a *sigspec* is **DEBUG**, the command *arg* is executed before every *simple command*, *for* command, *case* command, *select* command, every arithmetic *for* command, and before the first command executes in a shell function (see **SHELL GRAMMAR** above). Refer to the description of the **extdeb ug** option to the **shopt** builtin for details of its effect on the **DEBUG** trap. If a *sigspec* is **RETURN**, the command *arg* is executed each time a shell function or a script executed with the **.** or **source** builtins finishes executing.

If a *sigspec* is **ERR**, the command *arg* is executed whenever a pipeline (which may consist of a single simple command), a list, or a compound command returns a non-zero exit status, subject to the following conditions. The **ERR** trap is not executed if the failed command is part of the command list immediately following a **while** or **until** keyword, part of the test in an **if** statement, part of a command executed in a **&&** or **||** list except the command following the final **&&** or **||**, any command in a pipeline but the last, or if the command's return value is being inverted using **!**. These are the same conditions obeyed by the **errexit** (**-e**) option.

Signals ignored upon entry to the shell cannot be trapped or reset. Trapped signals that are not being ignored are reset to their original values in a subshell or subshell environment when one is created. The return status is false if any *sigspec* is invalid; otherwise **trap** returns true.

type [**-a****f****t****P**] *name* [*name* ...]

With no options, indicate how each *name* would be interpreted if used as a command name. If the **-t** option is used, **type** prints a string which is one of *alias*, *keyword*, *function*, *builtin*, or *file* if *name* is an alias, shell reserved word, function, builtin, or disk file, respectively. If the *name* is not found, then nothing is printed, and an exit status of false is returned. If the **-p** option is used, **type** either returns the name of the disk file that would be executed if *name* were specified as a command name, or nothing if **type -t name** would not return *file*. The **-P** option forces a **P ATH** search for each *name*, even if **type -t name** would not return *file*. If a command is hashed, **-p** and **-P** print the hashed value, which is not necessarily the file that appears first in **PATH**. If the **-a** option is used, **type** prints all of the places that contain an executable named *name*. This includes aliases and functions, if and only if the **-p** option is not also used. The table of hashed commands is not consulted when using **-a**. The **-f** option suppresses shell function lookup, as with the **command** builtin. **type** returns true if all of the arguments are found, false if any are not found.

ulimit [**-HS**] **-a**
ulimit [**-HS**] [**-bcdefiklmnpqrstuvxPRT** [*limit*]]

Provides control over the resources available to the shell and to processes started by it, on systems that allow such control. The **-H** and **-S** options specify that the hard or soft limit is set for the given resource. A hard limit cannot be increased by a non-root user once it is set; a soft limit may be increased up to the value of the hard limit. If neither **-H** nor **-S** is specified, both the soft and hard limits are set. The value of *limit* can be a number in the unit specified for the resource or one of the special values **hard**, **soft**, or **unlimited**, which stand for the current hard limit, the current soft limit, and no limit, respectively. If *limit* is omitted, the current value of the soft limit of the resource is printed, unless the **-H** option is given. When more than one resource is specified, the limit name and unit, if appropriate, are printed before the value. Other options are interpreted as follows:

- a** All current limits are reported; no limits are set
- b** The maximum socket buffer size
- c** The maximum size of core files created
- d** The maximum size of a process's data segment
- e** The maximum scheduling priority ("nice")
- f** The maximum size of files written by the shell and its children
- i** The maximum number of pending signals
- k** The maximum number of kqueues that may be allocated
- l** The maximum size that may be locked into memory
- m** The maximum resident set size (many systems do not honor this limit)
- n** The maximum number of open file descriptors (most systems do not allow this value to be set)
- p** The pipe size in 512-byte blocks (this may not be set)
- q** The maximum number of bytes in POSIX message queues
- r** The maximum real-time scheduling priority
- s** The maximum stack size
- t** The maximum amount of cpu time in seconds
- u** The maximum number of processes available to a single user
- v** The maximum amount of virtual memory available to the shell and, on some systems, to its children
- x** The maximum number of file locks
- P** The maximum number of pseudoterminals
- R** The maximum time a real-time process can run before blocking, in microseconds
- T** The maximum number of threads

If *limit* is given, and the **-a** option is not used, *limit* is the new value of the specified resource. If no option is given, then **-f** is assumed. Values are in 1024-byte increments, except for **-t**, which is in seconds; **-R**, which is in microseconds; **-p**, which is in units of 512-byte blocks; **-P**, **-T**, **-b**, **-k**, **-n**, and **-u**, which are unscaled values; and, when in posix mode, **-c** and **-f**, which are in 512-byte increments. The return status is 0 unless an invalid option or argument is supplied, or an error occurs while setting a new limit.

umask [**-p**] [**-S**] [*mode*]

The user file-creation mask is set to *mode*. If *mode* begins with a digit, it is interpreted as an octal number; otherwise it is interpreted as a symbolic mode mask similar to that accepted by *chmod(1)*. If *mode* is omitted, the current value of the mask is printed. The **-S** option causes the mask to be printed in symbolic form; the default output is an octal number. If the **-p** option is supplied, and *mode* is omitted, the output is in a form that may be reused as input. The return status is 0 if the mode was successfully changed or if no *mode* argument was supplied, and false otherwise.

unalias [**-a**] [*name* ...]

Remove each *name* from the list of defined aliases. If **-a** is supplied, all alias definitions are removed. The return value is true unless a supplied *name* is not a defined alias.

unset [**-fv**] [**-n**] [*name* ...]

For each *name*, remove the corresponding variable or function. If the **-v** option is given, each *name* refers to a shell variable, and that variable is removed. Read-only variables may not be unset. If **-f** is specified, each *name* refers to a shell function, and the function definition is removed. If the **-n** option is supplied, and *name* is a variable with the *nameref* attribute, *name* will be unset rather than the variable it references. **-n** has no effect if the **-f** option is supplied. If no options are supplied, each *name* refers to a variable; if there is no variable by that name, a function with that name, if any, is unset. Each unset variable or function is removed from the environment passed to subsequent commands. If any of **BASH_ALIASES**, **BASH_ARGV0**, **BASH_CMDS**, **BASH_COMMAND**, **BASH_SUBSHELL**, **BASHPID**, **COMP_WORDBREAKS**, **DIRSTACK**, **EPOCHREALTIME**, **EPOCHSECONDS**, **FUNCNAME**, **GROUPS**, **HISTCMD**, **LINENO**, **RANDOM**, **SECONDS**, or **RANDOM** are unset, they lose their special properties, even if they are subsequently reset. The exit status is true unless a *name* is readonly.

wait [**-fn**] [**-p** *varname*] [*id* ...]

Wait for each specified child process and return its termination status. Each *id* may be a process ID or a job specification; if a job spec is given, all processes in that job's pipeline are waited for. If *id* is not given, **wait** waits for all running background jobs and the last-executed process substitution, if its process id is the same as **!\$!**, and the return status is zero. If the **-n** option is supplied, **wait** waits for a single job from the list of *ids* or, if no *ids* are supplied, any job, to complete and returns its exit status. If none of the supplied arguments is a child of the shell, or if no arguments are supplied and the shell has no unwaited-for children, the exit status is 127. If the **-p** option is supplied, the process or job identifier of the job for which the exit status is returned is assigned to the variable *varname* named by the option argument. The variable will be unset initially, before any assignment. This is useful only when the **-n** option is supplied. Supplying the **-f** option, when job control is enabled, forces **wait** to wait for *id* to terminate before returning its status, instead of returning when it changes status. If *id* specifies a non-existent process or job, the return status is 127. Otherwise, the return status is the exit status of the last process or job waited for.

SHELL COMPATIBILITY MODE

Bash-4.0 introduced the concept of a ‘shell compatibility level’, specified as a set of options to the shopt builtin **compat31**, **compat32**, **compat40**, **compat41**, and so on). There is only one current compatibility level -- each option is mutually exclusive. The compatibility level is intended to allow users to select behavior from previous versions that is incompatible with newer versions while they migrate scripts to use current features and behavior. It’s intended to be a temporary solution.

This section does not mention behavior that is standard for a particular version (e.g., setting **compat32** means that quoting the rhs of the regexp matching operator quotes special regexp characters in the word, which is default behavior in bash-3.2 and above).

If a user enables, say, **compat32**, it may affect the behavior of other compatibility levels up to and including the current compatibility level. The idea is that each compatibility level controls behavior that changed in that version of **bash**, but that behavior may have been present in earlier versions. For instance, the change to use locale-based comparisons with the `[[` command came in bash-4.1, and earlier versions used ASCII-based comparisons, so enabling **compat32** will enable ASCII-based comparisons as well. That granularity may not be sufficient for all uses, and as a result users should employ compatibility levels carefully. Read the documentation for a particular feature to find out the current behavior.

Bash-4.3 introduced a new shell variable: **BASH_COMPAT**. The value assigned to this variable (a decimal version number like 4.2, or an integer corresponding to the **compatNN** option, like 42) determines the compatibility level.

Starting with bash-4.4, Bash has begun deprecating older compatibility levels. Eventually, the options will be removed in favor of **BASH_COMPAT**.

Bash-5.0 is the final version for which there will be an individual shopt option for the previous version. Users should use **BASH_COMPAT** on bash-5.0 and later versions.

The following table describes the behavior changes controlled by each compatibility level setting. The **compatNN** tag is used as shorthand for setting the compatibility level to *NN* using one of the following mechanisms. For versions prior to bash-5.0, the compatibility level may be set using the corresponding **compatNN** shopt option. For bash-4.3 and later versions, the **BASH_COMPAT** variable is preferred, and it is required for bash-5.1 and later versions.

compat31

- quoting the rhs of the `[[` command's regexp matching operator (`=~`) has no special effect

compat32

- interrupting a command list such as "a ; b ; c" causes the execution of the next command in the list (in bash-4.0 and later versions, the shell acts as if it received the interrupt, so interrupting one command in a list aborts the execution of the entire list)

compat40

- the `<` and `>` operators to the `[[` command do not consider the current locale when comparing strings; they use ASCII ordering. Bash versions prior to bash-4.1 use ASCII collation and *strcmp(3)*; bash-4.1 and later use the current locale's collation sequence and *strcoll(3)*.

compat41

- in *posix* mode, **time** may be followed by options and still be recognized as a reserved word (this is POSIX interpretation 267)
- in *posix* mode, the parser requires that an even number of single quotes occur in the *word* portion of a double-quoted parameter expansion and treats them specially, so that characters within the single quotes are considered quoted (this is POSIX interpretation 221)

compat42

- the replacement string in double-quoted pattern substitution does not undergo quote removal, as it does in versions after bash-4.2
- in *posix* mode, single quotes are considered special when expanding the *word* portion of a double-quoted parameter expansion and can be used to quote a closing brace or other special character (this is part of POSIX interpretation 221); in later versions, single quotes are not special within double-quoted word expansions

compat43

- the shell does not print a warning message if an attempt is made to use a quoted compound assignment as an argument to declare (declare -a foo='(1 2)'). Later versions warn that this usage is deprecated
- word expansion errors are considered non-fatal errors that cause the current command to fail, even in *posix* mode (the default behavior is to make them fatal errors that cause the shell to exit)

- when executing a shell function, the loop state (while/until/etc.) is not reset, so **break** or **continue** in that function will break or continue loops in the calling context. Bash-4.4 and later reset the loop state to prevent this

compat44

- the shell sets up the values used by **BASH_ARGV** and **BASH_ARGC** so they can expand to the shell's positional parameters even if extended debugging mode is not enabled
- a subshell inherits loops from its parent context, so **break** or **continue** will cause the subshell to exit. Bash-5.0 and later reset the loop state to prevent the exit
- variable assignments preceding builtins like **export** and **readonly** that set attributes continue to affect variables with the same name in the calling environment even if the shell is not in posix mode

compat50

- Bash-5.1 changed the way **\$RANDOM** is generated to introduce slightly more randomness. If the shell compatibility level is set to 50 or lower, it reverts to the method from bash-5.0 and previous versions, so seeding the random number generator by assigning a value to **RANDOM** will produce the same sequence as in bash-5.0
- If the command hash table is empty, bash versions prior to bash-5.1 printed an informational message to that effect, even when producing output that can be reused as input. Bash-5.1 suppresses that message when the **-I** option is supplied.

RESTRICTED SHELL

If **bash** is started with the name **rbash**, or the **-r** option is supplied at invocation, the shell becomes restricted. A restricted shell is used to set up an environment more controlled than the standard shell. It behaves identically to **bash** with the exception that the following are disallowed or not performed:

- changing directories with **cd**
- setting or unsetting the values of **SHELL**, **PATH**, **HISTFILE**, **ENV**, or **BASH_ENV**
- specifying command names containing /
- specifying a filename containing a / as an argument to the . builtin command
- specifying a filename containing a slash as an argument to the **history** builtin command
- specifying a filename containing a slash as an argument to the **-p** option to the **hash** builtin command
- importing function definitions from the shell environment at startup
- parsing the value of **SHELLOPTS** from the shell environment at startup
- redirecting output using the >, >|, <>, >&, &>, and >> redirection operators
- using the **exec** builtin command to replace the shell with another command
- adding or deleting builtin commands with the **-f** and **-d** options to the **enable** builtin command
- using the **enable** builtin command to enable disabled shell builtins
- specifying the **-p** option to the **command** builtin command
- turning off restricted mode with **set +r** or **set +o restricted**.

These restrictions are enforced after any startup files are read.

When a command that is found to be a shell script is executed (see **COMMAND EXECUTION** above), **rbash** turns off any restrictions in the shell spawned to execute the script.

BUG REPORTS

If you find a bug in **bash**, you should report it. But first, you should make sure that it really is a bug, and that it appears in the latest version of **bash**. The latest version is always available from <ftp://ftp.gnu.org/pub/gnu/bash/>.

Once you have determined that a bug actually exists, use the *bashbug* command to submit a bug report. If you have a fix, you are encouraged to mail that as well! Suggestions and ‘philosophical’ bug reports may be mailed to *bug-bash@gnu.org* or posted to the Usenet newsgroup **gnu.bash.bug**.

ALL bug reports should include:

- The version number of **bash**
- The hardware and operating system
- The compiler used to compile
- A description of the bug behaviour
- A short script or ‘recipe’ which exercises the bug

bashbug inserts the first three items automatically into the template it provides for filing a bug report.

Comments and bug reports concerning this manual page should be directed to *chet.ramey@case.edu*.

BUGS

It’s too big and too slow.

There are some subtle differences between **bash** and traditional versions of **sh**, mostly because of the **POSIX** specification.

Aliases are confusing in some uses.

Shell builtin commands and functions are not stoppable/restartable.

Compound commands and command sequences of the form ‘a ; b ; c’ are not handled gracefully when process suspension is attempted. When a process is stopped, the shell immediately executes the next command in the sequence. It suffices to place the sequence of commands between parentheses to force it into a subshell, which may be stopped as a unit.

Array variables may not (yet) be exported.

There may be only one active coprocess at a time.

NAME

blkid – locate/print block device attributes

SYNOPSIS

blkid **--label** *label* | **--uuid** *uuid*

blkid [**--no-encoding** **--garbage-collect** **--list-one** **--cache-file** *file*] [**--output** *format*]
[**--match-tag** *tag*] [**--match-token** *NAME=value*] [*device...*]

blkid **--probe** [**--offset** *offset*] [**--output** *format*] [**--size** *size*] [**--match-tag** *tag*] [**--match-types** *list*]
[**--usages** *list*] [**--no-part-details**] *device...*

blkid **--info** [**--output** *format*] [**--match-tag** *tag*] *device...*

DESCRIPTION

The **blkid** program is the command-line interface to working with the **libblkid**(3) library. It can determine the type of content (e.g., filesystem or swap) that a block device holds, and also the attributes (tokens, NAME=value pairs) from the content metadata (e.g., LABEL or UUID fields).

It is recommended to use lsblk(8) command to get information about block devices, or lsblk --fs to get an overview of filesystems, or findmnt(8) to search in already mounted filesystems.

lsblk(8) provides more information, better control on output formatting, easy to use in scripts and it does not require root permissions to get actual information. **blkid** reads information directly from devices and for non-root users it returns cached unverified information. **blkid** is mostly designed for system services and to test **libblkid**(3) functionality.

When *device* is specified, tokens from only this device are displayed. It is possible to specify multiple *device* arguments on the command line. If none is given, all partitions or unpartitioned devices which appear in */proc/partitions* are shown, if they are recognized.

blkid has two main forms of operation: either searching for a device with a specific NAME=value pair, or displaying NAME=value pairs for one or more specified devices.

For security reasons **blkid** silently ignores all devices where the probing result is ambivalent (multiple colliding filesystems are detected). The low-level probing mode (**-p**) provides more information and extra exit status in this case. It's recommended to use **wipefs(8)** to get a detailed overview and to erase obsolete stuff (magic strings) from the device.

OPTIONS

The *size* and *offset* arguments may be followed by the multiplicative suffixes like KiB (=1024), MiB (=1024*1024), and so on for GiB, TiB, PiB, EiB, ZiB and YiB (the "iB" is optional, e.g., "K" has the same meaning as "KiB"), or the suffixes KB (=1000), MB (=1000*1000), and so on for GB, TB, PB, EB, ZB and YB.

-c, --cache-file *cachefile*

Read from *cachefile* instead of reading from the default cache file (see the **CONFIGURATION FILE** section for more details). If you want to start with a clean cache (i.e., don't report devices previously scanned but not necessarily available at this time), specify */dev/null*.

-d, --no-encoding

Don't encode non-printing characters. The non-printing characters are encoded by ^ and M- notation by default. Note that the **--output udev** output format uses a different encoding which cannot be disabled.

-D, --no-part-details

Don't print information (PART_ENTRY_* tags) from partition table in low-level probing mode.

-g, --garbage-collect

Perform a garbage collection pass on the blkid cache to remove devices which no longer exist.

-H, --hint *setting*

Set probing hint. The hints are an optional way to force probing functions to check, for example, another location. The currently supported is "session_offset=number" to set session offset on multi-session UDF.

-i, --info

Display information about I/O Limits (aka I/O topology). The 'export' output format is automatically enabled. This option can be used together with the **--probe** option.

-k, --list-filesystems

List all known filesystems and RAIDs and exit.

-l, --list-one

Look up only one device that matches the search parameter specified with the **--match-token** option. If there are multiple devices that match the specified search parameter, then the device with the highest priority is returned, and/or the first device found at a given priority (but see below note about udev). Device types in order of decreasing priority are: Device Mapper, EVMS, LVM, MD, and finally regular block devices. If this option is not specified, **blkid** will print all of the devices that match the search parameter.

This option forces **blkid** to use udev when used for LABEL or UUID tokens in **--match-token**. The goal is to provide output consistent with other utils (like **mount(8)**, etc.) on systems where the same tag is used for multiple devices.

-L, --label *label*

Look up the device that uses this filesystem *label*; this is equal to **--list-one --output device --match-token LABEL=label**. This lookup method is able to reliably use /dev/disk/by-label udev symlinks (dependent on a setting in */etc/blkid.conf*). Avoid using the symlinks directly; it is not reliable to use the symlinks without verification. The **--label** option works on systems with and without udev.

Unfortunately, the original **blkid(8)** from e2fsprogs uses the **-L** option as a synonym for **-o list**. For better portability, use **-l -o device -t LABEL=label** and **-o list** in your scripts rather than the **-L** option.

-n, --match-types *list*

Restrict the probing functions to the specified (comma-separated) *list* of superblock types (names). The list items may be prefixed with "no" to specify the types which should be ignored. For example:

```
blkid --probe --match-types vfat,ext3,ext4 /dev/sda1
```

probes for vfat, ext3 and ext4 filesystems, and

```
blkid --probe --match-types nominix /dev/sda1
```

probes for all supported formats except minix filesystems. This option is only useful together with **--probe**.

-o, --output *format*

Use the specified output format. Note that the order of variables and devices is not fixed. See also option **-s**. The *format* parameter may be:

full

print all tags (the default)

value

print the value of the tags

list

print the devices in a user-friendly format; this output format is unsupported for low-level probing (**--probe** or **--info**).

This output format is **DEPRECATED** in favour of the **lsblk(8)** command.

device

print the device name only; this output format is always enabled for the **--label** and **--uuid** options

udev

print key="value" pairs for easy import into the udev environment; the keys are prefixed by ID_FS_ or ID_PART_ prefixes. The value may be modified to be safe for udev environment; allowed is plain ASCII, hex-escaping and valid UTF-8, everything else (including whitespaces) is replaced with '_'. The keys with _ENC postfix use hex-escaping for unsafe chars.

The udev output returns the ID_FS_AMBIVALENT tag if more superblocks are detected, and ID_PART_ENTRY_* tags are always returned for all partitions including empty partitions.

This output format is **DEPRECATED**.

export

print key=value pairs for easy import into the environment; this output format is automatically enabled when I/O Limits (**--info** option) are requested.

The non-printing characters are encoded by ^ and M- notation and all potentially unsafe characters are escaped.

-O, --offset *offset*

Probe at the given *offset* (only useful with **--probe**). This option can be used together with the **--info** option.

-p, --probe

Switch to low-level superblock probing mode (bypassing the cache).

Note that low-level probing also returns information about partition table type (PTTYPE tag) and partitions (PART_ENTRY_* tags). The tag names produced by low-level probing are based on names used internally by libblkid and it may be different than when executed without **--probe** (for example PART_ENTRY_UUID= vs PARTUUID=). See also **--no-part-details**.

-s, --match-tag *tag*

For each (specified) device, show only the tags that match *tag*. It is possible to specify multiple **--match-tag** options. If no tag is specified, then all tokens are shown for all (specified) devices. In order to just refresh the cache without showing any tokens, use **--match-tag none** with no other options.

-S, --size *size*

Override the size of device/file (only useful with **--probe**).

-t, --match-token *NAME=value*

Search for block devices with tokens named *NAME* that have the value *value*, and display any devices which are found. Common values for *NAME* include **TYPE**, **LABEL**, and **UUID**. If there are no devices specified on the command line, all block devices will be searched; otherwise only the specified devices are searched.

-u, --usages *list*

Restrict the probing functions to the specified (comma-separated) *list* of "usage" types. Supported usage types are: filesystem, raid, crypto and other. The list items may be prefixed with "no" to specify the usage types which should be ignored. For example:

blkid --probe --usages filesystem,other /dev/sda1

probes for all filesystem and other (e.g., swap) formats, and

blkid --probe --usages noraid /dev/sda1

probes for all supported formats except RAIDs. This option is only useful together with **--probe**.

-U, --uuid *uuid*

Look up the device that uses this filesystem *uuid*. For more details see the **--label** option.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

EXIT STATUS

If the specified device or device addressed by specified token (option **--match-token**) was found and it's possible to gather any information about the device, an exit status 0 is returned. Note the option **--match-tag** filters output tags, but it does not affect exit status.

If the specified token was not found, or no (specified) devices could be identified, or it is impossible to gather any information about the device identifiers or device content an exit status of 2 is returned.

For usage or other errors, an exit status of 4 is returned.

If an ambivalent probing result was detected by low-level probing mode (**-p**), an exit status of 8 is returned.

CONFIGURATION FILE

The standard location of the */etc/blkid.conf* config file can be overridden by the environment variable **BLKID_CONF**. The following options control the libblkid library:

SEND_UEVENT=<yes/not>

Sends uevent when */dev/disk/by-{label,uuid,partuuid,partlabel}*/ symlink does not match with LABEL, UUID, PARTUUID or PARTLABEL on the device. Default is "yes".

CACHE_FILE=<path>

Overrides the standard location of the cache file. This setting can be overridden by the environment variable **BLKID_FILE**. Default is */run/blkid/blkid.tab*, or */etc/blkid.tab* on systems without a */run* directory.

EVALUATE=<methods>

Defines LABEL and UUID evaluation method(s). Currently, the libblkid library supports the "udev" and "scan" methods. More than one method may be specified in a comma-separated list. Default is "udev,scan". The "udev" method uses udev */dev/disk/by-** symlinks and the "scan" method scans all block devices from the */proc/partitions* file.

ENVIRONMENT

Setting *LIBBLKID_DEBUG=all* enables debug output.

AUTHORS

blkid was written by Andreas Dilger for libblkid and improved by Theodore Ts'o and Karel Zak.

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **blkid** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

btrfs-man5 – topics about the BTRFS filesystem (mount options, supported file attributes and other)

DESCRIPTION

This document describes topics related to BTRFS that are not specific to the tools. Currently covers:

1. mount options
2. filesystem features
3. checksum algorithms
4. compression
5. filesystem exclusive operations
6. filesystem limits
7. bootloader support
8. file attributes
9. zoned mode
10. control device
11. filesystems with multiple block group profiles
12. seeding device
13. raid56 status and recommended practices
14. storage model

15.

hardware considerations

MOUNT OPTIONS

This section describes mount options specific to BTRFS. For the generic mount options please refer to **mount(8)** manpage. The options are sorted alphabetically (discarding the *no* prefix).

Note

most mount options apply to the whole filesystem and only options in the first mounted subvolume will take effect. This is due to lack of implementation and may change in the future. This means that (for example) you can't set per-subvolume *nodatacow*, *nodatasum*, or *compress* using mount options. This should eventually be fixed, but it has proved to be difficult to implement correctly within the Linux VFS framework.

Mount options are processed in order, only the last occurrence of an option takes effect and may disable other options due to constraints (see eg. *nodatacow* and *compress*). The output of *mount* command shows which options have been applied.

acl, noacl

(default: on)

Enable/disable support for Posix Access Control Lists (ACLs). See the **acl(5)** manual page for more information about ACLs.

The support for ACL is build-time configurable (BTRFS_FS_POSIX_ACL) and mount fails if *acl* is requested but the feature is not compiled in.

autodefrag, noautodefrag

(since: 3.0, default: off)

Enable automatic file defragmentation. When enabled, small random writes into files (in a range of tens of kilobytes, currently it's 64K) are detected and queued up for the defragmentation process. Not well suited for large database workloads.

The read latency may increase due to reading the adjacent blocks that make up the range for defragmentation, successive write will merge the blocks in the new location.

Warning

Defragmenting with Linux kernel versions < 3.9 or ≥ 3.14-rc2 as well as with Linux stable kernel versions ≥ 3.10.31, ≥ 3.12.12 or ≥ 3.13.4 will break up the reflinks of COW data (for example files copied with **cp --reflink**, snapshots or de-duplicated data). This may cause considerable increase of space usage depending on the broken up reflinks.

barrier, nobarrier

(default: on)

Ensure that all IO write operations make it through the device cache and are stored permanently when the filesystem is at its consistency checkpoint. This typically means that a flush command is sent to the device that will synchronize all pending data and ordinary metadata blocks, then writes the superblock and issues another flush.

The write flushes incur a slight hit and also prevent the IO block scheduler to reorder requests in a more effective way. Disabling barriers gets rid of that penalty but will most certainly lead to a corrupted filesystem in case of a crash or power loss. The ordinary metadata blocks could be yet unwritten at the time the new superblock is stored permanently, expecting that the block pointers to metadata were stored permanently before.

On a device with a volatile battery-backed write-back cache, the *nobarrier* option will not lead to filesystem corruption as the pending blocks are supposed to make it to the permanent storage.

check_int, check_int_data, check_int_print_mask=value

(since: 3.0, default: off)

These debugging options control the behavior of the integrity checking module (the BTRFS_FS_CHECK_INTEGRITY config option required). The main goal is to verify that all blocks from a given transaction period are properly linked.

check_int enables the integrity checker module, which examines all block write requests to ensure on-disk consistency, at a large memory and CPU cost.

check_int_data includes extent data in the integrity checks, and implies the *check_int* option.

check_int_print_mask takes a bitmask of BTRFSIC_PRINT_MASK_* values as defined in *fs/btrfs/check-integrity.c*, to control the integrity checker module behavior.

See comments at the top of *fs/btrfs/check-integrity.c* for more information.

clear_cache

Force clearing and rebuilding of the disk space cache if something has gone wrong. See also: *space_cache*.

commit=seconds

(since: 3.12, default: 30)

Set the interval of periodic transaction commit when data are synchronized to permanent storage. Higher interval values lead to larger amount of unwritten data, which has obvious consequences when the system crashes. The upper bound is not forced, but a warning is printed if it's more than 300 seconds (5 minutes). Use with care.

compress, compress=type[:level], compress-force, compress-force=type[:level]

(default: off, level support since: 5.1)

Control BTRFS file data compression. Type may be specified as *zlib*, *lzo*, *zstd* or *no* (for no compression, used for remounting). If no type is specified, *zlib* is used. If *compress-force* is specified, then compression will always be attempted, but the data may end up uncompressed if the compression would make them larger.

Both *zlib* and *zstd* (since version 5.1) expose the compression level as a tunable knob with higher levels trading speed and memory (*zstd*) for higher compression ratios. This can be set by appending a colon and the desired level. Zlib accepts the range [1, 9] and zstd accepts [1, 15]. If no level is set, both currently use a default level of 3. The value 0 is an alias for the default level.

Otherwise some simple heuristics are applied to detect an incompressible file. If the first blocks written to a file are not compressible, the whole file is permanently marked to skip compression. As this is too simple, the *compress-force* is a workaround that will compress most of the files at the cost of some wasted CPU cycles on failed attempts. Since kernel 4.15, a set of heuristic algorithms have been improved by using frequency sampling, repeated pattern detection and Shannon entropy calculation to avoid that.

Note

If compression is enabled, *nodatacow* and *nodatasum* are disabled.

datacow, nodatacow

(default: on)

Enable data copy-on-write for newly created files. *Nodacow* implies *nodatasum*, and disables *compression*. All files created under *nodacow* are also set the NOCOW file attribute (see **chattr(1)**).

Note

If *nodacow* or *nodatasum* are enabled, compression is disabled.

Updates in-place improve performance for workloads that do frequent overwrites, at the cost of potential partial writes, in case the write is interrupted (system crash, device failure).

datasum, nodatasum

(default: on)

Enable data checksumming for newly created files. *Datasum* implies *datacow*, ie. the normal mode of operation. All files created under *nodatasum* inherit the "no checksums" property, however there's no corresponding file attribute (see **chattr(1)**).

Note

If *nodacow* or *nodatasum* are enabled, compression is disabled.

There is a slight performance gain when checksums are turned off, the corresponding metadata blocks holding the checksums do not need to be updated. The cost of checksumming of the blocks in memory is much lower than the IO, modern CPUs feature hardware support of the checksumming algorithm.

degraded

(default: off)

Allow mounts with less devices than the RAID profile constraints require. A read-write mount (or remount) may fail when there are too many devices missing, for example if a stripe member is completely missing from RAID0.

Since 4.14, the constraint checks have been improved and are verified on the chunk level, not at the device level. This allows degraded mounts of filesystems with mixed RAID profiles for data and metadata, even if the device number constraints would not be satisfied for some of the profiles.

Example: metadata — raid1, data — single, devices — /dev/sda, /dev/sdb

Suppose the data are completely stored on *sda*, then missing *sdb* will not prevent the mount, even if 1 missing device would normally prevent (any) *single* profile to mount. In case some of the data chunks are stored on *sdb*, then the constraint of single/data is not satisfied and the filesystem cannot be mounted.

device=devicepath

Specify a path to a device that will be scanned for BTRFS filesystem during mount. This is usually done automatically by a device manager (like udev) or using the **btrfs device scan** command (eg. run from the initial ramdisk). In cases where this is not possible the *device* mount option can help.

Note

booting eg. a RAID1 system may fail even if all filesystem's *device* paths are provided as the actual device nodes may not be discovered by the system at that point.

discard, discard=sync, discard=async, nodiscard

(default: off, async support since: 5.6)

Enable discarding of freed file blocks. This is useful for SSD devices, thinly provisioned LUNs, or virtual machine images; however, every storage layer must support discard for it to work.

In the synchronous mode (*sync* or without option value), lack of asynchronous queued TRIM on the backing device TRIM can severely degrade performance, because a synchronous TRIM operation will be attempted instead. Queued TRIM requires newer than SATA revision 3.1 chipsets and devices.

The asynchronous mode (*async*) gathers extents in larger chunks before sending them to the devices for TRIM. The overhead and performance impact should be negligible compared to the previous mode and it's supposed to be the preferred mode if needed.

If it is not necessary to immediately discard freed blocks, then the **fstrim** tool can be used to discard all free blocks in a batch. Scheduling a TRIM during a period of low system activity will prevent latent interference with the performance of other operations. Also, a device may ignore the TRIM command if the range is too small, so running a batch discard has a greater probability of actually discarding the blocks.

enospc_debug, noenospc_debug

(default: off)

Enable verbose output for some ENOSPC conditions. It's safe to use but can be noisy if the system reaches near-full state.

fatal_errors=*action*

(since: 3.4, default: bug)

Action to take when encountering a fatal error.

bug

BUG() on a fatal error, the system will stay in the crashed state and may be still partially usable, but reboot is required for full operation

panic

panic() on a fatal error, depending on other system configuration, this may be followed by a reboot. Please refer to the documentation of kernel boot parameters, eg. *panic*, *oops* or *crashkernel*.

flushoncommit, noflushoncommit

(default: off)

This option forces any data dirtied by a write in a prior transaction to commit as part of the current commit, effectively a full filesystem sync.

This makes the committed state a fully consistent view of the file system from the application's perspective (i.e. it includes all completed file system operations). This was previously the behavior only when a snapshot was created.

When off, the filesystem is consistent but buffered writes may last more than one transaction commit.

fragment=type

(depends on compile-time option BTRFS_DEBUG, since: 4.4, default: off)

A debugging helper to intentionally fragment given *type* of block groups. The type can be *data*, *metadata* or *all*. This mount option should not be used outside of debugging environments and is not recognized if the kernel config option *BTRFS_DEBUG* is not enabled.

nologreplay

(default: off, even read-only)

The tree-log contains pending updates to the filesystem until the full commit. The log is replayed on next mount, this can be disabled by this option. See also *treelog*. Note that *nologreplay* is the same as *norecovery*.

Warning

currently, the tree log is replayed even with a read-only mount! To disable that behaviour, mount also with *nologreplay*.

max_inline=bytes

(default: min(2048, page size))

Specify the maximum amount of space, that can be inlined in a metadata B-tree leaf. The value is specified in bytes, optionally with a K suffix (case insensitive). In practice, this value is limited by the filesystem block size (named *sectorsize* at mkfs time), and memory page size of the system. In case of *sectorsize* limit, there's some space unavailable due to leaf headers. For example, a 4k *sectorsize*, maximum size of inline data is about 3900 bytes.

Inlining can be completely turned off by specifying 0. This will increase data block slack if file sizes are much smaller than block size but will reduce metadata consumption in return.

Note

the default value has changed to 2048 in kernel 4.6.

metadata_ratio=value

(default: 0, internal logic)

Specifies that 1 metadata chunk should be allocated after every *value* data chunks. Default behaviour depends on internal logic, some percent of unused metadata space is attempted to be maintained but is not always possible if there's not enough space left for chunk allocation. The option could be useful to override the internal logic in favor of the metadata allocation if the expected workload is supposed to be metadata intense (snapshots, reflinks, xattrs, inlined files).

norecovery

(since: 4.5, default: off)

Do not attempt any data recovery at mount time. This will disable *logreplay* and avoids other write operations. Note that this option is the same as *nologreplay*.

Note

The opposite option *recovery* used to have different meaning but was changed for consistency with other filesystems, where *norecovery* is used for skipping log replay. BTRFS does the same and in general will try

to avoid any write operations.

rescan_uuid_tree

(since: 3.12, default: off)

Force check and rebuild procedure of the UUID tree. This should not normally be needed.

rescue

(since: 5.9)

Modes allowing mount with damaged filesystem structures.

-
- *usebackuproot* (since: 5.9, replaces standalone option *usebackuproot*)
-
- *nologreplay* (since: 5.9, replaces standalone option *nologreplay*)
-
- *ignorebadroots, ibadroots* (since: 5.11)
-
- *ignoredatacsums, idatacsums* (since: 5.11)
-
- *all* (since: 5.9)

skip_balance

(since: 3.3, default: off)

Skip automatic resume of an interrupted balance operation. The operation can later be resumed with **btrfs balance resume**, or the paused state can be removed with **btrfs balance cancel**. The default behaviour is to resume an interrupted balance immediately after a volume is mounted.

space_cache, space_cache=version, nospace_cache

(*nospace_cache* since: 3.2, *space_cache=v1* and *space_cache=v2* since 4.5, default: *space_cache=v1*)

Options to control the free space cache. The free space cache greatly improves performance when reading block group free space into memory. However, managing the space cache consumes some resources, including a small amount of disk space.

There are two implementations of the free space cache. The original one, referred to as *v1*, is the safe default. The *v1* space cache can be disabled at mount time with *nospace_cache* without clearing.

On very large filesystems (many terabytes) and certain workloads, the performance of the *v1* space cache may degrade drastically. The *v2* implementation, which adds a new B-tree called the free space tree, addresses this issue. Once enabled, the *v2* space cache will always be used and cannot be disabled unless it is cleared. Use *clear_cache,space_cache=v1* or *clear_cache,nospace_cache* to do so. If *v2* is enabled, kernels without *v2* support will only be able to mount the filesystem in read-only mode.

The **btrfs-check(8)** and **mkfs.btrfs(8)** commands have full *v2* free space cache support since v4.19.

If a version is not explicitly specified, the default implementation will be chosen, which is *v1*.

ssd, ssd_spread, nossd, nossd_spread

(default: SSD autodetected)

Options to control SSD allocation schemes. By default, BTRFS will enable or disable SSD optimizations depending on status of a device with respect to rotational or non-rotational type. This is determined by the contents of */sys/block/DEV/queue/rotational*. If it is 0, the *ssd* option is turned on. The option *nossd* will disable the autodetection.

The optimizations make use of the absence of the seek penalty that's inherent for the rotational devices. The blocks can be typically written faster and are not offloaded to separate threads.

Note

Since 4.14, the block layout optimizations have been dropped. This used to help with first generations of SSD devices. Their FTL (flash translation layer) was not effective and the optimization was supposed to improve the wear by better aligning blocks. This is no longer true with modern SSD devices and the optimization had no real benefit. Furthermore it caused increased fragmentation. The layout tuning has been kept intact for the option *ssd_spread*.

The *ssd_spread* mount option attempts to allocate into bigger and aligned chunks of unused space, and may perform better on low-end SSDs. *ssd_spread* implies *ssd*, enabling all other SSD heuristics as well. The option *nossd* will disable all SSD options while *nossd_spread* only disables *ssd_spread*.

subvol=*path*

Mount subvolume from *path* rather than the toplevel subvolume. The *path* is always treated as relative to the toplevel subvolume. This mount option overrides the default subvolume set for the given filesystem.

subvolid=subvolid

Mount subvolume specified by a *subvolid* number rather than the toplevel subvolume. You can use **btrfs subvolume list** or **btrfs subvolume show** to see subvolume ID numbers. This mount option overrides the default subvolume set for the given filesystem.

Note

if both *subvolid* and *subvol* are specified, they must point at the same subvolume, otherwise the mount will fail.

thread_pool=number

(default: min(NRPCUS + 2, 8))

The number of worker threads to start. NRPCUS is number of on-line CPUs detected at the time of mount. Small number leads to less parallelism in processing data and metadata, higher numbers could lead to a performance hit due to increased locking contention, process scheduling, cache-line bouncing or costly data transfers between local CPU memories.

treelog, notreelog

(default: on)

Enable the tree logging used for *fsync* and *O_SYNC* writes. The tree log stores changes without the need of a full filesystem sync. The log operations are flushed at sync and transaction commit. If the system crashes between two such syncs, the pending tree log operations are replayed during mount.

Warning

currently, the tree log is replayed even with a read-only mount! To disable that behaviour, also mount with *nologreplay*.

The tree log could contain new files/directories, these would not exist on a mounted filesystem if the log is not replayed.

usebackuproot

(since: 4.6, default: off)

Enable autorecovery attempts if a bad tree root is found at mount time. Currently this scans a backup list of several previous tree roots and tries to use the first readable. This can be used with read-only

mounts as well.

Note

This option has replaced *recovery*.

user_subvol_rm_allowed

(default: off)

Allow subvolumes to be deleted by their respective owner. Otherwise, only the root user can do that.

Note

historically, any user could create a snapshot even if he was not owner of the source subvolume, the subvolume deletion has been restricted for that reason. The subvolume creation has been restricted but this mount option is still required. This is a usability issue. Since 4.18, the **rmdir(2)** syscall can delete an empty subvolume just like an ordinary directory. Whether this is possible can be detected at runtime, see *rmdir_subvol* feature in *FILESYSTEM FEATURES*.

DEPRECATED MOUNT OPTIONS

List of mount options that have been removed, kept for backward compatibility.

recovery

(since: 3.2, default: off, deprecated since: 4.5)

Note

this option has been replaced by *usebackuproot* and should not be used but will work on 4.5+ kernels.

inode_cache, noinode_cache

(removed in: 5.11, since: 3.0, default: off)

Note

the functionality has been removed in 5.11, any stale data created by previous use of the *inode_cache* option can be removed by **btrfs check --clear-ino-cache**.

NOTES ON GENERIC MOUNT OPTIONS

Some of the general mount options from **mount(8)** that affect BTRFS and are worth mentioning.

noatime

under read intensive work–loads, specifying *noatime* significantly improves performance because no new access time information needs to be written. Without this option, the default is *relatime*, which only reduces the number of inode atime updates in comparison to the traditional *strictatime*. The worst case for atime updates under *relatime* occurs when many files are read whose atime is older than 24 h

and which are freshly snapshotted. In that case the atime is updated *and* COW happens – for each file – in bulk. See also <https://lwn.net/Articles/499293/> – *Atime and btrfs: a bad combination?* (LWN, 2012-05-31).

Note that *noatime* may break applications that rely on atime uptimes like the venerable Mutt (unless you use maildir mailboxes).

FILESYSTEM FEATURES

The basic set of filesystem features gets extended over time. The backward compatibility is maintained and the features are optional, need to be explicitly asked for so accidental use will not create incompatibilities.

There are several classes and the respective tools to manage the features:

at mkfs time only

This is namely for core structures, like the b-tree nodesize or checksum algorithm, see **mkfs.btrfs(8)** for more details.

after mkfs, on an unmounted filesystem

Features that may optimize internal structures or add new structures to support new functionality, see **btrfstune(8)**. The command **btrfs inspect–internal dump–super device** will dump a superblock, you can map the value of *incompat_flags* to the features listed below

after mkfs, on a mounted filesystem

The features of a filesystem (with a given UUID) are listed in **/sys/fs/btrfs/UUID/features/**, one file per feature. The status is stored inside the file. The value *1* is for enabled and active, while *0* means the feature was enabled at mount time but turned off afterwards.

Whether a particular feature can be turned on a mounted filesystem can be found in the directory **/sys/fs/btrfs/features/**, one file per feature. The value *1* means the feature can be enabled.

List of features (see also **mkfs.btrfs(8)** section *FILESYSTEM FEATURES*):

big_metadata

(since: 3.4)

the filesystem uses *nodesize* for metadata blocks, this can be bigger than the page size

compress_lzo

(since: 2.6.38)

the *lzo* compression has been used on the filesystem, either as a mount option or via **btrfs filesystem defrag**.

compress_zstd

(since: 4.14)

the *zstd* compression has been used on the filesystem, either as a mount option or via **btrfs filesystem defrag**.

default_subvol

(since: 2.6.34)

the default subvolume has been set on the filesystem

extended_iref

(since: 3.7)

increased hardlink limit per file in a directory to 65536, older kernels supported a varying number of hardlinks depending on the sum of all file name sizes that can be stored into one metadata block

free_space_tree

(since: 4.5)

free space representation using a dedicated b-tree, successor of v1 space cache

metadata_uuid

(since: 5.0)

the main filesystem UUID is the metadata_uuid, which stores the new UUID only in the superblock while all metadata blocks still have the UUID set at mkfs time, see **btrfstune(8)** for more

mixed_backref

(since: 2.6.31)

the last major disk format change, improved backreferences, now default

mixed_groups

(since: 2.6.37)

mixed data and metadata block groups, ie. the data and metadata are not separated and occupy the same block groups, this mode is suitable for small volumes as there are no constraints how the remaining space should be used (compared to the split mode, where empty metadata space cannot be used for data and vice versa)

on the other hand, the final layout is quite unpredictable and possibly highly fragmented, which means worse performance

no_holes

(since: 3.14)

improved representation of file extents where holes are not explicitly stored as an extent, saves a few percent of metadata if sparse files are used

raid1c34

(since: 5.5)

extended RAID1 mode with copies on 3 or 4 devices respectively

raid56

(since: 3.9)

the filesystem contains or contained a raid56 profile of block groups

rmdir_subvol

(since: 4.18)

indicate that **rmdir(2)** syscall can delete an empty subvolume just like an ordinary directory. Note that this feature only depends on the kernel version.**skinny_metadata**

(since: 3.10)

reduced-size metadata for extent references, saves a few percent of metadata

send_stream_version

(since: 5.10)

number of the highest supported send stream version

supported_checksums

(since: 5.5)

list of checksum algorithms supported by the kernel module, the respective modules or built-in implementing the algorithms need to be present to mount the filesystem, see *CHECKSUM ALGORITHMS***supported_sectorsizes**

(since: 5.13)

list of values that are accepted as sector sizes (**mkfs.btrfs --sectorsize**) by the running kernel

supported_rescue_options

(since: 5.11)

list of values for the mount option *rescue* that are supported by the running kernel, see **btrfs(5)**

zoned

(since: 5.12)

zoned mode is allocation/write friendly to host-managed zoned devices, allocation space is partitioned into fixed-size zones that must be updated sequentially, see *ZONED MODE*

SWAPFILE SUPPORT

The swapfile is supported since kernel 5.0. Use **swapon(8)** to activate the swapfile. There are some limitations of the implementation in btrfs and linux swap subsystem:

- filesystem – must be only single device
- filesystem – must have only *single* data profile
- swapfile – the containing subvolume cannot be snapshotted
- swapfile – must be preallocated
- swapfile – must be nodatacow (ie. also nodatasum)
- swapfile – must not be compressed

The limitations come namely from the COW-based design and mapping layer of blocks that allows the advanced features like relocation and multi-device filesystems. However, the swap subsystem expects simpler mapping and no background changes of the file blocks once they've been attached to swap.

With active swapfiles, the following whole–filesystem operations will skip swapfile extents or may fail:

-
- balance – block groups with swapfile extents are skipped and reported, the rest will be processed normally
-
- resize grow – unaffected
-
- resize shrink – works as long as the extents are outside of the shrunk range
-
- device add – a new device does not interfere with existing swapfile and this operation will work, though no new swapfile can be activated afterwards
-
- device delete – if the device has been added as above, it can be also deleted
-
- device replace – ditto

When there are no active swapfiles and a whole–filesystem exclusive operation is running (ie. balance, device delete, shrink), the swapfiles cannot be temporarily activated. The operation must finish first.

To create and activate a swapfile run the following commands:

```
# truncate -s 0 swapfile
# chattr +C swapfile
# fallocate -l 2G swapfile
# chmod 0600 swapfile
# mkswap swapfile
# swapon swapfile
```

Please note that the UUID returned by the *mkswap* utility identifies the swap "filesystem" and because it's stored in a file, it's not generally visible and usable as an identifier unlike if it was on a block device.

The file will appear in */proc/swaps*:

```
# cat /proc/swaps
Filename      Type      Size      Used      Priority
/path/swapfile  file    2097152     0      -2
```

The swapfile can be created as one–time operation or, once properly created, activated on each boot by the *swapon -a* command (usually started by the service manager). Add the following entry to */etc/fstab*, assuming the filesystem that provides the */path* has been already mounted at this point. Additional mount options relevant for the swapfile can be set too (like priority, not the btrfs mount options).

```
/path/swapfile    none    swap    defaults    0 0
```

CHECKSUM ALGORITHMS

There are several checksum algorithms supported. The default and backward compatible is *crc32c*. Since kernel 5.5 there are three more with different characteristics and trade-offs regarding speed and strength. The following list may help you to decide which one to select.

CRC32C (32bit digest)

default, best backward compatibility, very fast, modern CPUs have instruction-level support, not collision-resistant but still good error detection capabilities

XXHASH (64bit digest)

can be used as CRC32C successor, very fast, optimized for modern CPUs utilizing instruction pipelining, good collision resistance and error detection

SHA256 (256bit digest)

a cryptographic-strength hash, relatively slow but with possible CPU instruction acceleration or specialized hardware cards, FIPS certified and in wide use

BLAKE2b (256bit digest)

a cryptographic-strength hash, relatively fast with possible CPU acceleration using SIMD extensions, not standardized but based on BLAKE which was a SHA3 finalist, in wide use, the algorithm used is BLAKE2b-256 that's optimized for 64bit platforms

The *digest size* affects overall size of data block checksums stored in the filesystem. The metadata blocks have a fixed area up to 256bits (32 bytes), so there's no increase. Each data block has a separate checksum stored, with additional overhead of the b-tree leaves.

Approximate relative performance of the algorithms, measured against CRC32C using reference software implementations on a 3.5GHz intel CPU:

```
[ cols="^,>,>,>",width="50%" ]
```

Digest	Cycles/4KiB	Ratio	Implementation
CRC32C	1700	1.00	CPU instruction
XXHASH	2500	1.44	reference impl.
SHA256	105000	61	reference impl.
SHA256	36000	21	libgcrypt/AVX2
SHA256	63000	37	libsodium/AVX2
BLAKE2b	22000	13	reference impl.
BLAKE2b	19000	11	libgcrypt/AVX2
BLAKE2b	19000	11	libsodium/AVX2

Many kernels are configured with SHA256 as built-in and not as a module. The accelerated versions are however provided by the modules and must be loaded explicitly (**modprobe sha256**) before mounting the filesystem to make use of them. You can check in `/sys/fs/btrfs/FSID/checksum` which one is used. If you see `sha256-generic`, then you may want to unmount and mount the filesystem again, changing that on a mounted filesystem is not possible. Check the file `/proc/crypto`, when the implementation is built-in, you'd find

```
name      : sha256
driver    : sha256-generic
module    : kernel
priority  : 100
...

```

while accelerated implementation is e.g.

```
name      : sha256
driver    : sha256-avx2
module    : sha256_ssse3
priority  : 170
...

```

COMPRESSION

Btrfs supports transparent file compression. There are three algorithms available: ZLIB, LZO and ZSTD (since v4.14). Basically, compression is on a file by file basis. You can have a single btrfs mount point that has some files that are uncompressed, some that are compressed with LZO, some with ZLIB, for instance (though you may not want it that way, it is supported).

To enable compression, mount the filesystem with options `compress` or `compress-force`. Please refer to section *MOUNT OPTIONS*. Once compression is enabled, all new writes will be subject to compression. Some files may not compress very well, and these are typically not recompressed but still written

uncompressed.

Each compression algorithm has different speed/ratio trade offs. The levels can be selected by a mount option and affect only the resulting size (ie. no compatibility issues).

Basic characteristics:

ZLIB slower, higher compression ratio

-
- levels: 1 to 9, mapped directly, default level is 3
-
- good backward compatibility

LZO faster compression and decompression than zlib, worse compression ratio, designed to be fast

-
- no levels
-

good backward compatibility

ZSTD compression comparable to zlib with higher compression/decompression speeds and different ratio

-
- levels: 1 to 15
-

since 4.14, levels since 5.1

The differences depend on the actual data set and cannot be expressed by a single number or recommendation. Higher levels consume more CPU time and may not bring a significant improvement, lower levels are close to real time.

The algorithms could be mixed in one file as they're stored per extent. The compression can be changed on a file by **btrfs filesystem defrag** command, using the *-c* option, or by **btrfs property set** using the *compression* property. Setting compression by *chattr +c* utility will set it to zlib.

INCOMPRESSIBLE DATA

Files with already compressed data or with data that won't compress well with the CPU and memory constraints of the kernel implementations are using a simple decision logic. If the first portion of data being compressed is not smaller than the original, the compression of the file is disabled — unless the filesystem is mounted with *compress-force*. In that case compression will always be attempted on the file only to be later discarded. This is not optimal and subject to optimizations and further development.

If a file is identified as incompressible, a flag is set (NOCOMPRESS) and it's sticky. On that file compression won't be performed unless forced. The flag can be also set by *chattr +m* (since e2fsprogs 1.46.2) or by properties with value *no* or *none*. Empty value will reset it to the default that's currently applicable on the mounted filesystem.

There are two ways to detect incompressible data:

- actual compression attempt – data are compressed, if the result is not smaller, it's discarded, so this depends on the algorithm and level
- pre-compression heuristics – a quick statistical evaluation on the data is performed and based on the result either compression is performed or skipped, the NOCOMPRESS bit is not set just by the heuristic, only if the compression algorithm does not make an improvement

PRE-COMPRESSION HEURISTICS

The heuristics aim to do a few quick statistical tests on the compressed data in order to avoid probably costly compression that would turn out to be inefficient. Compression algorithms could have internal detection of incompressible data too but this leads to more overhead as the compression is done in another thread and has to write the data anyway. The heuristic is read-only and can utilize cached memory.

The tests performed based on the following: data sampling, long repeated pattern detection, byte frequency, Shannon entropy.

COMPATIBILITY WITH OTHER FEATURES

Compression is done using the COW mechanism so it's incompatible with *nodatacow*. Direct IO works on compressed files but will fall back to buffered writes. Currently *nodatasum* and compression don't work together.

FILESYSTEM EXCLUSIVE OPERATIONS

There are several operations that affect the whole filesystem and cannot be run in parallel. Attempt to start one while another is running will fail.

Since kernel 5.10 the currently running operation can be obtained from `/sys/fs/UUID/exclusive_operation` with following values and operations:

- balance
- device add

- - device delete
- - device replace
- - resize
- - swapfile activate
- - none

Enqueuing is supported for several btrfs subcommands so they can be started at once and then serialized.

FILESYSTEM LIMITS

maximum file name length

255

maximum symlink target length

depends on the *nodesize* value, for 4k it's 3949 bytes, for larger nodesize it's 4095 due to the system limit PATH_MAX

The symlink target may not be a valid path, ie. the path name components can exceed the limits (NAME_MAX), there's no content validation at **symlink(3)** creation.

maximum number of inodes

264 but depends on the available metadata space as the inodes are created dynamically

inode numbers

minimum number: 256 (for subvolumes), regular files and directories: 257

maximum file length

inherent limit of btrfs is 264 (16 EiB) but the linux VFS limit is 263 (8 EiB)

maximum number of subvolumes

the subvolume ids can go up to 264 but the number of actual subvolumes depends on the available metadata space, the space consumed by all subvolume metadata includes bookkeeping of shared extents can be large (MiB, GiB)

maximum number of hardlinks of a file in a directory

65536 when the **extref** feature is turned on during mkfs (default), roughly 100 otherwise

minimum filesystem size

the minimal size of each device depends on the *mixed-bg* feature, without that (the default) it's about 109MiB, with mixed-bg it's 16MiB

BOOTLOADER SUPPORT

GRUB2 (<https://www.gnu.org/software/grub>) has the most advanced support of booting from BTRFS with respect to features.

U-boot (<https://www.denx.de/wiki/U-Boot/>) has decent support for booting but not all BTRFS features are implemented, check the documentation.

EXTLINUX (from the <https://syslinux.org> project) can boot but does not support all features. Please check the upstream documentation before you use it.

The first 1MiB on each device is unused with the exception of primary superblock that is on the offset 64KiB and spans 4KiB.

FILE ATTRIBUTES

The btrfs filesystem supports setting file attributes or flags. Note there are old and new interfaces, with confusing names. The following list should clarify that:

-

attributes: **chattr(1)** or **lsattr(1)** utilities (the ioctls are FS_IOC_GETFLAGS and FS_IOC_SETFLAGS), due to the ioctl names the attributes are also called flags

-

xflags: to distinguish from the previous, it's extended flags, with tunable bits similar to the attributes but extensible and new bits will be added in the future (the ioctls are FS_IOC_FSGETXATTR and FS_IOC_FSSETXATTR but they are not related to extended attributes that are also called xattrs), there's no standard tool to change the bits, there's support in **xfs_io(8)** as command **xfs_io -c chattr**

ATTRIBUTES**a**

append only, new writes are always written at the end of the file

A

no atime updates

c

compress data, all data written after this attribute is set will be compressed. Please note that compression is also affected by the mount options or the parent directory attributes.

When set on a directory, all newly created files will inherit this attribute. This attribute cannot be set with *m* at the same time.

C

no copy-on-write, file data modifications are done in-place

When set on a directory, all newly created files will inherit this attribute.

Note

due to implementation limitations, this flag can be set/unset only on empty files.

d

no dump, makes sense with 3rd party tools like **dump(8)**, on BTRFS the attribute can be set/unset but no other special handling is done

D

synchronous directory updates, for more details search **open(2)** for *O_SYNC* and *O_DSYNC*

i

immutable, no file data and metadata changes allowed even to the root user as long as this attribute is

set (obviously the exception is unsetting the attribute)

m

no compression, permanently turn off compression on the given file. Any compression mount options will not affect this file. (**chattr** support added in 1.46.2)

When set on a directory, all newly created files will inherit this attribute. This attribute cannot be set with *c* at the same time.

S

synchronous updates, for more details search **open(2)** for *O_SYNC* and *O_DSYNC*

No other attributes are supported. For the complete list please refer to the **chattr(1)** manual page.

XFLAGS

There's overlap of letters assigned to the bits with the attributes, this list refers to what **xfs_io(8)** provides:

i

immutable, same as the attribute

a

append only, same as the attribute

s

synchronous updates, same as the attribute *S*

A

no atime updates, same as the attribute

d

no dump, same as the attribute

ZONED MODE

Since version 5.12 btrfs supports so called *zoned mode*. This is a special on-disk format and allocation/write strategy that's friendly to zoned devices. In short, a device is partitioned into fixed-size zones and each zone can be updated by append-only manner, or reset. As btrfs has no fixed data structures, except the super blocks, the zoned mode only requires block placement that follows the device constraints. You can learn about the whole architecture at <https://zonedstorage.io>.

The devices are also called SMR/ZBC/ZNS, in *host-managed* mode. Note that there are devices that appear as non-zoned but actually are, this is *drive-managed* and using zoned mode won't help.

The zone size depends on the device, typical sizes are 256MiB or 1GiB. In general it must be a power of two. Emulated zoned devices like *null_blk* allow to set various zone sizes.

REQUIREMENTS, LIMITATIONS

- all devices must have the same zone size
- maximum zone size is 8GiB
- mixing zoned and non-zoned devices is possible, the zone writes are emulated, but this is namely for testing
- the super block is handled in a special way and is at different locations than on a non-zoned filesystem:
 - primary: 0B (and the next two zones)
 - secondary: 512G (and the next two zones)
 - tertiary: 4TiB (4096GiB, and the next two zones)

INCOMPATIBLE FEATURES

The main constraint of the zoned devices is lack of in-place update of the data. This is inherently incompatible with some features:

- nodatacow – overwrite in-place, cannot create such files
- fallocate – preallocating space for in-place first write

-
- mixed-bg – unordered writes to data and metadata, fixing that means using separate data and metadata block groups
-
- booting – the zone at offset 0 contains superblock, resetting the zone would destroy the bootloader data

Initial support lacks some features but they're planned:

-
- only single profile is supported
-
- fstrim – due to dependency on free space cache v1

SUPER BLOCK

As said above, super block is handled in a special way. In order to be crash safe, at least one zone in a known location must contain a valid superblock. This is implemented as a ring buffer in two consecutive zones, starting from known offsets 0, 512G and 4TiB. The values are different than on non-zoned devices. Each new super block is appended to the end of the zone, once it's filled, the zone is reset and writes continue to the next one. Looking up the latest super block needs to read offsets of both zones and determine the last written version.

The amount of space reserved for super block depends on the zone size. The secondary and tertiary copies are at distant offsets as the capacity of the devices is expected to be large, tens of terabytes. Maximum zone size supported is 8GiB, which would mean that eg. offset 0–16GiB would be reserved just for the super block on a hypothetical device of that zone size. This is wasteful but required to guarantee crash safety.

CONTROL DEVICE

There's a character special device **/dev/btrfs-control** with major and minor numbers 10 and 234 (the device can be found under the *misc* category).

```
$ ls -l /dev/btrfs-control
crw----- 1 root root 10, 234 Jan 1 12:00 /dev/btrfs-control
```

The device accepts some ioctl calls that can perform following actions on the filesystem module:

-
- scan devices for btrfs filesystem (ie. to let multi-device filesystems mount automatically) and register them with the kernel module
-
- similar to scan, but also wait until the device scanning process is finished for a given filesystem
-
- get the supported features (can be also found under */sys/fs/btrfs/features*)

The device is created when btrfs is initialized, either as a module or a built-in functionality and makes sense only in connection with that. Running eg. mkfs without the module loaded will not register the device and will probably warn about that.

In rare cases when the module is loaded but the device is not present (most likely accidentally deleted), it's possible to recreate it by

```
# mknod --mode=600 /dev/btrfs-control c 10 234
```

or (since 5.11) by a convenience command

```
# btrfs rescue create-control-device
```

The control device is not strictly required but the device scanning will not work and a workaround would need to be used to mount a multi-device filesystem. The mount option *device* can trigger the device scanning during mount, see also **btrfs device scan**.

FILESYSTEM WITH MULTIPLE PROFILES

It is possible that a btrfs filesystem contains multiple block group profiles of the same type. This could happen when a profile conversion using balance filters is interrupted (see **btrfs-balance(8)**). Some *btrfs* commands perform a test to detect this kind of condition and print a warning like this:

WARNING: Multiple block group profiles detected, see 'man btrfs(5)'.

WARNING: Data: single, raid1

WARNING: Metadata: single, raid1

The corresponding output of **btrfs filesystem df** might look like:

WARNING: Multiple block group profiles detected, see 'man btrfs(5)'.

WARNING: Data: single, raid1

WARNING: Metadata: single, raid1

Data, RAID1: total=832.00MiB, used=0.00B

Data, single: total=1.63GiB, used=0.00B

System, single: total=4.00MiB, used=16.00KiB

Metadata, single: total=8.00MiB, used=112.00KiB

Metadata, RAID1: total=64.00MiB, used=32.00KiB

GlobalReserve, single: total=16.25MiB, used=0.00B

There's more than one line for type *Data* and *Metadata*, while the profiles are *single* and *RAID1*.

This state of the filesystem OK but most likely needs the user/administrator to take an action and finish the interrupted tasks. This cannot be easily done automatically, also the user knows the expected final profiles.

In the example above, the filesystem started as a single device and *single* block group profile. Then another device was added, followed by balance with *convert=raid1* but for some reason hasn't finished. Restarting the balance with *convert=raid1* will continue and end up with filesystem with all block group profiles *RAID1*.

Note

If you're familiar with balance filters, you can use *convert=raid1,profiles=single,soft*, which will take only the unconverted *single* profiles and convert them to *raid1*. This may speed up the conversion as it would not try to

rewrite the already convert *raid1* profiles.

Having just one profile is desired as this also clearly defines the profile of newly allocated block groups, otherwise this depends on internal allocation policy. When there are multiple profiles present, the order of selection is RAID6, RAID5, RAID10, RAID1, RAID0 as long as the device number constraints are satisfied.

Commands that print the warning were chosen so they're brought to user attention when the filesystem state is being changed in that regard. This is: *device add*, *device delete*, *balance cancel*, *balance pause*. Commands that report space usage: *filesystem df*, *device usage*. The command *filesystem usage* provides a line in the overall summary:

Multiple profiles:	yes (data, metadata)
--------------------	----------------------

SEEDING DEVICE

The COW mechanism and multiple devices under one hood enable an interesting concept, called a seeding device: extending a read-only filesystem on a single device filesystem with another device that captures all writes. For example imagine an immutable golden image of an operating system enhanced with another device that allows to use the data from the golden image and normal operation. This idea originated on CD-ROMs with base OS and allowing to use them for live systems, but this became obsolete. There are technologies providing similar functionality, like *unionmount*, *overlays* or *qcow2* image snapshot.

The seeding device starts as a normal filesystem, once the contents is ready, **btrfs tune -S 1** is used to flag it as a seeding device. Mounting such device will not allow any writes, except adding a new device by **btrfs device add**. Then the filesystem can be remounted as read-write.

Given that the filesystem on the seeding device is always recognized as read-only, it can be used to seed multiple filesystems, at the same time. The UUID that is normally attached to a device is automatically changed to a random UUID on each mount.

Once the seeding device is mounted, it needs the writable device. After adding it, something like *remount -o remount,rw /path* makes the filesystem at */path* ready for use. The simplest usecase is to throw away all changes by unmounting the filesystem when convenient.

Alternatively, deleting the seeding device from the filesystem can turn it into a normal filesystem, provided that the writable device can also contain all the data from the seeding device.

The seeding device flag can be cleared again by **btrfs tune -f -s 0**, eg. allowing to update with newer data but please note that this will invalidate all existing filesystems that use this particular seeding device. This works for some usecases, not for others, and a forcing flag to the command is mandatory to avoid accidental mistakes.

Example how to create and use one seeding device:

```
# mkfs.btrfs /dev/sda
# mount /dev/sda /mnt/mnt1
# ... fill mnt1 with data
# umount /mnt/mnt1
# btrfs tune -S 1 /dev/sda
# mount /dev/sda /mnt/mnt1
# btrfs device add /dev/sdb /mnt
# mount -o remount,rw /mnt/mnt1
# ... /mnt/mnt1 is now writable
```

Now `/mnt/mnt1` can be used normally. The device `/dev/sda` can be mounted again with another writable device:

```
# mount /dev/sda /mnt/mnt2
# btrfs device add /dev/sdc /mnt/mnt2
# mount -o remount,rw /mnt/mnt2
# ... /mnt/mnt2 is now writable
```

The writable device (`/dev/sdb`) can be decoupled from the seeding device and used independently:

```
# btrfs device delete /dev/sda /mnt/mnt1
```

As the contents originated in the seeding device, it's possible to turn `/dev/sdb` to a seeding device again and repeat the whole process.

A few things to note:

- it's recommended to use only single device for the seeding device, it works for multiple devices but the *single* profile must be used in order to make the seeding device deletion work
- block group profiles *single* and *dup* support the usecases above
- the label is copied from the seeding device and can be changed by **btrfs filesystem label**
- each new mount of the seeding device gets a new random UUID

RAID56 STATUS AND RECOMMENDED PRACTICES

The RAID56 feature provides striping and parity over several devices, same as the traditional RAID5/6. There are some implementation and design deficiencies that make it unreliable for some corner cases and the feature **should not be used in production, only for evaluation or testing**. The power failure safety for metadata with RAID56 is not 100%.

Metadata

Do not use `raid5` nor `raid6` for metadata. Use `raid1` or `raid1c3` respectively.

The substitute profiles provide the same guarantees against loss of 1 or 2 devices, and in some respect can be an improvement. Recovering from one missing device will only need to access the remaining 1st or 2nd copy, that in general may be stored on some other devices due to the way RAID1 works on btrfs, unlike on a striped profile (similar to `raid0`) that would need all devices all the time.

The space allocation pattern and consumption is different (eg. on N devices): for `raid5` as an example, a 1GiB chunk is reserved on each device, while with `raid1` there's each 1GiB chunk stored on 2 devices. The consumption of each 1GiB of used metadata is then $N * 1GiB$ for vs $2 * 1GiB$. Using `raid1` is also more convenient for balancing/converting to other profile due to lower requirement on the available chunk space.

Missing/incomplete support

When RAID56 is on the same filesystem with different raid profiles, the space reporting is inaccurate, eg. `df`, `btrfs filesystem df` or `btrfs filesystem usage`. When there's only one profile per block group type (eg. raid5 for data) the reporting is accurate.

When scrub is started on a RAID56 filesystem, it's started on all devices that degrade the performance. The workaround is to start it on each device separately. Due to that the device stats may not match the actual state and some errors might get reported multiple times.

The *write hole* problem.

STORAGE MODEL

A storage model is a model that captures key physical aspects of data structure in a data store. A filesystem is the logical structure organizing data on top of the storage device.

The filesystem assumes several features or limitations of the storage device and utilizes them or applies measures to guarantee reliability. BTRFS in particular is based on a COW (copy on write) mode of writing, ie. not updating data in place but rather writing a new copy to a different location and then atomically switching the pointers.

In an ideal world, the device does what it promises. The filesystem assumes that this may not be true so additional mechanisms are applied to either detect misbehaving hardware or get valid data by other means. The devices may (and do) apply their own detection and repair mechanisms but we won't assume any.

The following assumptions about storage devices are considered (sorted by importance, numbers are for further reference):

1.

atomicity of reads and writes of blocks/sectors (the smallest unit of data the device presents to the upper layers)

2.

there's a flush command that instructs the device to forcibly order writes before and after the command; alternatively there's a barrier command that facilitates the ordering but may not flush the data

3.

data sent to write to a given device offset will be written without further changes to the data and to the offset

4.

writes can be reordered by the device, unless explicitly serialized by the flush command

5.

reads and writes can be freely reordered and interleaved

The consistency model of BTRFS builds on these assumptions. The logical data updates are grouped, into a generation, written on the device, serialized by the flush command and then the super block is written ending the generation. All logical links among metadata comprising a consistent view of the data may not cross the generation boundary.

WHEN THINGS GO WRONG

No or partial atomicity of block reads/writes (1)

-
- Problem:* a partial block contents is written (*torn write*), eg. due to a power glitch or other electronics failure during the read/write
-
- Detection:* checksum mismatch on read
-
- Repair:* use another copy or rebuild from multiple blocks using some encoding scheme

The flush command does not flush (2)

This is perhaps the most serious problem and impossible to mitigate by filesystem without limitations and design restrictions. What could happen in the worst case is that writes from one generation bleed to another one, while still letting the filesystem consider the generations isolated. Crash at any point would leave data on the device in an inconsistent state without any hint what exactly got written, what is missing and leading to stale metadata link information.

Devices usually honor the flush command, but for performance reasons may do internal caching, where the flushed data are not yet persistently stored. A power failure could lead to a similar scenario as above, although it's less likely that later writes would be written before the cached ones. This is beyond what a filesystem can take into account. Devices or controllers are usually equipped with batteries or capacitors to write the cache contents even after power is cut. (*Battery backed write cache*)

Data get silently changed on write (3)

Such thing should not happen frequently, but still can happen spuriously due the complex internal workings of devices or physical effects of the storage media itself.

-
- Problem:* while the data are written atomically, the contents get changed
-
- Detection:* checksum mismatch on read
-
- Repair:* use another copy or rebuild from multiple blocks using some encoding scheme

Data get silently written to another offset (3)

This would be another serious problem as the filesystem has no information when it happens. For that reason the measures have to be done ahead of time. This problem is also commonly called *ghost write*.

The metadata blocks have the checksum embedded in the blocks, so a correct atomic write would not corrupt the checksum. It's likely that after reading such block the data inside would not be consistent with the rest. To rule that out there's embedded block number in the metadata block. It's the logical block number because this is what the logical structure expects and verifies.

HARDWARE CONSIDERATIONS

The following is based on information publicly available, user feedback, community discussions or bug report analyses. It's not complete and further research is encouraged when in doubt.

MAIN MEMORY

The data structures and raw data blocks are temporarily stored in computer memory before they get written to the device. It is critical that memory is reliable because even simple bit flips can have vast consequences and lead to damaged structures, not only in the filesystem but in the whole operating system.

Based on experience in the community, memory bit flips are more common than one would think. When it happens, it's reported by the tree-checker or by a checksum mismatch after reading blocks. There are some very obvious instances of bit flips that happen, e.g. in an ordered sequence of keys in metadata blocks. We can easily infer from the other data what values get damaged and how. However, fixing that is not straightforward and would require cross-referencing data from the entire filesystem to see the scope.

If available, ECC memory should lower the chances of bit flips, but this type of memory is not available in all cases. A memory test should be performed in case there's a visible bit flip pattern, though this may not detect a faulty memory module because the actual load of the system could be the factor making the problems appear. In recent years attacks on how the memory modules operate have been demonstrated (*rowhammer*) achieving specific bits to be flipped. While these were targeted, this shows that a series of reads or writes can affect unrelated parts of memory.

Further reading:

-

https://en.wikipedia.org/wiki/Row_hammer

What to do:

-

run *memtest*, note that sometimes memory errors happen only when the system is under heavy load that the default memtest cannot trigger

-

memory errors may appear as filesystem going read-only due to "pre write" check, that verify meta data before they get written but fail some basic consistency checks

DIRECT MEMORY ACCESS (DMA)

Another class of errors is related to DMA (direct memory access) performed by device drivers. While this could be considered a software error, the data transfers that happen without CPU assistance may accidentally corrupt other pages. Storage devices utilize DMA for performance reasons, the filesystem structures and data pages are passed back and forth, making errors possible in case page life time is not properly tracked.

There are lots of quirks (device-specific workarounds) in Linux kernel drivers (regarding not only DMA) that are added when found. The quirks may avoid specific errors or disable some features to avoid worse problems.

What to do:

-

- use up-to-date kernel (recent releases or maintained long term support versions)

-

- as this may be caused by faulty drivers, keep the systems up-to-date

ROTATIONAL DISKS (HDD)

Rotational HDDs typically fail at the level of individual sectors or small clusters. Read failures are caught on the levels below the filesystem and are returned to the user as *EIO – Input/output error*. Reading the blocks repeatedly may return the data eventually, but this is better done by specialized tools and filesystem takes the result of the lower layers. Rewriting the sectors may trigger internal remapping but this inevitably leads to data loss.

Disk firmware is technically software but from the filesystem perspective is part of the hardware. IO requests are processed, and caching or various other optimizations are performed, which may lead to bugs under high load or unexpected physical conditions or unsupported use cases.

Disks are connected by cables with two ends, both of which can cause problems when not attached properly. Data transfers are protected by checksums and the lower layers try hard to transfer the data correctly or not at all. The errors from badly-connecting cables may manifest as large amount of failed read or write requests, or as short error bursts depending on physical conditions.

What to do:

-

- check *smartctl* for potential issues

SOLID STATE DRIVES (SSD)

The mechanism of information storage is different from HDDs and this affects the failure mode as well. The data are stored in cells grouped in large blocks with limited number of resets and other write constraints. The firmware tries to avoid unnecessary resets and performs optimizations to maximize the storage media lifetime. The known techniques are deduplication (blocks with same fingerprint/hash are mapped to same physical block), compression or internal remapping and garbage collection of used memory cells. Due to the additional processing there are measures to verify the data e.g. by ECC codes.

The observations of failing SSDs show that the whole electronic fails at once or affects a lot of data (e.g. stored on one chip). Recovering such data may need specialized equipment and reading data repeatedly does not help as it's possible with HDDs.

There are several technologies of the memory cells with different characteristics and price. The lifetime is directly affected by the type and frequency of data written. Writing "too much" distinct data (e.g. encrypted) may render the internal deduplication ineffective and lead to a lot of rewrites and increased wear of the memory cells.

There are several technologies and manufacturers so it's hard to describe them but there are some that exhibit similar behaviour:

-

- expensive SSD will use more durable memory cells and is optimized for reliability and high load

-

- cheap SSD is projected for a lower load ("desktop user") and is optimized for cost, it may employ the optimizations and/or extended error reporting partially or not at all

It's not possible to reliably determine the expected lifetime of an SSD due to lack of information about how it works or due to lack of reliable stats provided by the device.

Metadata writes tend to be the biggest component of lifetime writes to a SSD, so there is some value in reducing them. Depending on the device class (high end/low end) the features like DUP block group profiles may affect the reliability in both ways:

-
- *high end* are typically more reliable and using *single* for data and metadata could be suitable to reduce device wear
-
- *low end* could lack ability to identify errors so an additional redundancy at the filesystem level (checksums, *DUP*) could help

Only users who consume 50 to 100% of the SSD's actual lifetime writes need to be concerned by the write amplification of btrfs DUP metadata. Most users will be far below 50% of the actual lifetime, or will write the drive to death and discover how many writes 100% of the actual lifetime was. SSD firmware often adds its own write multipliers that can be arbitrary and unpredictable and dependent on application behavior, and these will typically have far greater effect on SSD lifespan than DUP metadata. It's more or less impossible to predict when a SSD will run out of lifetime writes to within a factor of two, so it's hard to justify wear reduction as a benefit.

-
- [https://www.snia.org/educational-library/how-controllers-maximize\(ssd-life\)-2013](https://www.snia.org/educational-library/how-controllers-maximize(ssd-life)-2013)

What to do:

-
- run *smartctl* or self-tests to look for potential issues
-
- keep the firmware up-to-date

NVM EXPRESS, NON-VOLATILE MEMORY (NVMe)

NVMe is a type of persistent memory usually connected over a system bus (PCIe) or similar interface and the speeds are an order of magnitude faster than SSD. It is also a non-rotating type of storage, and is not typically connected by a cable. It's not a SCSI type device either but rather a complete specification for

logical device interface.

In a way the errors could be compared to a combination of SSD class and regular memory. Errors may exhibit as random bit flips or IO failures. There are tools to access the internal log (*nvme log* and *nvme-cl*) for a more detailed analysis.

There are separate error detection and correction steps performed e.g. on the bus level and in most cases never making it to the filesystem level. Once this happens it could mean there's some systematic error like overheating or bad physical connection of the device. You may want to run self-tests (using *smartctl*).

- https://en.wikipedia.org/wiki/NVM_Express

- https://www.smartmontools.org/wiki/NVMe_Support

DRIVE FIRMWARE

Firmware is technically still software but embedded into the hardware. As all software has bugs, so does firmware. Storage devices can update the firmware and fix known bugs. In some cases it's possible to avoid certain bugs by quirks (device-specific workarounds) in Linux kernel.

A faulty firmware can cause wide range of corruptions from small and localized to large affecting lots of data. Self-repair capabilities may not be sufficient.

What to do:

- check for firmware updates in case there are known problems, note that updating firmware can be risky on itself

- use up-to-date kernel (recent releases or maintained long term support versions)

SD FLASH CARDS

There are a lot of devices with low power consumption and thus using storage media based on low power consumption too, typically flash memory stored on a chip enclosed in a detachable card package. An improperly inserted card may be damaged by electrical spikes when the device is turned on or off. The chips storing data in turn may be damaged permanently. All types of flash memory have a limited number of rewrites, so the data are internally translated by FTL (flash translation layer). This is implemented in firmware (technically a software) and prone to bugs that manifest as hardware errors.

Adding redundancy like using DUP profiles for both data and metadata can help in some cases but a full backup might be the best option once problems appear and replacing the card could be required as well.

HARDWARE AS THE MAIN SOURCE OF FILESYSTEM CORRUPTIONS

If you use unreliable hardware and don't know about that, don't blame the filesystem when it tells you.

NAME

btrfs – a toolbox to manage btrfs filesystems

SYNOPSIS

btrfs <command> [<args>]

DESCRIPTION

The **btrfs** utility is a toolbox for managing btrfs filesystems. There are command groups to work with subvolumes, devices, for whole filesystem or other specific actions. See section **COMMANDS**.

There are also standalone tools for some tasks like **btrfs-convert** or **btrfstune** that were separate historically and/or haven't been merged to the main utility. See section **STANDALONE TOOLS** for more details.

For other topics (mount options, etc) please refer to the separate manual page **btrfs(5)**.

COMMAND SYNTAX

Any command name can be shortened so long as the shortened form is unambiguous, however, it is recommended to use full command names in scripts. All command groups have their manual page named **btrfs-<group>**.

For example: it is possible to run **btrfs sub snaps** instead of **btrfs subvolume snapshot**. But **btrfs file s** is not allowed, because **file s** may be interpreted both as **filesystem show** and as **filesystem sync**.

If the command name is ambiguous, the list of conflicting options is printed.

For an overview of a given command use *btrfs command --help* or *btrfs [command...] --help --full* to print all available options.

COMMANDS

balance

Balance btrfs filesystem chunks across single or several devices.

See **btrfs–balance(8)** for details.

check

Do off-line check on a btrfs filesystem.

See **btrfs–check(8)** for details.

device

Manage devices managed by btrfs, including add/delete/scan and so on.

See **btrfs–device(8)** for details.

filesystem

Manage a btrfs filesystem, including label setting-sync and so on.

See **btrfs–filesystem(8)** for details.

inspect–internal

Debug tools for developers/hackers.

See **btrfs–inspect–internal(8)** for details.

property

Get/set a property from/to a btrfs object.

See **btrfs–property(8)** for details.

qgroup

Manage quota group(qgroup) for btrfs filesystem.

See **btrfs-qgroup(8)** for details.

quota

Manage quota on btrfs filesystem like enabling/rescan and etc.

See **btrfs-quota(8)** and **btrfs-qgroup(8)** for details.

receive

Receive subvolume data from stdin/file for restore and etc.

See **btrfs-receive(8)** for details.

replace

Replace btrfs devices.

See **btrfs-replace(8)** for details.

rescue

Try to rescue damaged btrfs filesystem.

See **btrfs-rescue(8)** for details.

restore

Try to restore files from a damaged btrfs filesystem.

See **btrfs-restore(8)** for details.

scrub

Scrub a btrfs filesystem.

See **btrfs-scrub(8)** for details.

send

Send subvolume data to stdout/file for backup and etc.

See **btrfs-send(8)** for details.

subvolume

Create/delete/list/manage btrfs subvolume.

See **btrfs-subvolume(8)** for details.

STANDALONE TOOLS

New functionality could be provided using a standalone tool. If the functionality proves to be useful, then the standalone tool is declared obsolete and its functionality is copied to the main tool. Obsolete tools are removed after a long (years) depreciation period.

Tools that are still in active use without an equivalent in **btrfs**:

btrfs-convert

in-place conversion from ext2/3/4 filesystems to btrfs

btrfstune

tweak some filesystem properties on a unmounted filesystem

btrfs-select-super

rescue tool to overwrite primary superblock from a spare copy

btrfs-find-root

rescue helper to find tree roots in a filesystem

Deprecated and obsolete tools:

btrfs-debug-tree

moved to **btrfs inspect-internal dump-tree**. Removed from source distribution.

btrfs-show-super

moved to **btrfs inspect-internal dump-super**, standalone removed.

btrfs-zero-log

moved to **btrfs rescue zero-log**, standalone removed.

For space-constrained environments, it's possible to build a single binary with functionality of several standalone tools. This is following the concept of busybox where the file name selects the functionality. This works for symlinks or hardlinks. The full list can be obtained by **btrfs help --box**.

EXIT STATUS

btrfs returns a zero exit status if it succeeds. Non zero is returned in case of failure.

AVAILABILITY

btrfs is part of btrfs-progs. Please refer to the btrfs wiki <http://btrfs.wiki.kernel.org> for further details.

NAME

btrfs-check – check or repair a btrfs filesystem

SYNOPSIS

btrfs check [options] <device>

DESCRIPTION

The filesystem checker is used to verify structural integrity of a filesystem and attempt to repair it if requested. It is recommended to unmount the filesystem prior to running the check, but it is possible to start checking a mounted filesystem (see *--force*).

By default, **btrfs check** will not modify the device but you can reaffirm that by the option *--readonly*.

btrfsck is an alias of **btrfs check** command and is now deprecated.

Warning

Do not use *--repair* unless you are advised to do so by a developer or an experienced user, and then only after having accepted that no *fsck* successfully repair all types of filesystem corruption. Eg. some other software or hardware bugs can fatally damage a volume.

The structural integrity check verifies if internal filesystem objects or data structures satisfy the constraints, point to the right objects or are correctly connected together.

There are several cross checks that can detect wrong reference counts of shared extents, backreferences, missing extents of inodes, directory and inode connectivity etc.

The amount of memory required can be high, depending on the size of the filesystem, similarly the run time. Check the modes that can also affect that.

SAFE OR ADVISORY OPTIONS

-b|—backup

use the first valid set of backup roots stored in the superblock

This can be combined with *--super* if some of the superblocks are damaged.

--check-data-csum

verify checksums of data blocks

This expects that the filesystem is otherwise OK, and is basically an offline *scrub* that does not repair data from spare copies.

--chunk-root <bytenr>

use the given offset *bytenr* for the chunk tree root

-E|—subvol-extents <subvolid>

show extent state for the given subvolume

-p|—progress

indicate progress at various checking phases

-Q|—qgroup-report

verify qgroup accounting and compare against filesystem accounting

-r|—tree-root <bytenr>

use the given offset *bytenr* for the tree root

--readonly

(default) run in read-only mode, this option exists to calm potential panic when users are going to run the checker

-s|—super <superblock>

use 'superblock'th superblock copy, valid values are 0, 1 or 2 if the respective superblock offset is

within the device size

This can be used to use a different starting point if some of the primary superblock is damaged.

--clear-space-cache v1|v2

completely wipe all free space cache of given type

For free space cache *v1*, the *clear_cache* kernel mount option only rebuilds the free space cache for block groups that are modified while the filesystem is mounted with that option. Thus, using this option with *v1* makes it possible to actually clear the entire free space cache.

For free space cache *v2*, the *clear_cache* kernel mount option destroys the entire free space cache. This option, with *v2* provides an alternative method of clearing the free space cache that doesn't require mounting the filesystem.

--clear-ino-cache

remove leftover items pertaining to the deprecated inode map feature

DANGEROUS OPTIONS

--repair

enable the repair mode and attempt to fix problems where possible

Note

there's a warning and 10 second delay when this option is run without *--force* to give users a chance to think twice before running repair, the warnings in documentation have shown to be insufficient

--init-csum-tree

create a new checksum tree and recalculate checksums in all files

Note

Do not blindly use this option to fix checksum mismatch problems.

--init-extent-tree

build the extent tree from scratch

Note

Do not use unless you know what you're doing.

--mode <MODE>

select mode of operation regarding memory and IO

The *MODE* can be one of:

original

The metadata are read into memory and verified, thus the requirements are high on large filesystems and can even lead to out-of-memory conditions. The possible workaround is to export the block device over network to a machine with enough memory.

lowmem

This mode is supposed to address the high memory consumption at the cost of increased IO when it needs to re-read blocks. This may increase run time.

Note

lowmem mode does not work with *--repair* yet, and is still considered experimental.

--force

allow work on a mounted filesystem. Note that this should work fine on a quiescent or read-only mounted filesystem but may crash if the device is changed externally, eg. by the kernel module. Repair without mount checks is not supported right now.

This option also skips the delay and warning in the repair mode (see *--repair*).

EXIT STATUS

btrfs check returns a zero exit status if it succeeds. Non zero is returned in case of failure.

AVAILABILITY

btrfs is part of btrfs-progs. Please refer to the btrfs wiki <http://btrfs.wiki.kernel.org> for further details.

NAME

bzip2, **bunzip2** – a block-sorting file compressor, v1.0.8
bzcat – decompresses files to stdout
bzip2recover – recovers data from damaged bzip2 files

SYNOPSIS

```
bzip2 [ -cdfkqstvzVL123456789 ] [ filenames ... ]
bzip2 [ -h|--help ]
bunzip2 [ -fkvsVL ] [ filenames ... ]
bunzip2 [ -h|--help ]
bzcat [ -s ] [ filenames ... ]
bzcat [ -h|--help ]
bzip2recover filename
```

DESCRIPTION

bzip2 compresses files using the Burrows-Wheeler block sorting text compression algorithm, and Huffman coding. Compression is generally considerably better than that achieved by more conventional LZ77/LZ78-based compressors, and approaches the performance of the PPM family of statistical compressors.

The command-line options are deliberately very similar to those of *GNU gzip*, but they are not identical.

bzip2 expects a list of file names to accompany the command-line flags. Each file is replaced by a compressed version of itself, with the name "original_name.bz2". Each compressed file has the same modification date, permissions, and, when possible, ownership as the corresponding original, so that these properties can be correctly restored at decompression time. File name handling is naive in the sense that there is no mechanism for preserving original file names, permissions, ownerships or dates in filesystems which lack these concepts, or have serious file name length restrictions, such as MS-DOS.

bzip2 and *bunzip2* will by default not overwrite existing files. If you want this to happen, specify the *-f* flag.

If no file names are specified, *bzip2* compresses from standard input to standard output. In this case, *bzip2* will decline to write compressed output to a terminal, as this would be entirely incomprehensible and therefore pointless.

bunzip2 (or *bzip2 -d*) decompresses all specified files. Files which were not created by *bzip2* will be detected and ignored, and a warning issued. *bzip2* attempts to guess the filename for the decompressed file from that of the compressed file as follows:

filename.bz2	becomes	filename
filename.bz	becomes	filename
filename.tbz2	becomes	filename.tar
filename.tbz	becomes	filename.tar
anyothername	becomes	anyothername.out

If the file does not end in one of the recognised endings, *.bz2*, *.bz*, *.tbz2* or *.tbz*, *bzip2* complains that it cannot guess the name of the original file, and uses the original name with *.out* appended.

As with compression, supplying no filenames causes decompression from standard input to standard output.

bunzip2 will correctly decompress a file which is the concatenation of two or more compressed files. The result is the concatenation of the corresponding uncompressed files. Integrity testing (*-t*) of concatenated compressed files is also supported.

You can also compress or decompress files to the standard output by giving the `-c` flag. Multiple files may be compressed and decompressed like this. The resulting outputs are fed sequentially to `stdout`. Compression of multiple files in this manner generates a stream containing multiple compressed file representations. Such a stream can be decompressed correctly only by *bzip2* version 0.9.0 or later. Earlier versions of *bzip2* will stop after decompressing the first file in the stream.

bzcat (or *bzip2 -dc*) decompresses all specified files to the standard output.

bzip2 will read arguments from the environment variables *BZIP2* and *BZIP*, in that order, and will process them before any arguments read from the command line. This gives a convenient way to supply default arguments.

Compression is always performed, even if the compressed file is slightly larger than the original. Files of less than about one hundred bytes tend to get larger, since the compression mechanism has a constant overhead in the region of 50 bytes. Random data (including the output of most file compressors) is coded at about 8.05 bits per byte, giving an expansion of around 0.5%.

As a self-check for your protection, *bzip2* uses 32-bit CRCs to make sure that the decompressed version of a file is identical to the original. This guards against corruption of the compressed data, and against undetected bugs in *bzip2* (hopefully very unlikely). The chances of data corruption going undetected is microscopic, about one chance in four billion for each file processed. Be aware, though, that the check occurs upon decompression, so it can only tell you that something is wrong. It can't help you recover the original uncompressed data. You can use *bzip2recover* to try to recover data from damaged files.

Return values: 0 for a normal exit, 1 for environmental problems (file not found, invalid flags, I/O errors, &c), 2 to indicate a corrupt compressed file, 3 for an internal consistency error (eg, bug) which caused *bzip2* to panic.

OPTIONS

-c --stdout

Compress or decompress to standard output.

-d --decompress

Force decompression. *bzip2*, *bunzip2* and *bzcat* are really the same program, and the decision about what actions to take is done on the basis of which name is used. This flag overrides that mechanism, and forces *bzip2* to decompress.

-z --compress

The complement to `-d`: forces compression, regardless of the invocation name.

-t --test

Check integrity of the specified file(s), but don't decompress them. This really performs a trial decompression and throws away the result.

-f --force

Force overwrite of output files. Normally, *bzip2* will not overwrite existing output files. Also forces *bzip2* to break hard links to files, which it otherwise wouldn't do.

bzip2 normally declines to decompress files which don't have the correct magic header bytes. If forced (`-f`), however, it will pass such files through unmodified. This is how GNU *gzip* behaves.

-k --keep

Keep (don't delete) input files during compression or decompression.

-s --small

Reduce memory usage, for compression, decompression and testing. Files are decompressed and tested using a modified algorithm which only requires 2.5 bytes per block byte. This means any file can be decompressed in 2300 k of memory, albeit at about half the normal speed.

During compression, `-s` selects a block size of 200 k, which limits memory use to around the same figure, at the expense of your compression ratio. In short, if your machine is low on memory (8 megabytes or less), use `-s` for everything. See MEMORY MANAGEMENT below.

`-q --quiet`

Suppress non-essential warning messages. Messages pertaining to I/O errors and other critical events will not be suppressed.

`-v --verbose`

Verbose mode -- show the compression ratio for each file processed. Further `-v`'s increase the verbosity level, spewing out lots of information which is primarily of interest for diagnostic purposes.

`-h --help`

Print a help message and exit.

`-L --license -V --version`

Display the software version, license terms and conditions.

`-1 (or --fast) to -9 (or --best)`

Set the block size to 100 k, 200 k ... 900 k when compressing. Has no effect when decompressing. See MEMORY MANAGEMENT below. The `--fast` and `--best` aliases are primarily for GNU gzip compatibility. In particular, `--fast` doesn't make things significantly faster. And `--best` merely selects the default behaviour.

`--` Treats all subsequent arguments as file names, even if they start with a dash. This is so you can handle files with names beginning with a dash, for example: `bzip2 -- myfilename`.

`--repetitive-fast --repetitive-best`

These flags are redundant in versions 0.9.5 and above. They provided some coarse control over the behaviour of the sorting algorithm in earlier versions, which was sometimes useful. 0.9.5 and above have an improved algorithm which renders these flags irrelevant.

MEMORY MANAGEMENT

bzip2 compresses large files in blocks. The block size affects both the compression ratio achieved, and the amount of memory needed for compression and decompression. The flags `-1` through `-9` specify the block size to be 100,000 bytes through 900,000 bytes (the default) respectively. At decompression time, the block size used for compression is read from the header of the compressed file, and *bunzip2* then allocates itself just enough memory to decompress the file. Since block sizes are stored in compressed files, it follows that the flags `-1` to `-9` are irrelevant to and so ignored during decompression.

Compression and decompression requirements, in bytes, can be estimated as:

Compression: $400 \text{ k} + (8 \times \text{block size})$

Decompression: $100 \text{ k} + (4 \times \text{block size})$, or
 $100 \text{ k} + (2.5 \times \text{block size})$

Larger block sizes give rapidly diminishing marginal returns. Most of the compression comes from the first two or three hundred k of block size, a fact worth bearing in mind when using *bzip2* on small machines. It is also important to appreciate that the decompression memory requirement is set at compression time by the choice of block size.

For files compressed with the default 900 k block size, *bunzip2* will require about 3700 kbytes to decompress. To support decompression of any file on a 4 megabyte machine, *bunzip2* has an option to decompress using approximately half this amount of memory, about 2300 kbytes. Decompression speed is also halved, so you should use this option only where necessary. The relevant flag is `-s`.

In general, try and use the largest block size memory constraints allow, since that maximises the

compression achieved. Compression and decompression speed are virtually unaffected by block size.

Another significant point applies to files which fit in a single block -- that means most files you'd encounter using a large block size. The amount of real memory touched is proportional to the size of the file, since the file is smaller than a block. For example, compressing a file 20,000 bytes long with the flag -9 will cause the compressor to allocate around 7600 k of memory, but only touch 400 k + 20000 * 8 = 560 kbytes of it. Similarly, the decompressor will allocate 3700 k but only touch 100 k + 20000 * 4 = 180 kbytes.

Here is a table which summarises the maximum memory usage for different block sizes. Also recorded is the total compressed size for 14 files of the Calgary Text Compression Corpus totalling 3,141,622 bytes. This column gives some feel for how compression varies with block size. These figures tend to underestimate the advantage of larger block sizes for larger files, since the Corpus is dominated by smaller files.

Flag	Compress usage	Decompress usage	Decompress -s usage	Corpus Size
-1	1200k	500k	350k	914704
-2	2000k	900k	600k	877703
-3	2800k	1300k	850k	860338
-4	3600k	1700k	1100k	846899
-5	4400k	2100k	1350k	845160
-6	5200k	2500k	1600k	838626
-7	6100k	2900k	1850k	834096
-8	6800k	3300k	2100k	828642
-9	7600k	3700k	2350k	828642

RECOVERING DATA FROM DAMAGED FILES

bzip2 compresses files in blocks, usually 900 kbytes long. Each block is handled independently. If a media or transmission error causes a multi-block .bz2 file to become damaged, it may be possible to recover data from the undamaged blocks in the file.

The compressed representation of each block is delimited by a 48-bit pattern, which makes it possible to find the block boundaries with reasonable certainty. Each block also carries its own 32-bit CRC, so damaged blocks can be distinguished from undamaged ones.

bzip2recover is a simple program whose purpose is to search for blocks in .bz2 files, and write each block out into its own .bz2 file. You can then use *bzip2* -t to test the integrity of the resulting files, and decompress those which are undamaged.

bzip2recover takes a single argument, the name of the damaged file, and writes a number of files "rec00001file.bz2", "rec00002file.bz2", etc., containing the extracted blocks. The output filenames are designed so that the use of wildcards in subsequent processing -- for example, "bzip2 -dc rec*file.bz2 > recovered_data" -- processes the files in the correct order.

bzip2recover should be of most use dealing with large .bz2 files, as these will contain many blocks. It is clearly futile to use it on damaged single-block files, since a damaged block cannot be recovered. If you wish to minimise any potential data loss through media or transmission errors, you might consider compressing with a smaller block size.

PERFORMANCE NOTES

The sorting phase of compression gathers together similar strings in the file. Because of this, files containing very long runs of repeated symbols, like "aabbaabaab ..." (repeated several hundred times) may compress more slowly than normal. Versions 0.9.5 and above fare much better than previous versions in this respect. The ratio between worst-case and average-case compression time is in the region of 10:1. For

previous versions, this figure was more like 100:1. You can use the `-vvvv` option to monitor progress in great detail, if you want.

Decompression speed is unaffected by these phenomena.

bzip2 usually allocates several megabytes of memory to operate in, and then charges all over it in a fairly random fashion. This means that performance, both for compressing and decompressing, is largely determined by the speed at which your machine can service cache misses. Because of this, small changes to the code to reduce the miss rate have been observed to give disproportionately large performance improvements. I imagine *bzip2* will perform best on machines with very large caches.

CAVEATS

I/O error messages are not as helpful as they could be. *bzip2* tries hard to detect I/O errors and exit cleanly, but the details of what the problem is sometimes seem rather misleading.

This manual page pertains to version 1.0.8 of *bzip2*. Compressed data created by this version is entirely forwards and backwards compatible with the previous public releases, versions 0.1pl2, 0.9.0, 0.9.5, 1.0.0, 1.0.1, 1.0.2 and above, but with the following exception: 0.9.0 and above can correctly decompress multiple concatenated compressed files. 0.1pl2 cannot do this; it will stop after decompressing just the first file in the stream.

bzip2recover versions prior to 1.0.2 used 32-bit integers to represent bit positions in compressed files, so they could not handle compressed files more than 512 megabytes long. Versions 1.0.2 and above use 64-bit ints on some platforms which support them (GNU supported targets, and Windows). To establish whether or not *bzip2recover* was built with such a limitation, run it without arguments. In any event you can build yourself an unlimited version if you can recompile it with `MaybeUInt64` set to be an unsigned 64-bit integer.

AUTHOR

Julian Seward, jseward@acm.org.

<https://sourceware.org/bzip2/>

The ideas embodied in *bzip2* are due to (at least) the following people: Michael Burrows and David Wheeler (for the block sorting transformation), David Wheeler (again, for the Huffman coder), Peter Fenwick (for the structured coding model in the original *bzip*, and many refinements), and Alistair Moffat, Radford Neal and Ian Witten (for the arithmetic coder in the original *bzip*). I am much indebted for their help, support and advice. See the manual in the source distribution for pointers to sources of documentation. Christian von Roques encouraged me to look for faster sorting algorithms, so as to speed up compression. Bela Lubkin encouraged me to improve the worst-case compression performance. Donna Robinson XMLised the documentation. The bz* scripts are derived from those of GNU gzip. Many people sent patches, helped with portability problems, lent machines, gave advice and were generally helpful.

NAME

cal, ncal — displays a calendar and the date of Easter

SYNOPSIS

```
cal [-3hjy] [-A number] [-B number] [[month] year]
cal [-3hj] [-A number] [-B number] -m month [year]
ncal [-3bhjJpwySM] [-A number] [-B number] [-W number] [-s country_code]
      [[month] year]
ncal [-Jeo] [-A number] [-B number] [year]
ncal [-CN] [-H YYYY-mm-dd] [-d YYYY-mm]
```

DESCRIPTION

The **cal** utility displays a simple calendar in traditional format and **ncal** offers an alternative layout, more options and the date of Easter. The new format is a little cramped but it makes a year fit on a 25x80 terminal. If arguments are not specified, the current month is displayed.

The options are as follows:

- h** Turns off highlighting of today.
- J** Display Julian Calendar, if combined with the **-o** option, display date of Orthodox Easter according to the Julian Calendar.
- e** Display date of Easter (for western churches).
- j** Display Julian days (days one-based, numbered from January 1).
- m month** Display the specified *month*. If *month* is specified as a decimal number, appending ‘f’ or ‘p’ displays the same month of the following or previous year respectively.
- o** Display date of Orthodox Easter (Greek and Russian Orthodox Churches).
- p** Print the country codes and switching days from Julian to Gregorian Calendar as they are assumed by **ncal**. The country code as determined from the local environment is marked with an asterisk.
- s country_code** Assume the switch from Julian to Gregorian Calendar at the date associated with the *country_code*. If not specified, **ncal** tries to guess the switch date from the local environment or falls back to September 2, 1752. This was when Great Britain and her colonies switched to the Gregorian Calendar.
- w** Print the number of the week below each week column.
- y** Display a calendar for the specified year. This option is implied when a year but no month are specified on the command line.
- 3** Display the previous, current and next month surrounding today.
- 1** Display only the current month. This is the default.
- A number** Months to add after. The specified number of months is added to the end of the display. This is in addition to any date range selected by the **-y**, **-3**, or **-1** options. For example, “**cal -y -B2 -A2**” shows everything from November of the previous year to February of the following year. Negative numbers are allowed, in which case the specified number of months is subtracted. For example, “**cal -y -B-6**” shows July to December. And “**cal -A11**” simply shows the next 12 months.

-B *number*

Months to add before. The specified number of months is added to the beginning of the display. See **-A** for examples.

-C

Completely switch to **cal** mode. For **cal** like output only, use **-b** instead.

-d *YYYY-mm*

Use *YYYY-mm* as the current date (for debugging of date selection).

-H *YYYY-mm-dd*

Use *YYYY-mm-dd* as the current date (for debugging of highlighting).

-M

Weeks start on Monday.

-S

Weeks start on Sunday.

-W *number*

First week of the year has at least *number* days.

-b

Use oldstyle format for ncal output.

A single parameter specifies the year (1–9999) to be displayed; note the year must be fully specified: “**cal 89**” will not display a calendar for 1989. Two parameters denote the month and year; the month is either a number between 1 and 12, or a full or abbreviated name as specified by the current locale. Month and year default to those of the current system clock and time zone (so “**cal -m 8**” will display a calendar for the month of August in the current year).

Not all options can be used together. For example the options **-y**, **-3**, and **-1** are mutually exclusive. If inconsistent options are given, the later ones take precedence over the earlier ones.

A year starts on January 1.

Highlighting of dates is disabled if stdout is not a tty.

SEE ALSO

[calendar\(3\)](#), [strftime\(3\)](#)

STANDARDS

The **cal** utility is compliant with the X/Open System Interfaces option of the IEEE Std 1003.1-2008 (“POSIX.1”) specification.

The flags [**-3hyJeopw**], as well as the ability to specify a month name as a single argument, are extensions to that specification.

The week number computed by **-w** is compliant with the ISO 8601 specification.

HISTORY

A **cal** command appeared in Version 1 AT&T UNIX. Then **ncal** command appeared in FreeBSD 2.2.6. The output of the **cal** command is supposed to be bit for bit compatible to the original Unix **cal** command, because its output is processed by other programs like CGI scripts, that should not be broken. Therefore it will always output 8 lines, even if only 7 contain data. This extra blank line also appears with the original **cal** command, at least on Solaris 8

AUTHORS

The **ncal** command and manual were written by Wolfgang Helbig <helbig@FreeBSD.org>.

BUGS

The assignment of Julian–Gregorian switching dates to country codes is historically naive for many countries.

Not all options are compatible and using them in different orders will give varying results.

It is not possible to display Monday as the first day of the week with **cal**.

NAME

cat – concatenate files and print on the standard output

SYNOPSIS

cat [*OPTION*]... [*FILE*]...

DESCRIPTION

Concatenate FILE(s) to standard output.

With no FILE, or when FILE is **-**, read standard input.

-A, --show-all

equivalent to **-vET**

-b, --number-nonblank

number nonempty output lines, overrides **-n**

-e equivalent to **-vE**

-E, --show-ends

display \$ at end of each line

-n, --number

number all output lines

-s, --squeeze-blank

suppress repeated empty output lines

-t equivalent to **-vT**

-T, --show-tabs

display TAB characters as ^I

-u (ignored)

-v, --show-nonprinting

use ^ and M- notation, except for LFD and TAB

--help display this help and exit

--version

output version information and exit

EXAMPLES

cat f - g

Output f's contents, then standard input, then g's contents.

cat Copy standard input to standard output.

NAME

cfdisk – display or manipulate a disk partition table

SYNOPSIS

cfdisk [options] [*device*]

DESCRIPTION

cfdisk is a curses-based program for partitioning any block device. The default device is */dev/sda*.

Note that **cfdisk** provides basic partitioning functionality with a user-friendly interface. If you need advanced features, use **fdisk(8)** instead.

All disk label changes will remain in memory only, and the disk will be unmodified until you decide to write your changes. Be careful before using the write command.

Since version 2.25 **cfdisk** supports MBR (DOS), GPT, SUN and SGI disk labels, but no longer provides any functionality for CHS (Cylinder–Head–Sector) addressing. CHS has never been important for Linux, and this addressing concept does not make any sense for new devices.

Since version 2.25 **cfdisk** also does not provide a 'print' command any more. This functionality is provided by the utilities **partx(8)** and **lsblk(8)** in a very comfortable and rich way.

If you want to remove an old partition table from a device, use **wipefs(8)**.

OPTIONS

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

-L, --color[=when]

Colorize the output. The optional argument *when* can be **auto**, **never** or **always**. If the *when* argument is omitted, it defaults to **auto**. The colors can be disabled, for the current built-in default see **--help** output. See also the **COLORS** section.

--lock[=mode]

Use exclusive BSD lock for device or file it operates. The optional argument *mode* can be **yes**, **no** (or 1 and 0) or **nonblock**. If the *mode* argument is omitted, it defaults to **yes**. This option overwrites environment variable **\$LOCK_BLOCK_DEVICE**. The default is not to use any lock at all, but it's recommended to avoid collisions with **systemd-udevd(8)** or other tools.

-r, --read-only

Forced open in read-only mode.

-z, --zero

Start with an in-memory zeroed partition table. This option does not zero the partition table on the disk; rather, it simply starts the program without reading the existing partition table. This option allows you to create a new partition table from scratch or from an **sfdisk(8)**-compatible script.

COMMANDS

The commands for **cfdisk** can be entered by pressing the corresponding key (pressing *Enter* after the command is not necessary). Here is a list of the available commands:

b

Toggle the bootable flag of the current partition. This allows you to select which primary partition is bootable on the drive. This command may not be available for all partition label types.

d

Delete the current partition. This will convert the current partition into free space and merge it with any free space immediately surrounding the current partition. A partition already marked as free space or marked as unusable cannot be deleted.

h

Show the help screen.

n

Create a new partition from free space. **cfdisk** then prompts you for the size of the partition you want to create. The default size is equal to the entire available free space at the current position.

The size may be followed by a multiplicative suffix: KiB (=1024), MiB (=1024*1024), and so on for GiB, TiB, PiB, EiB, ZiB and YiB (the "iB" is optional, e.g., "K" has the same meaning as "KiB").

q

Quit the program. This will exit the program without writing any data to the disk.

r

Reduce or enlarge the current partition. **cfdisk** then prompts you for the new size of the partition. The default size is the current size. A partition marked as free space or marked as unusable cannot be resized.

Note that reducing the size of a partition might destroy data on that partition.

s

Sort the partitions in ascending start-sector order. When deleting and adding partitions, it is likely that the numbering of the partitions will no longer match their order on the disk. This command restores that match.

t

Change the partition type. By default, new partitions are created as *Linux* partitions.

u

Dump the current in-memory partition table to an **sfdisk(8)**-compatible script file.

The script files are compatible between **cfdisk**, **fdisk(8)** **sfdisk(8)** and other libfdisk applications. For more details see **sfdisk(8)**.

It is also possible to load an **sfdisk**-script into **cfdisk** if there is no partition table on the device or when you start **cfdisk** with the **--zero** command-line option.

W

Write the partition table to disk (you must enter an uppercase W). Since this might destroy data on the disk, you must either confirm or deny the write by entering 'yes' or 'no'. If you enter 'yes', **cfdisk** will write the partition table to disk and then tell the kernel to re-read the partition table from the disk.

The re-reading of the partition table does not always work. In such a case you need to inform the kernel about any new partitions by using **partprobe(8)** or **partx(8)**, or by rebooting the system.

x

Toggle extra information about a partition.

Up Arrow, Down Arrow

Move the cursor to the previous or next partition. If there are more partitions than can be displayed on a screen, you can display the next (previous) set of partitions by moving down (up) at the last (first) partition displayed on the screen.

Left Arrow, Right Arrow

Select the preceding or the next menu item. Hitting *Enter* will execute the currently selected item.

All commands can be entered with either uppercase or lowercase letters (except for **Write**). When in a submenu or at a prompt, you can hit the *Esc* key to return to the main menu.

COLORS

The output colorization is implemented by **terminal-colors.d(5)** functionality. Implicit coloring can be disabled by an empty file

/etc/terminal-colors.d/cfdisk.disable

for the **cfdisk** command or for all tools by

/etc/terminal-colors.d/disable

The user-specific *\$XDG_CONFIG_HOME/terminal-colors.d* or *\$HOME/.config/terminal-colors.d* overrides the global setting.

Note that the output colorization may be enabled by default, and in this case *terminal-colors.d* directories do not have to exist yet.

cfdisk does not support color customization with a color-scheme file.

ENVIRONMENT

CFDISK_DEBUG=all

enables cfdisk debug output.

LIBFDISK_DEBUG=all

enables libfdisk debug output.

LIBBLKID_DEBUG=all

enables libblkid debug output.

LIBSMARTCOLS_DEBUG=all

enables libsmartcols debug output.

LIBSMARTCOLS_DEBUG_PADDING=on

use visible padding characters. Requires enabled **LIBSMARTCOLS_DEBUG**.

LOCK_BLOCK_DEVICE=<mode>

use exclusive BSD lock. The mode is "1" or "0". See **--lock** for more details.

AUTHORS

Karel Zak <kzak@redhat.com>

The current **cfdisk** implementation is based on the original **cfdisk** from Kevin E. Martin <martin@cs.unc.edu>.

SEE ALSO

fdisk(8), parted(8), partprobe(8), partx(8), sfdisk(8)

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **cfdisk** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

cgdisk – Curses-based GUID partition table (GPT) manipulator

SYNOPSIS

cgdisk [-a] *device*

DESCRIPTION

GPT fdisk is a text-mode family of programs for creation and manipulation of partition tables. The **cgdisk** member of this family employs a curses-based user interface for interaction using a text-mode menuing system. It will automatically convert an old-style Master Boot Record (MBR) partition table or BSD disklabel stored without an MBR carrier partition to the newer Globally Unique Identifier (GUID) Partition Table (GPT) format, or will load a GUID partition table. Other members of this program family are **gdisk** (the most feature-rich program of the group, with a non-curses-based interactive user interface) and **sgdisk** (which is driven via command-line options for use by experts or in scripts). FixParts is a related program for fixing a limited set of problems with MBR disks.

For information on MBR vs. GPT, as well as GPT terminology and structure, see the extended GPT fdisk documentation at <http://www.rodsbooks.com/gdisk/> or consult Wikipedia.

The **cgdisk** program employs a user interface similar to that of Linux's **cfdisk**, but **cgdisk** modifies GPT partitions. It also has the capability of transforming MBR partitions or BSD disklabels into GPT partitions. Like the original **cfdisk** program, **cgdisk** does not modify disk structures until you explicitly write them to disk, so if you make a mistake, you can exit from the program with the Quit option to leave your partitions unmodified.

Ordinarily, **cgdisk** operates on disk device files, such as */dev/sda* or */dev/hda* under Linux, */dev/disk0* under Mac OS X, or */dev/ad0* or */dev/da0* under FreeBSD. The program can also operate on disk image files, which can be either copies of whole disks (made with **dd**, for instance) or raw disk images used by emulators such as QEMU or VMWare. Note that only *raw* disk images are supported; **cgdisk** cannot work on compressed or other advanced disk image formats.

Upon start, **cgdisk** attempts to identify the partition type in use on the disk. If it finds valid GPT data, **cgdisk** will use it. If **cgdisk** finds a valid MBR or BSD disklabel but no GPT data, it will attempt to convert the MBR or disklabel into GPT form. (BSD disklabels are likely to have unusable first and/or final partitions because they overlap with the GPT data structures, though.) Upon exiting with the 'w' option, **cgdisk** replaces the MBR or disklabel with a GPT. *This action is potentially dangerous!* Your system may become unbootable, and partition type codes may become corrupted if the disk uses unrecognized type codes. Boot problems are particularly likely if you're multi-booting with any GPT-unaware OS. If you mistakenly launch **cgdisk** on an MBR disk, you can safely exit the program without making any changes by using the Quit option.

When creating a fresh partition table, certain considerations may be in order:

- * For data (non-boot) disks, and for boot disks used on BIOS-based computers with GRUB as the boot loader, partitions may be created in whatever order and in whatever sizes are desired.
- * Boot disks for EFI-based systems require an *EFI System Partition* (GPT fdisk internal code 0xEF00) formatted as FAT-32. The recommended size of this partition is between 100 and 300 MiB. Boot-related files are stored here. (Note that GNU Parted identifies such partitions as having the "boot flag" set.)
- * The GRUB 2 boot loader for BIOS-based systems makes use of a *BIOS Boot Partition* (GPT fdisk internal code 0xEF02), in which the secondary boot loader is stored, without the benefit of a

filesystem. This partition can typically be quite small (roughly 32 KiB to 1 MiB), but you should consult your boot loader documentation for details.

- * If Windows is to boot from a GPT disk, a partition of type *Microsoft Reserved* (GPT fdisk internal code 0x0C01) is recommended. This partition should be about 128 MiB in size. It ordinarily follows the EFI System Partition and immediately precedes the Windows data partitions. (Note that old versions of GNU Parted create all FAT partitions as this type, which actually makes the partition unusable for normal file storage in both Windows and Mac OS X.)
- * Some OSes' GPT utilities create some blank space (typically 128 MiB) after each partition. The intent is to enable future disk utilities to use this space. Such free space is not required of GPT disks, but creating it may help in future disk maintenance. You can use GPT fdisk's relative partition positioning option (specifying the starting sector as '+128M', for instance) to simplify creating such gaps.

OPTIONS

Only one command-line option is accepted, aside from the device filename: *-a*. This option alters the highlighting of partitions and blocks of free space: Instead of using ncurses, when *-a* is used **cgdisk** uses a ">" symbol to the left of the selected partition or free space. This option is intended for use on limited display devices such as teletypes and screen readers.

Interactions with **cgdisk** occur with its interactive text-mode menus. The display is broken into two interactive parts:

- * The partition display area, in which partitions and gaps between them (marked as "free space") are summarized.
- * The option selection area, in which buttons for the main options appear.

In addition, the top of the display shows the program's name and version number, the device filename associated with the disk, and the disk's size in both sectors and IEEE-1541 units (GiB, TiB, and so on).

You can use the following keys to move among the various options and to select among them:

up arrow

This key moves the partition selection up by one partition.

down arrow

This key moves the partition selection down by one partition.

Page Up

This key moves the partition selection up by one screen.

Page Down

This key moves the partition selection down by one screen.

right arrow

This key moves the option selection to the right by one item.

left arrow

This key moves the option selection to the left by one item.

- Enter** This key activates the currently selected option. You can also activate an option by typing the capitalized letter in the option's name on the keyboard, such as **a** to activate the Align option.

If more partitions exist than can be displayed in one screen, you can scroll between screens using the partition selection keys, much as in a text editor.

Available options are as described below. (Note that **cgdisk** provides a much more limited set of options than its sibling **gdisk**. If you need to perform partition table recovery, hybrid MBR modification, or other advanced operations, you should consult the **gdisk** documentation.)

- Align** Change the sector alignment value. Disks with more logical sectors than physical sectors (such as modern Advanced Format drives), some RAID configurations, and many SSD devices, can suffer performance problems if partitions are not aligned properly for their internal data structures. On new disks, GPT fdisk attempts to align partitions on 1 MiB boundaries (2048–sectors on disks with 512-byte sectors) by default, which optimizes performance for all of these disk types. On pre-partitioned disks, GPT fdisk attempts to identify the alignment value used on that disk, but will set 8-sector alignment on disks larger than 300 GB even if lesser alignment values are detected. In either case, it can be changed by using this option.

Backup

Save partition data to a backup file. You can back up your current in–memory partition table to a disk file using this option. The resulting file is a binary file consisting of the protective MBR, the main GPT header, the backup GPT header, and one copy of the partition table, in that order. Note that the backup is of the current in–memory data structures, so if you launch the program, make changes, and then use this option, the backup will reflect your changes.

- Delete** Delete a partition. This action deletes the entry from the partition table but does not disturb the data within the sectors originally allocated to the partition on the disk. If a corresponding hybrid MBR partition exists, **gdisk** deletes it, as well, and expands any adjacent 0xEE (EFI GPT) MBR protective partition to fill the new free space.

- Help** Print brief descriptions of all the options.

- Info** Show detailed partition information. The summary information shown in the partition display area necessarily omits many details, such as the partitions' unique GUIDs and the partitions' sector-exact start and end points. The Info option displays this information for a single partition.

- Load** Load partition data from a backup file. This option is the reverse of the Backup option. Note that restoring partition data from anything but the original disk is not recommended.

- naMe** Change the GPT name of a partition. This name is encoded as a UTF–16 string, but proper entry and display of anything beyond basic ASCII values requires suitable locale and font support. For the most part, Linux ignores the partition name, but it may be important in some OSes. GPT fdisk sets a default name based on the partition type code. Note that the GPT partition name is different from the filesystem name, which is encoded in the filesystem's data structures. Note also that to activate this item by typing its alphabetic equivalent, you must use **M**, not the more obvious **N**, because the latter is used by the next option....

- New** Create a new partition. You enter a starting sector, a size, a type code, and a name. The start sector can be specified in absolute terms as a sector number or as a position measured in kibibytes (K), mebibytes (M), gibibytes (G), tebibytes (T), or pebibytes (P); for instance, **40M** specifies a position 40MiB from the start of the disk. You can specify locations relative to the start or end of the specified default range by preceding the number by a '+' symbol, as in **+2G** to specify a point 2GiB after the default start sector. The size value can use the K, M, G, T, and P suffixes, too. Pressing the Enter key with no input specifies the default value, which is the start of the largest available block for the start sector and the full available size for the size.
- Quit** Quit from the program *without saving your changes*. Use this option if you just wanted to view information or if you make a mistake and want to back out of all your changes.
- Type** Change a single partition's type code. You enter the type code using a two-byte hexadecimal number. You may also enter a GUID directly, if you have one and **cgdisk** doesn't know it. If you don't know the type code for your partition, you can type **L** to see a list of known type codes. The type code list may optionally be filtered by a search string; for instance, entering **linux** shows only partition type codes with descriptions that include the string *Linux*. This search is performed case-insensitively.
- Verify** Verify disk. This option checks for a variety of problems, such as incorrect CRCs and mismatched main and backup data. This option does not automatically correct most problems, though; for that, you must use **gdisk**. If no problems are found, this command displays a summary of unallocated disk space.
- Write** Write data. Use this command to save your changes.

BUGS

Known bugs and limitations include:

- * The program compiles correctly only on Linux, FreeBSD, and Mac OS X. In theory, it should compile under Windows if the Ncurses library for Windows is installed, but I have not tested this capability. Linux versions for x86-64 (64-bit), x86 (32-bit), and PowerPC (32-bit) have been tested, with the x86-64 version having seen the most testing. Under FreeBSD, 32-bit (x86) and 64-bit (x86-64) versions have been tested. Only 32-bit versions for Mac OS X has been tested by the author.
- * The FreeBSD version of the program can't write changes to the partition table to a disk when existing partitions on that disk are mounted. (The same problem exists with many other FreeBSD utilities, such as **gpt**, **fdisk**, and **dd**.) This limitation can be overcome by typing **sysctl kern.geom.debugflags=16** at a shell prompt.
- * The program can load only up to 128 partitions (4 primary partitions and 124 logical partitions) when converting from MBR format. This limit can be raised by changing the `#define MAX_MBR_PARTS` line in the `basicmbr.h` source code file and recompiling; however, such a change will require using a larger-than-normal partition table. (The limit of 128 partitions was chosen because that number equals the 128 partitions supported by the most common partition table size.)
- * Converting from MBR format sometimes fails because of insufficient space at the start or (more commonly) the end of the disk. Resizing the partition table (using the 's' option in the experts' menu in **gdisk**) can sometimes overcome this problem; however, in extreme cases it may be

necessary to resize a partition using GNU Parted or a similar tool prior to conversion with GPT fdisk.

- * MBR conversions work only if the disk has correct LBA partition descriptors. These descriptors should be present on any disk over 8 GiB in size or on smaller disks partitioned with any but very ancient software.
- * BSD disklabel support can create first and/or last partitions that overlap with the GPT data structures. This can sometimes be compensated by adjusting the partition table size, but in extreme cases the affected partition(s) may need to be deleted.
- * Because of the highly variable nature of BSD disklabel structures, conversions from this form may be unreliable — partitions may be dropped, converted in a way that creates overlaps with other partitions, or converted with incorrect start or end values. Use this feature with caution!
- * Booting after converting an MBR or BSD disklabel disk is likely to be disrupted. Sometimes re-installing a boot loader will fix the problem, but other times you may need to switch boot loaders. Except on EFI-based platforms, Windows through at least Windows 7 doesn't support booting from GPT disks. Creating a hybrid MBR (using the 'h' option on the recovery & transformation menu in **gdisk**) or abandoning GPT in favor of MBR may be your only options in this case.
- * The **cgdisk** Verify function and the partition type listing obtainable by typing *L* in the Type function (or when specifying a partition type while creating a new partition) both currently exit ncurses mode. This limitation is a minor cosmetic blemish that does not affect functionality.

AVAILABILITY

The **cgdisk** command is part of the *GPTfdisk* package and is available from Rod Smith.

NAME

cgroups – Linux control groups

DESCRIPTION

Control groups, usually referred to as cgroups, are a Linux kernel feature which allow processes to be organized into hierarchical groups whose usage of various types of resources can then be limited and monitored. The kernel's cgroup interface is provided through a pseudo-filesystem called cgroupfs. Grouping is implemented in the core cgroup kernel code, while resource tracking and limits are implemented in a set of per-resource-type subsystems (memory, CPU, and so on).

Terminology

A *cgroup* is a collection of processes that are bound to a set of limits or parameters defined via the cgroup filesystem.

A *subsystem* is a kernel component that modifies the behavior of the processes in a cgroup. Various subsystems have been implemented, making it possible to do things such as limiting the amount of CPU time and memory available to a cgroup, accounting for the CPU time used by a cgroup, and freezing and resuming execution of the processes in a cgroup. Subsystems are sometimes also known as *resource controllers* (or simply, controllers).

The cgroups for a controller are arranged in a *hierarchy*. This hierarchy is defined by creating, removing, and renaming subdirectories within the cgroup filesystem. At each level of the hierarchy, attributes (e.g., limits) can be defined. The limits, control, and accounting provided by cgroups generally have effect throughout the subhierarchy underneath the cgroup where the attributes are defined. Thus, for example, the limits placed on a cgroup at a higher level in the hierarchy cannot be exceeded by descendant cgroups.

Cgroups version 1 and version 2

The initial release of the cgroups implementation was in Linux 2.6.24. Over time, various cgroup controllers have been added to allow the management of various types of resources. However, the development of these controllers was largely uncoordinated, with the result that many inconsistencies arose between controllers and management of the cgroup hierarchies became rather complex. A longer description of these problems can be found in the kernel source file *Documentation/admin-guide/cgroup-v2.rst* (or *Documentation/cgroup-v2.txt* in Linux 4.17 and earlier).

Because of the problems with the initial cgroups implementation (cgroups version 1), starting in Linux 3.10, work began on a new, orthogonal implementation to remedy these problems. Initially marked experimental, and hidden behind the *-o _DEVEL_sane_behavior* mount option, the new version (cgroups version 2) was eventually made official with the release of Linux 4.5. Differences between the two versions are described in the text below. The file *cgroup.sane_behavior*, present in cgroups v1, is a relic of this mount option. The file always reports "0" and is only retained for backward compatibility.

Although cgroups v2 is intended as a replacement for cgroups v1, the older system continues to exist (and for compatibility reasons is unlikely to be removed). Currently, cgroups v2 implements only a subset of the controllers available in cgroups v1. The two systems are implemented so that both v1 controllers and v2 controllers can be mounted on the same system. Thus, for example, it is possible to use those controllers that are supported under version 2, while also using version 1 controllers where version 2 does not yet support those controllers. The only restriction here is that a controller can't be simultaneously employed in both a cgroups v1 hierarchy and in the cgroups v2 hierarchy.

CGROUPS VERSION 1

Under cgroups v1, each controller may be mounted against a separate cgroup filesystem that provides its own hierarchical organization of the processes on the system. It is also possible to comount multiple (or even all) cgroups v1 controllers against the same cgroup filesystem, meaning that the comounted controllers manage the same hierarchical organization of processes.

For each mounted hierarchy, the directory tree mirrors the control group hierarchy. Each control group is represented by a directory, with each of its child control cgroups represented as a child directory. For instance, */user/joe/1.session* represents control group *1.session*, which is a child of cgroup *joe*, which is a child of */user*. Under each cgroup directory is a set of files which can be read or written to, reflecting resource limits and a few general cgroup properties.

Tasks (threads) versus processes

In cgroups v1, a distinction is drawn between *processes* and *tasks*. In this view, a process can consist of multiple tasks (more commonly called threads, from a user-space perspective, and called such in the remainder of this man page). In cgroups v1, it is possible to independently manipulate the cgroup memberships of the threads in a process.

The cgroups v1 ability to split threads across different cgroups caused problems in some cases. For example, it made no sense for the *memory* controller, since all of the threads of a process share a single address space. Because of these problems, the ability to independently manipulate the cgroup memberships of the threads in a process was removed in the initial cgroups v2 implementation, and subsequently restored in a more limited form (see the discussion of "thread mode" below).

Mounting v1 controllers

The use of cgroups requires a kernel built with the **CONFIG_CGROUP** option. In addition, each of the v1 controllers has an associated configuration option that must be set in order to employ that controller.

In order to use a v1 controller, it must be mounted against a cgroup filesystem. The usual place for such mounts is under a **tmpfs(5)** filesystem mounted at `/sys/fs/cgroup`. Thus, one might mount the *cpu* controller as follows:

```
mount -t cgroup -o cpu none /sys/fs/cgroup/cpu
```

It is possible to comount multiple controllers against the same hierarchy. For example, here the *cpu* and *cpuacct* controllers are comounted against a single hierarchy:

```
mount -t cgroup -o cpu,cpuacct none /sys/fs/cgroup/cpu,cpuacct
```

Comounting controllers has the effect that a process is in the same cgroup for all of the comounted controllers. Separately mounting controllers allows a process to be in cgroup `/foo1` for one controller while being in `/foo2/foo3` for another.

It is possible to comount all v1 controllers against the same hierarchy:

```
mount -t cgroup -o all cgroup /sys/fs/cgroup
```

(One can achieve the same result by omitting *-o all*, since it is the default if no controllers are explicitly specified.)

It is not possible to mount the same controller against multiple cgroup hierarchies. For example, it is not possible to mount both the *cpu* and *cpuacct* controllers against one hierarchy, and to mount the *cpu* controller alone against another hierarchy. It is possible to create multiple mount with exactly the same set of comounted controllers. However, in this case all that results is multiple mount points providing a view of the same hierarchy.

Note that on many systems, the v1 controllers are automatically mounted under `/sys/fs/cgroup`; in particular, **systemd(1)** automatically creates such mounts.

Unmounting v1 controllers

A mounted cgroup filesystem can be unmounted using the **umount(8)** command, as in the following example:

```
umount /sys/fs/cgroup/pids
```

But note well: a cgroup filesystem is unmounted only if it is not busy, that is, it has no child cgroups. If this is not the case, then the only effect of the **umount(8)** is to make the mount invisible. Thus, to ensure that the mount is really removed, one must first remove all child cgroups, which in turn can be done only after all member processes have been moved from those cgroups to the root cgroup.

Cgroups version 1 controllers

Each of the cgroups version 1 controllers is governed by a kernel configuration option (listed below). Additionally, the availability of the cgroups feature is governed by the **CONFIG_CGROUPS** kernel configuration option.

***cpu* (since Linux 2.6.24; **CONFIG_CGROUP_SCHED**)**

Cgroups can be guaranteed a minimum number of "CPU shares" when a system is busy. This does not limit a cgroup's CPU usage if the CPUs are not busy. For further information, see *Documentation/scheduler/sched-design-CFS.rst* (or *Documentation/scheduler/sched-design-CFS.txt* in Linux 5.2 and earlier).

In Linux 3.2, this controller was extended to provide CPU "bandwidth" control. If the kernel is configured with **CONFIG_CFS_BANDWIDTH**, then within each scheduling period (defined via a file in the cgroup directory), it is possible to define an upper limit on the CPU time allocated to the processes in a cgroup. This upper limit applies even if there is no other competition for the CPU. Further information can be found in the kernel source file *Documentation/scheduler/sched-bwc.rst* (or *Documentation/scheduler/sched-bwc.txt* in Linux 5.2 and earlier).

***cpuacct* (since Linux 2.6.24; **CONFIG_CGROUP_CPUACCT**)**

This provides accounting for CPU usage by groups of processes.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/cpuacct.rst* (or *Documentation/cgroup-v1/cpuacct.txt* in Linux 5.2 and earlier).

***cpuset* (since Linux 2.6.24; **CONFIG_CPUSETS**)**

This cgroup can be used to bind the processes in a cgroup to a specified set of CPUs and NUMA nodes.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/cpusets.rst* (or *Documentation/cgroup-v1/cpusets.txt* in Linux 5.2 and earlier).

***memory* (since Linux 2.6.25; **CONFIG_MEMCG**)**

The memory controller supports reporting and limiting of process memory, kernel memory, and swap used by cgroups.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/memory.rst* (or *Documentation/cgroup-v1/memory.txt* in Linux 5.2 and earlier).

***devices* (since Linux 2.6.26; **CONFIG_CGROUP_DEVICE**)**

This supports controlling which processes may create (mknod) devices as well as open them for reading or writing. The policies may be specified as allow-lists and deny-lists. Hierarchy is enforced, so new rules must not violate existing rules for the target or ancestor cgroups.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/devices.rst* (or *Documentation/cgroup-v1/devices.txt* in Linux 5.2 and earlier).

***freezer* (since Linux 2.6.28; **CONFIG_CGROUP_FREEZER**)**

The *freezer* cgroup can suspend and restore (resume) all processes in a cgroup. Freezing a cgroup /A also causes its children, for example, processes in /A/B, to be frozen.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/freezer-subsystem.rst* (or *Documentation/cgroup-v1/freezer-subsystem.txt* in Linux 5.2 and earlier).

***net_cls* (since Linux 2.6.29; **CONFIG_CGROUP_NET_CLASSID**)**

This places a classid, specified for the cgroup, on network packets created by a cgroup. These classids can then be used in firewall rules, as well as used to shape traffic using **tc(8)**. This applies only to packets leaving the cgroup, not to traffic arriving at the cgroup.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/net_cls.rst* (or *Documentation/cgroup-v1/net_cls.txt* in Linux 5.2 and earlier).

***blkio* (since Linux 2.6.33; **CONFIG_BLK_CGROUP**)**

The *blkio* cgroup controls and limits access to specified block devices by applying IO control in the form of throttling and upper limits against leaf nodes and intermediate nodes in the storage hierarchy.

Two policies are available. The first is a proportional-weight time-based division of disk implemented with CFQ. This is in effect for leaf nodes using CFQ. The second is a throttling policy which specifies upper I/O rate limits on a device.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/blkio-controller.rst* (or *Documentation/cgroup-v1/blkio-controller.txt* in Linux 5.2 and earlier).

***perf_event* (since Linux 2.6.39; **CONFIG_CGROUP_PERF**)**

This controller allows *perf* monitoring of the set of processes grouped in a cgroup.

Further information can be found in the kernel source files

***net_prio* (since Linux 3.3; **CONFIG_CGROUP_NET_PRIO**)**

This allows priorities to be specified, per network interface, for cgroups.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/net_prio.rst* (or *Documentation/cgroup-v1/net_prio.txt* in Linux 5.2 and earlier).

***hugetlb* (since Linux 3.5; **CONFIG_CGROUP_HUGETLB**)**

This supports limiting the use of huge pages by cgroups.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/hugetlb.rst* (or *Documentation/cgroup-v1/hugetlb.txt* in Linux 5.2 and earlier).

***pids* (since Linux 4.3; **CONFIG_CGROUP_PIDS**)**

This controller permits limiting the number of process that may be created in a cgroup (and its descendants).

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/pids.rst* (or *Documentation/cgroup-v1/pids.txt* in Linux 5.2 and earlier).

***rdma* (since Linux 4.11; **CONFIG_CGROUP_RDMA**)**

The RDMA controller permits limiting the use of RDMA/IB-specific resources per cgroup.

Further information can be found in the kernel source file *Documentation/admin-guide/cgroup-v1/rdma.rst* (or *Documentation/cgroup-v1/rdma.txt* in Linux 5.2 and earlier).

Creating cgroups and moving processes

A cgroup filesystem initially contains a single root cgroup, `'/'`, which all processes belong to. A new cgroup is created by creating a directory in the cgroup filesystem:

```
mkdir /sys/fs/cgroup/cpu/cg1
```

This creates a new empty cgroup.

A process may be moved to this cgroup by writing its PID into the cgroup's *cgroup.procs* file:

```
echo $$ > /sys/fs/cgroup/cpu/cg1/cgroup.procs
```

Only one PID at a time should be written to this file.

Writing the value 0 to a *cgroup.procs* file causes the writing process to be moved to the corresponding cgroup.

When writing a PID into the *cgroup.procs*, all threads in the process are moved into the new cgroup at once.

Within a hierarchy, a process can be a member of exactly one cgroup. Writing a process's PID to a *cgroup.procs* file automatically removes it from the cgroup of which it was previously a member.

The *cgroup.procs* file can be read to obtain a list of the processes that are members of a cgroup. The returned list of PIDs is not guaranteed to be in order. Nor is it guaranteed to be free of duplicates. (For example, a PID may be recycled while reading from the list.)

In cgroups v1, an individual thread can be moved to another cgroup by writing its thread ID (i.e., the kernel thread ID returned by **clone(2)** and **gettid(2)**) to the *tasks* file in a cgroup directory. This file can be read to discover the set of threads that are members of the cgroup.

Removing cgroups

To remove a cgroup, it must first have no child cgroups and contain no (nonzombie) processes. So long as that is the case, one can simply remove the corresponding directory pathname. Note that files in a cgroup directory cannot and need not be removed.

Cgroups v1 release notification

Two files can be used to determine whether the kernel provides notifications when a cgroup becomes empty. A cgroup is considered to be empty when it contains no child cgroups and no member processes.

A special file in the root directory of each cgroup hierarchy, *release_agent*, can be used to register the pathname of a program that may be invoked when a cgroup in the hierarchy becomes empty. The pathname of the newly empty cgroup (relative to the cgroup mount point) is provided as the sole command-line argument when the *release_agent* program is invoked. The *release_agent* program might remove the cgroup directory, or perhaps repopulate it with a process.

The default value of the *release_agent* file is empty, meaning that no release agent is invoked.

The content of the *release_agent* file can also be specified via a mount option when the cgroup filesystem is mounted:

```
mount -o release_agent=pathname ...
```

Whether or not the *release_agent* program is invoked when a particular cgroup becomes empty is determined by the value in the *notify_on_release* file in the corresponding cgroup directory. If this file contains the value 0, then the *release_agent* program is not invoked. If it contains the value 1, the *release_agent* program is invoked. The default value for this file in the root cgroup is 0. At the time when a new cgroup is created, the value in this file is inherited from the corresponding file in the parent cgroup.

Cgroup v1 named hierarchies

In cgroups v1, it is possible to mount a cgroup hierarchy that has no attached controllers:

```
mount -t cgroup -o none,name=somename none /some/mount/point
```

Multiple instances of such hierarchies can be mounted; each hierarchy must have a unique name. The only purpose of such hierarchies is to track processes. (See the discussion of release notification below.) An example of this is the *name=systemd* cgroup hierarchy that is used by **systemd(1)** to track services and user sessions.

Since Linux 5.0, the *cgroup_no_v1* kernel boot option (described below) can be used to disable cgroup v1 named hierarchies, by specifying *cgroup_no_v1=named*.

CGROUPS VERSION 2

In cgroups v2, all mounted controllers reside in a single unified hierarchy. While (different) controllers may be simultaneously mounted under the v1 and v2 hierarchies, it is not possible to mount the same controller simultaneously under both the v1 and the v2 hierarchies.

The new behaviors in cgroups v2 are summarized here, and in some cases elaborated in the following subsections.

- Cgroups v2 provides a unified hierarchy against which all controllers are mounted.
- "Internal" processes are not permitted. With the exception of the root cgroup, processes may reside only in leaf nodes (cgroups that do not themselves contain child cgroups). The details are somewhat more subtle than this, and are described below.
- Active cgroups must be specified via the files *cgroup.controllers* and *cgroup.subtree_control*.

- The *tasks* file has been removed. In addition, the *cgroup.oup.clone_children* file that is employed by the *cpuset* controller has been removed.
- An improved mechanism for notification of empty cgroups is provided by the *cgroup.events* file.

For more changes, see the *Documentation/admin-guide/cgroup-v2.rst* file in the kernel source (or *Documentation/cgroup-v2.txt* in Linux 4.17 and earlier).

Some of the new behaviors listed above saw subsequent modification with the addition in Linux 4.14 of "thread mode" (described below).

Cgroups v2 unified hierarchy

In cgroups v1, the ability to mount different controllers against different hierarchies was intended to allow great flexibility for application design. In practice, though, the flexibility turned out to be less useful than expected, and in many cases added complexity. Therefore, in cgroups v2, all available controllers are mounted against a single hierarchy. The available controllers are automatically mounted, meaning that it is not necessary (or possible) to specify the controllers when mounting the cgroup v2 filesystem using a command such as the following:

```
mount -t cgroup2 none /mnt/cgroup2
```

A cgroup v2 controller is available only if it is not currently in use via a mount against a cgroup v1 hierarchy. Or, to put things another way, it is not possible to employ the same controller against both a v1 hierarchy and the unified v2 hierarchy. This means that it may be necessary first to unmount a v1 controller (as described above) before that controller is available in v2. Since **systemd(1)** makes heavy use of some v1 controllers by default, it can in some cases be simpler to boot the system with selected v1 controllers disabled. To do this, specify the *cgroup_no_v1=list* option on the kernel boot command line; *list* is a comma-separated list of the names of the controllers to disable, or the word *all* to disable all v1 controllers. (This situation is correctly handled by **systemd(1)**, which falls back to operating without the specified controllers.)

Note that on many modern systems, **systemd(1)** automatically mounts the *cgroup2* filesystem at */sys/fs/cgroup/unified* during the boot process.

Cgroups v2 mount options

The following options (*mount -o*) can be specified when mounting the group v2 filesystem:

nsdelegate (since Linux 4.15)

Treat cgroup namespaces as delegation boundaries. For details, see below.

memory.localevents (since Linux 5.2)

The *memory.events* should show statistics only for the cgroup itself, and not for any descendant cgroups. This was the behavior before Linux 5.2. Starting in Linux 5.2, the default behavior is to include statistics for descendant cgroups in *memory.events*, and this mount option can be used to revert to the legacy behavior. This option is system wide and can be set on mount or modified through remount only from the initial mount namespace; it is silently ignored in noninitial namespaces.

Cgroups v2 controllers

The following controllers, documented in the kernel source file *Documentation/admin-guide/cgroup-v2.rst* (or *Documentation/cgroup-v2.txt* in Linux 4.17 and earlier), are supported in cgroups version 2:

cpu (since Linux 4.15)

This is the successor to the version 1 *cpu* and *cpuacct* controllers.

cpuset (since Linux 5.0)

This is the successor of the version 1 *cpuset* controller.

freezer (since Linux 5.2)

This is the successor of the version 1 *freezer* controller.

hugetlb (since Linux 5.6)

This is the successor of the version 1 *hugetlb* controller.

io (since Linux 4.5)

This is the successor of the version 1 *blkio* controller.

memory (since Linux 4.5)

This is the successor of the version 1 *memory* controller.

perf_event (since Linux 4.11)

This is the same as the version 1 *perf_event* controller.

pids (since Linux 4.5)

This is the same as the version 1 *pids* controller.

rdma (since Linux 4.11)

This is the same as the version 1 *rdma* controller.

There is no direct equivalent of the *net_cls* and *net_prio* controllers from cgroups version 1. Instead, support has been added to **iptables(8)** to allow eBPF filters that hook on cgroup v2 pathnames to make decisions about network traffic on a per-cgroup basis.

The v2 *devices* controller provides no interface files; instead, device control is gated by attaching an eBPF (**BPF_CGROUP_DEVICE**) program to a v2 cgroup.

Cgroups v2 subtree control

Each cgroup in the v2 hierarchy contains the following two files:

cgroup.controllers

This read-only file exposes a list of the controllers that are *available* in this cgroup. The contents of this file match the contents of the *cgroup.subtree_control* file in the parent cgroup.

cgroup.subtree_control

This is a list of controllers that are *active (enabled)* in the cgroup. The set of controllers in this file is a subset of the set in the *cgroup.controllers* of this cgroup. The set of active controllers is modified by writing strings to this file containing space-delimited controller names, each preceded by '+' (to enable a controller) or '-' (to disable a controller), as in the following example:

```
echo '+pids -memory' > x/y/cgroup.subtree_control
```

An attempt to enable a controller that is not present in *cgroup.controllers* leads to an **ENOENT** error when writing to the *cgroup.subtree_control* file.

Because the list of controllers in *cgroup.subtree_control* is a subset of those *cgroup.controllers*, a controller that has been disabled in one cgroup in the hierarchy can never be re-enabled in the subtree below that cgroup.

A cgroup's *cgroup.subtree_control* file determines the set of controllers that are exercised in the *child* cgroups. When a controller (e.g., *pids*) is present in the *cgroup.subtree_control* file of a parent cgroup, then the corresponding controller-interface files (e.g., *pids.max*) are automatically created in the children of that cgroup and can be used to exert resource control in the child cgroups.

Cgroups v2 "no internal processes" rule

Cgroups v2 enforces a so-called "no internal processes" rule. Roughly speaking, this rule means that, with the exception of the root cgroup, processes may reside only in leaf nodes (cgroups that do not themselves contain child cgroups). This avoids the need to decide how to partition resources between processes which are members of cgroup A and processes in child cgroups of A.

For instance, if cgroup */cg1/cg2* exists, then a process may reside in */cg1/cg2*, but not in */cg1*. This is to avoid an ambiguity in cgroups v1 with respect to the delegation of resources between processes in */cg1* and its child cgroups. The recommended approach in cgroups v2 is to create a subdirectory called *leaf* for any nonleaf cgroup which should contain processes, but no child cgroups. Thus, processes which previously would have gone into */cg1* would now go into */cg1/leaf*. This has the advantage of making explicit the relationship between processes in */cg1/leaf* and */cg1*'s other children.

The "no internal processes" rule is in fact more subtle than stated above. More precisely, the rule is that a (nonroot) cgroup can't both (1) have member processes, and (2) distribute resources into child cgroups—that is, have a nonempty *cgroup.subtree_control* file. Thus, it is possible for a cgroup to have both member processes and child cgroups, but before controllers can be enabled for that cgroup, the member processes must be moved out of the cgroup (e.g., perhaps into the child cgroups).

With the Linux 4.14 addition of "thread mode" (described below), the "no internal processes" rule has been relaxed in some cases.

Cgroups v2 cgroup.events file

Each nonroot cgroup in the v2 hierarchy contains a read-only file, *cgroup.events*, whose contents are key-value pairs (delimited by newline characters, with the key and value separated by spaces) providing state information about the cgroup:

```
$ cat mygrp/cgroup.events
populated 1
frozen 0
```

The following keys may appear in this file:

populated

The value of this key is either 1, if this cgroup or any of its descendants has member processes, or otherwise 0.

frozen (since Linux 5.2)

The value of this key is 1 if this cgroup is currently frozen, or 0 if it is not.

The *cgroup.events* file can be monitored, in order to receive notification when the value of one of its keys changes. Such monitoring can be done using *inotify(7)*, which notifies changes as **IN_MODIFY** events, or *poll(2)*, which notifies changes by returning the **POLLPRI** and **POLLERR** bits in the *revents* field.

Cgroup v2 release notification

Cgroups v2 provides a new mechanism for obtaining notification when a cgroup becomes empty. The cgroups v1 *release_agent* and *notify_on_release* files are removed, and replaced by the *populated* key in the *cgroup.events* file. This key either has the value 0, meaning that the cgroup (and its descendants) contain no (nonzombie) member processes, or 1, meaning that the cgroup (or one of its descendants) contains member processes.

The cgroups v2 release-notification mechanism offers the following advantages over the cgroups v1 *release_agent* mechanism:

- It allows for cheaper notification, since a single process can monitor multiple *cgroup.events* files (using the techniques described earlier). By contrast, the cgroups v1 mechanism requires the expense of creating a process for each notification.
- Notification for different cgroup subhierarchies can be delegated to different processes. By contrast, the cgroups v1 mechanism allows only one release agent for an entire hierarchy.

Cgroups v2 cgroup.stat file

Each cgroup in the v2 hierarchy contains a read-only *cgroup.stat* file (first introduced in Linux 4.14) that consists of lines containing key-value pairs. The following keys currently appear in this file:

nr_descendants

This is the total number of visible (i.e., living) descendant cgroups underneath this cgroup.

nr_dying_descendants

This is the total number of dying descendant cgroups underneath this cgroup. A cgroup enters the dying state after being deleted. It remains in that state for an undefined period (which will depend on system load) while resources are freed before the cgroup is destroyed. Note that the presence of some cgroups in the dying state is normal, and is not indicative of any problem.

A process can't be made a member of a dying cgroup, and a dying cgroup can't be brought back to life.

Limiting the number of descendant cgroups

Each cgroup in the v2 hierarchy contains the following files, which can be used to view and set limits on the number of descendant cgroups under that cgroup:

cgroup.max.depth (since Linux 4.14)

This file defines a limit on the depth of nesting of descendant cgroups. A value of 0 in this file means that no descendant cgroups can be created. An attempt to create a descendant whose nesting level exceeds the limit fails (*mkdir(2)* fails with the error **EAGAIN**).

Writing the string "max" to this file means that no limit is imposed. The default value in this file is "max".

cgroup.max.descendants (since Linux 4.14)

This file defines a limit on the number of live descendant cgroups that this cgroup may have. An attempt to create more descendants than allowed by the limit fails (*mkdir(2)* fails with the error **EAGAIN**).

Writing the string "max" to this file means that no limit is imposed. The default value in this file is "max".

CGROUPS DELEGATION: DELEGATING A HIERARCHY TO A LESS PRIVILEGED USER

In the context of cgroups, delegation means passing management of some subtree of the cgroup hierarchy to a nonprivileged user. Cgroups v1 provides support for delegation based on file permissions in the cgroup hierarchy but with less strict containment rules than v2 (as noted below). Cgroups v2 supports delegation with containment by explicit design. The focus of the discussion in this section is on delegation in cgroups v2, with some differences for cgroups v1 noted along the way.

Some terminology is required in order to describe delegation. *Adele gater* is a privileged user (i.e., root) who owns a parent cgroup. A *delegatee* is a nonprivileged user who will be granted the permissions needed to manage some subhierarchy under that parent cgroup, known as the *delegated subtree*.

To perform delegation, the delegator makes certain directories and files writable by the delegatee, typically by changing the ownership of the objects to be the user ID of the delegatee. Assuming that we want to delegate the hierarchy rooted at (say) */dlgt_grp* and that there are not yet any child cgroups under that cgroup, the ownership of the following is changed to the user ID of the delegatee:

/dlgt_grp

Changing the ownership of the root of the subtree means that any new cgroups created under the subtree (and the files they contain) will also be owned by the delegatee.

/dlgt_grp/cgroup.procs

Changing the ownership of this file means that the delegatee can move processes into the root of the delegated subtree.

/dlgt_grp/cgroup.subtree_control (cgroups v2 only)

Changing the ownership of this file means that the delegatee can enable controllers (that are present in */dlgt_grp/cgroup.controllers*) in order to further redistribute resources at lower levels in the subtree. (As an alternative to changing the ownership of this file, the delegator might instead add selected controllers to this file.)

/dlgt_grp/cgroup.threads (cgroups v2 only)

Changing the ownership of this file is necessary if a threaded subtree is being delegated (see the description of "thread mode", below). This permits the delegatee to write thread IDs to the file. (The ownership of this file can also be changed when delegating a domain subtree, but currently this serves no purpose, since, as described below, it is not possible to move a thread between domain cgroups by writing its thread ID to the *cgroup.threads* file.)

In cgroups v1, the corresponding file that should instead be delegated is the *tasks* file.

The delegator should *not* change the ownership of any of the controller interfaces files (e.g., *pids.max*, *memory.high*) in *dlgt_grp*. Those files are used from the next level above the delegated subtree in order to distribute resources into the subtree, and the delegatee should not have permission to change the resources

that are distributed into the delegated subtree.

See also the discussion of the */sys/kernel/cgroup/delegate* file in NOTES for information about further delegatable files in cgroups v2.

After the aforementioned steps have been performed, the delegatee can create child cgroups within the delegated subtree (the cgroup subdirectories and the files they contain will be owned by the delegatee) and move processes between cgroups in the subtree. If some controllers are present in *dlgt_grp/cgroup.subtree_control*, or the ownership of that file was passed to the delegatee, the delegatee can also control the further redistribution of the corresponding resources into the delegated subtree.

Cgroups v2 delegation: nsdelegate and cgroup namespaces

Starting with Linux 4.13, there is a second way to perform cgroup delegation in the cgroups v2 hierarchy. This is done by mounting or remounting the cgroup v2 filesystem with the *nsdelegate* mount option. For example, if the cgroup v2 filesystem has already been mounted, we can remount it with the *nsdelegate* option as follows:

```
mount -t cgroup2 -o remount,nsdelegate \
    none /sys/fs/cgroup/unified
```

The effect of this mount option is to cause cgroup namespaces to automatically become delegation boundaries. More specifically, the following restrictions apply for processes inside the cgroup namespace:

- Writes to controller interface files in the root directory of the namespace will fail with the error **EPERM**. Processes inside the cgroup namespace can still write to delegatable files in the root directory of the cgroup namespace such as *cgroup.procs* and *cgroup.subtree_control*, and can create subhierarchy underneath the root directory.
- Attempts to migrate processes across the namespace boundary are denied (with the error **ENOENT**). Processes inside the cgroup namespace can still (subject to the containment rules described below) move processes between cgroups *within* the subhierarchy under the namespace root.

The ability to define cgroup namespaces as delegation boundaries makes cgroup namespaces more useful. To understand why, suppose that we already have one cgroup hierarchy that has been delegated to a non-privileged user, *cecilia*, using the older delegation technique described above. Suppose further that *cecilia* wanted to further delegate a subhierarchy under the existing delegated hierarchy. (For example, the delegated hierarchy might be associated with an unprivileged container run by *cecilia*.) Even if a cgroup namespace was employed, because both hierarchies are owned by the unprivileged user *cecilia*, the following illegitimate actions could be performed:

- A process in the inferior hierarchy could change the resource controller settings in the root directory of that hierarchy. (These resource controller settings are intended to allow control to be exercised from the *parent* cgroup; a process inside the child cgroup should not be allowed to modify them.)
- A process inside the inferior hierarchy could move processes into and out of the inferior hierarchy if the cgroups in the superior hierarchy were somehow visible.

Employing the *nsdelegate* mount option prevents both of these possibilities.

The *nsdelegate* mount option only has an effect when performed in the initial mount namespace; in other mount namespaces, the option is silently ignored.

Note: On some systems, **systemd(1)** automatically mounts the cgroup v2 filesystem. In order to experiment with the *nsdelegate* operation, it may be useful to boot the kernel with the following command-line options:

```
cgroup_no_v1=all systemd.legacy_systemd_cgroup_controller
```

These options cause the kernel to boot with the cgroups v1 controllers disabled (meaning that the controllers are available in the v2 hierarchy), and tells **systemd(1)** not to mount and use the cgroup v2 hierarchy, so that the v2 hierarchy can be manually mounted with the desired options after boot-up.

Cgroup delegation containment rules

Some delegation *containment rules* ensure that the delegatee can move processes between cgroups within the delegated subtree, but can't move processes from outside the delegated subtree into the subtree or vice versa. A nonprivileged process (i.e., the delegatee) can write the PID of a "target" process into a *cgroup.procs* file only if all of the following are true:

- The writer has write permission on the *cgroup.procs* file in the destination cgroup.
- The writer has write permission on the *cgroup.procs* file in the nearest common ancestor of the source and destination cgroups. Note that in some cases, the nearest common ancestor may be the source or destination cgroup itself. This requirement is not enforced for cgroups v1 hierarchies, with the consequence that containment in v1 is less strict than in v2. (For example, in cgroups v1 the user that owns two distinct delegated subhierarchies can move a process between the hierarchies.)
- If the cgroup v2 filesystem was mounted with the *nsdelegate* option, the writer must be able to see the source and destination cgroups from its cgroup namespace.
- In cgroups v1: the effective UID of the writer (i.e., the delegatee) matches the real user ID or the saved set-user-ID of the target process. Before Linux 4.11, this requirement also applied in cgroups v2 (This was a historical requirement inherited from cgroups v1 that was later deemed unnecessary, since the other rules suffice for containment in cgroups v2.)

Note: one consequence of these delegation containment rules is that the unprivileged delegatee can't place the first process into the delegated subtree; instead, the delegater must place the first process (a process owned by the delegatee) into the delegated subtree.

CGROUPS VERSION 2 THREAD MODE

Among the restrictions imposed by cgroups v2 that were not present in cgroups v1 are the following:

- *No thread-granularity control:* all of the threads of a process must be in the same cgroup.
- *No internal processes:* a cgroup can't both have member processes and exercise controllers on child cgroups.

Both of these restrictions were added because the lack of these restrictions had caused problems in cgroups v1. In particular, the cgroups v1 ability to allow thread-level granularity for cgroup membership made no sense for some controllers. (A notable example was the *memory* controller: since threads share an address space, it made no sense to split threads across different *memory* cgroups.)

Notwithstanding the initial design decision in cgroups v2, there were use cases for certain controllers, notably the *cpu* controller, for which thread-level granularity of control was meaningful and useful. To accommodate such use cases, Linux 4.14 added *thread mode* for cgroups v2.

Thread mode allows the following:

- The creation of *threaded subtrees* in which the threads of a process may be spread across cgroups inside the tree. (A threaded subtree may contain multiple multithreaded processes.)
- The concept of *threaded controllers*, which can distribute resources across the cgroups in a threaded subtree.
- A relaxation of the "no internal processes rule", so that, within a threaded subtree, a cgroup can both contain member threads and exercise resource control over child cgroups.

With the addition of thread mode, each nonroot cgroup now contains a new file, *cgroup.type*, that exposes, and in some circumstances can be used to change, the "type" of a cgroup. This file contains one of the following type values:

domain This is a normal v2 cgroup that provides process-granularity control. If a process is a member of this cgroup, then all threads of the process are (by definition) in the same cgroup. This is the default cgroup type, and provides the same behavior that was provided for cgroups in the initial cgroups v2 implementation.

threaded

This cgroup is a member of a threaded subtree. Threads can be added to this cgroup, and controllers can be enabled for the cgroup.

domain threaded

This is a domain cgroup that serves as the root of a threaded subtree. This cgroup type is also known as "threaded root".

domain invalid

This is a cgroup inside a threaded subtree that is in an "invalid" state. Processes can't be added to the cgroup, and controllers can't be enabled for the cgroup. The only thing that can be done with this cgroup (other than deleting it) is to convert it to a *threaded* cgroup by writing the string "*threaded*" to the *cgroup.type* file.

The rationale for the existence of this "interim" type during the creation of a threaded subtree (rather than the kernel simply immediately converting all cgroups under the threaded root to the type *threaded*) is to allow for possible future extensions to the thread mode model

Threaded versus domain controllers

With the addition of threads mode, cgroups v2 now distinguishes two types of resource controllers:

- *Threaded* controllers: these controllers support thread-granularity for resource control and can be enabled inside threaded subtrees, with the result that the corresponding controller-interface files appear inside the cgroups in the threaded subtree. As at Linux 4.19, the following controllers are threaded: *cpu*, *perf_event*, and *pids*.
- *Domain* controllers: these controllers support only process granularity for resource control. From the perspective of a domain controller, all threads of a process are always in the same cgroup. Domain controllers can't be enabled inside a threaded subtree.

Creating a threaded subtree

There are two pathways that lead to the creation of a threaded subtree. The first pathway proceeds as follows:

- (1) We write the string "*threaded*" to the *cgroup.type* file of a cgroup *y/z* that currently has the type *domain*. This has the following effects:
 - The type of the cgroup *y/z* becomes *threaded*.
 - The type of the parent cgroup, *y*, becomes *domain threaded*. The parent cgroup is the root of a threaded subtree (also known as the "threaded root").
 - All other cgroups under *y* that were not already of type *threaded* (because they were inside already existing threaded subtrees under the new threaded root) are converted to type *domain invalid*. Any subsequently created cgroups under *y* will also have the type *domain invalid*.
- (2) We write the string "*threaded*" to each of the *domain invalid* cgroups under *y*, in order to convert them to the type *threaded*. As a consequence of this step, all threads under the threaded root now have the type *threaded* and the threaded subtree is now fully usable. The requirement to write "*threaded*" to each of these cgroups is somewhat cumbersome, but allows for possible future extensions to the thread-mode model.

The second way of creating a threaded subtree is as follows:

- (1) In an existing cgroup, *z*, that currently has the type *domain*, we (1.1) enable one or more threaded controllers and (1.2) make a process a member of *z*. (These two steps can be done in either order.) This has the following consequences:
 - The type of *z* becomes *domain threaded*.
 - All of the descendant cgroups of *x* that were not already of type *threaded* are converted to type *domain invalid*.
- (2) As before, we make the threaded subtree usable by writing the string "*threaded*" to each of the *domain invalid* cgroups under *y*, in order to convert them to the type *threaded*.

One of the consequences of the above pathways to creating a threaded subtree is that the threaded root cgroup can be a parent only to *threaded* (and *domain invalid*) cgroups. The threaded root cgroup can't be a parent of a *domain* cgroups, and a *threaded* cgroup can't have a sibling that is a *domain* cgroup.

Using a threaded subtree

Within a threaded subtree, threaded controllers can be enabled in each subgroup whose type has been changed to *threaded*; upon doing so, the corresponding controller interface files appear in the children of that cgroup.

A process can be moved into a threaded subtree by writing its PID to the *cgroup.procs* file in one of the cgroups inside the tree. This has the effect of making all of the threads in the process members of the corresponding cgroup and makes the process a member of the threaded subtree. The threads of the process can then be spread across the threaded subtree by writing their thread IDs (see **gettid(2)**) to the *cgroup.threads* files in different cgroups inside the subtree. The threads of a process must all reside in the same threaded subtree.

As with writing to *cgroup.procs*, some containment rules apply when writing to the *cgroup.threads* file:

- The writer must have write permission on the *cgroup.threads* file in the destination cgroup.
- The writer must have write permission on the *cgroup.procs* file in the common ancestor of the source and destination cgroups. (In some cases, the common ancestor may be the source or destination cgroup itself.)
- The source and destination cgroups must be in the same threaded subtree. (Outside a threaded subtree, an attempt to move a thread by writing its thread ID to the *cgroup.threads* file in a different *domain* cgroup fails with the error **EOPNOTSUPP**.)

The *cgroup.threads* file is present in each cgroup (including *domain* cgroups) and can be read in order to discover the set of threads that is present in the cgroup. The set of thread IDs obtained when reading this file is not guaranteed to be ordered or free of duplicates.

The *cgroup.procs* file in the threaded root shows the PIDs of all processes that are members of the threaded subtree. The *cgroup.procs* files in the other cgroups in the subtree are not readable.

Domain controllers can't be enabled in a threaded subtree; no controller-interface files appear inside the cgroups underneath the threaded root. From the point of view of a domain controller, threaded subtrees are invisible: a multithreaded process inside a threaded subtree appears to a domain controller as a process that resides in the threaded root cgroup.

Within a threaded subtree, the "no internal processes" rule does not apply: a cgroup can both contain member processes (or thread) and exercise controllers on child cgroups.

Rules for writing to *cgroup.type* and creating threaded subtrees

A number of rules apply when writing to the *cgroup.type* file:

- Only the string "*threaded*" may be written. In other words, the only explicit transition that is possible is to convert a *domain* cgroup to type *threaded*.
- The effect of writing "*threaded*" depends on the current value in *cgroup.type*, as follows:
 - *domain* or *domain threaded*: start the creation of a threaded subtree (whose root is the parent of this cgroup) via the first of the pathways described above;
 - *domain invalid*: convert this cgroup (which is inside a threaded subtree) to a usable (i.e., *threaded*) state;
 - *threaded*: no effect (a "no-op").
- We can't write to a *cgroup.type* file if the parent's type is *domain invalid*. In other words, the cgroups of a threaded subtree must be converted to the *threaded* state in a top-down manner.

There are also some constraints that must be satisfied in order to create a threaded subtree rooted at the cgroup *x*:

- There can be no member processes in the descendant cgroups of *x*. (The *cgroupx* can itself have member processes.)
- No domain controllers may be enabled in *x*'s *cgroup.subtree_control* file.

If any of the above constraints is violated, then an attempt to write "*threaded*" to a *cgroup.type* file fails with the error **ENOTSUP**.

The "domain threaded" cgroup type

According to the pathways described above, the type of a cgroup can change to *domain threaded* in either of the following cases:

- The string "*threaded*" is written to a child cgroup.
- A threaded controller is enabled inside the cgroup and a process is made a member of the cgroup.

A *domain threaded* cgroup, *x*, can revert to the type *domain* if the above conditions no longer hold true—that is, if all *threaded* child cgroups of *x* are removed and either *x* no longer has threaded controllers enabled or no longer has member processes.

When a *domain threaded* cgroup *x* reverts to the type *domain*:

- All *domain invalid* descendants of *x* that are not in lower-level threaded subtrees revert to the type *domain*.
- The root cgroups in any lower-level threaded subtrees revert to the type *domain threaded*.

Exceptions for the root cgroup

The root cgroup of the v2 hierarchy is treated exceptionally: it can be the parent of both *domain* and *threaded* cgroups. If the string "*threaded*" is written to the *cgroup.type* file of one of the children of the root cgroup, then

- The type of that cgroup becomes *threaded*.
- The type of any descendants of that cgroup that are not part of lower-level threaded subtrees changes to *domain invalid*.

Note that in this case, there is no cgroup whose type becomes *domain threaded*. (Notionally, the root cgroup can be considered as the threaded root for the cgroup whose type was changed to *threaded*.)

The aim of this exceptional treatment for the root cgroup is to allow a threaded cgroup that employs the *cpu* controller to be placed as high as possible in the hierarchy, so as to minimize the (small) cost of traversing the cgroup hierarchy.

The cgroups v2 "cpu" controller and realtime threads

As at Linux 4.19, the cgroups v2 *cpu* controller does not support control of realtime threads (specifically threads scheduled under any of the policies **SCHED_FIFO**, **SCHED_RR**, described **SCHED_DEADLINE**; see **sched(7)**). Therefore, the *cpu* controller can be enabled in the root cgroup only if all realtime threads are in the root cgroup. (If there are realtime threads in nonroot cgroups, then a **write(2)** of the string "+*cpu*" to the *cgroup.subtree_control* file fails with the error **EINVAL**.)

On some systems, **systemd(1)** places certain realtime threads in nonroot cgroups in the v2 hierarchy. On such systems, these threads must first be moved to the root cgroup before the *cpu* controller can be enabled.

ERRORS

The following errors can occur for **mount(2)**:

EBUSY

An attempt to mount a cgroup version 1 filesystem specified neither the *name=* option (to mount a named hierarchy) nor a controller name (or *all*).

NOTES

A child process created via **fork(2)** inherits its parent's cgroup memberships. A process's cgroup memberships are preserved across **execve(2)**.

The **clone3(2)** **CLONE_INTO_CGROUP** flag can be used to create a child process that begins its life in a

different version 2 cgroup from the parent process.

/proc files

/proc/cgroups (since Linux 2.6.24)

This file contains information about the controllers that are compiled into the kernel. An example of the contents of this file (reformatted for readability) is the following:

#subsys_name	hierarchy	num_cgroups	enabled
cpuset	4	1	1
cpu	8	1	1
cpuacct	8	1	1
blkio	6	1	1
memory	3	1	1
devices	10	84	1
freezer	7	1	1
net_cls	9	1	1
perf_event	5	1	1
net_prio	9	1	1
hugetlb	0	1	0
pids	2	1	1

The fields in this file are, from left to right:

- [1] The name of the controller.
- [2] The unique ID of the cgroup hierarchy on which this controller is mounted. If multiple cgroups v1 controllers are bound to the same hierarchy, then each will show the same hierarchy ID in this field. The value in this field will be 0 if:
 - the controller is not mounted on a cgroups v1 hierarchy;
 - the controller is bound to the cgroups v2 single unified hierarchy; or
 - the controller is disabled (see below).
- [3] The number of control groups in this hierarchy using this controller.
- [4] This field contains the value 1 if this controller is enabled, or 0 if it has been disabled (via the *cgroup_disable* kernel command-line boot parameter).

/proc/[pid]/cgroup (since Linux 2.6.24)

This file describes control groups to which the process with the corresponding PID belongs. The displayed information differs for cgroups version 1 and version 2 hierarchies.

For each cgroup hierarchy of which the process is a member, there is one entry containing three colon-separated fields:

hierarchy-ID:controller-list:cgroup-path

For example:

5:cpuacct,cpu,cpuset:/daemons

The colon-separated fields are, from left to right:

- [1] For cgroups version 1 hierarchies, this field contains a unique hierarchy ID number that can be matched to a hierarchy ID in /proc/cgroups. For the cgroups version 2 hierarchy, this field contains the value 0.
- [2] For cgroups version 1 hierarchies, this field contains a comma-separated list of the controllers bound to the hierarchy. For the cgroups version 2 hierarchy, this field is empty.
- [3] This field contains the pathname of the control group in the hierarchy to which the process belongs. This pathname is relative to the mount point of the hierarchy.

/sys/kernel/cgroup files*/sys/kernel/cgroup/delegate* (since Linux 4.15)

This file exports a list of the cgroups v2 files (one per line) that are delegatable (i.e., whose ownership should be changed to the user ID of the delegatee). In the future, the set of delegatable files may change or grow, and this file provides a way for the kernel to inform user-space applications of which files must be delegated. As at Linux 4.15, one sees the following when inspecting this file:

```
$ cat /sys/kernel/cgroup/delegate
cgroup.procs
cgroup.subtree_control
cgroup.threads
```

/sys/kernel/cgroup/features (since Linux 4.15)

Over time, the set of cgroups v2 features that are provided by the kernel may change or grow, or some features may not be enabled by default. This file provides a way for user-space applications to discover what features the running kernel supports and has enabled. Features are listed one per line:

```
$ cat /sys/kernel/cgroup/features
nsdelegate
memory_localevents
```

The entries that can appear in this file are:

memory_localevents (since Linux 5.2)

The kernel supports the *memory_localevents* mount option.

nsdelegate (since Linux 4.15)

The kernel supports the *nsdelegate* mount option.

memory_recursiveprot (since Linux 5.7)

The kernel supports the *memory_recursiveprot* mount option.

NAME

chage – change user password expiry information

SYNOPSIS

chage [*options*] *LOGIN*

DESCRIPTION

The **chage** command changes the number of days between password changes and the date of the last password change. This information is used by the system to determine when a user must change their password.

OPTIONS

The options which apply to the **chage** command are:

-d, --lastday *LAST_DAY*

Set the number of days since January 1st, 1970 when the password was last changed. The date may also be expressed in the format YYYY-MM-DD (or the format more commonly used in your area).

-E, --expiredate *EXPIRE_DATE*

Set the date or number of days since January 1, 1970 on which the user's account will no longer be accessible. The date may also be expressed in the format YYYY-MM-DD (or the format more commonly used in your area). A user whose account is locked must contact the system administrator before being able to use the system again.

Passing the number *-I* as the *EXPIRE_DATE* will remove an account expiration date.

-h, --help

Display help message and exit.

-i, --iso8601

When printing dates, use YYYY-MM-DD format.

-I, --inactive *INACTIVE*

Set the number of days of inactivity after a password has expired before the account is locked. The *INACTIVE* option is the number of days of inactivity. A user whose account is locked must contact the system administrator before being able to use the system again.

Passing the number *-I* as the *INACTIVE* will remove an account's inactivity.

-l, --list

Show account aging information.

-m, --mindays *MIN_DAYS*

Set the minimum number of days between password changes to *MIN_DAYS*. A value of zero for this field indicates that the user may change their password at any time.

-M, --maxdays *MAX_DAYS*

Set the maximum number of days during which a password is valid. When *MAX_DAYS* plus *LAST_DAY* is less than the current day, the user will be required to change their password before being able to use their account. This occurrence can be planned for in advance by use of the **-W** option, which provides the user with advance warning.

Passing the number *-I* as *MAX_DAYS* will remove checking a password's validity.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-W, --warndays *WARN_DAYS*

Set the number of days of warning before a password change is required. The *WARN_DAYS* option is the number of days prior to the password expiring that a user will be warned their password is about to expire.

If none of the options are selected, **chage** operates in an interactive fashion, prompting the user with the current values for all of the fields. Enter the new value to change the field, or leave the line blank to use the current value. The current value is displayed between a pair of [] marks.

NOTE

The **chage** program requires a shadow password file to be available.

The **chage** command is restricted to the root user, except for the **-l** option, which may be used by an unprivileged user to determine when their password or account is due to expire.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

FILES

/etc/passwd
User account information.

/etc/shadow
Secure user account information.

EXIT VALUES

The **chage** command exits with the following values:

0	success
1	permission denied
2	invalid command syntax
15	can't find the shadow password file

SEE ALSO

passwd(5), shadow(5).

NAME

chgpasswd – update group passwords in batch mode

SYNOPSIS

chgpasswd [*options*]

DESCRIPTION

The **chgpasswd** command reads a list of group name and password pairs from standard input and uses this information to update a set of existing groups. Each line is of the format:

group_name:password

By default the supplied password must be in clear-text, and is encrypted by **chgpasswd**.

The default encryption algorithm can be defined for the system with the **ENCRYPT_METHOD** variable of /etc/login.defs, and can be overwritten with the **-e**, **-m**, or **-c** options.

This command is intended to be used in a large system environment where many accounts are created at a single time.

OPTIONS

The options which apply to the **chgpasswd** command are:

-c, --crypt-method

Use the specified method to encrypt the passwords.

The available methods are DES, MD5, NONE, and SHA256 or SHA512 if your libc support these methods.

-e, --encrypted

Supplied passwords are in encrypted form.

-h, --help

Display help message and exit.

-m, --md5

Use MD5 encryption instead of DES when the supplied passwords are not encrypted.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-s, --sha-rounds

Use the specified number of rounds to encrypt the passwords.

The value 0 means that the system will choose the default number of rounds for the crypt method (5000).

A minimal value of 1000 and a maximal value of 999,999,999 will be enforced.

You can only use this option with the SHA256 or SHA512 crypt method.

By default, the number of rounds is defined by the **SHA_CRYPT_MIN_ROUNDS** and **SHA_CRYPT_MAX_ROUNDS** variables in /etc/login.defs.

CAVEATS

Remember to set permissions or umask to prevent readability of unencrypted files by other users.

You should make sure the passwords and the encryption method respect the system's password policy.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

ENCRYPT_METHOD (string)

This defines the system default encryption algorithm for encrypting passwords (if no algorithm are

specified on the command line).

It can take one of these values: *DES* (default), *MD5*, *SHA256*, *SHA512*.

Note: this parameter overrides the **MD5_CRYPT_ENAB** variable.

Note: This only affect the generation of group passwords. The generation of user passwords is done by PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

MD5_CRYPT_ENAB (boolean)

Indicate if passwords must be encrypted using the MD5-based algorithm. If set to *yes*, new passwords will be encrypted using the MD5-based algorithm compatible with the one used by recent releases of FreeBSD. It supports passwords of unlimited length and longer salt strings. Set to *no* if you need to copy encrypted passwords to other systems which don't understand the new algorithm. Default is *no*.

This variable is superseded by the **ENCRYPT_METHOD** variable or by any command line option used to configure the encryption algorithm.

This variable is deprecated. You should use **ENCRYPT_METHOD**.

Note: This only affect the generation of group passwords. The generation of user passwords is done by PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

SHA_CRYPT_MIN_ROUNDS (number), **SHA_CRYPT_MAX_ROUNDS** (number)

When **ENCRYPT_METHOD** is set to *SHA256* or *SHA512*, this defines the number of SHA rounds used by the encryption algorithm by default (when the number of rounds is not specified on the command line).

With a lot of rounds, it is more difficult to brute forcing the password. But note also that more CPU resources will be needed to authenticate users.

If not specified, the libc will choose the default number of rounds (5000).

The values must be inside the 1000–999,999,999 range.

If only one of the **SHA_CRYPT_MIN_ROUNDS** or **SHA_CRYPT_MAX_ROUNDS** values is set, then this value will be used.

If **SHA_CRYPT_MIN_ROUNDS > SHA_CRYPT_MAX_ROUNDS**, the highest value will be used.

Note: This only affect the generation of group passwords. The generation of user passwords is done by PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

NAME

chmod – change file mode bits

SYNOPSIS

```
chmod [OPTION]... MODE[,MODE]... FILE...
chmod [OPTION]... OCTAL-MODE FILE...
chmod [OPTION]... --reference=RFILE FILE...
```

DESCRIPTION

This manual page documents the GNU version of **chmod**. **chmod** changes the file mode bits of each given file according to *mode*, which can be either a symbolic representation of changes to make, or an octal number representing the bit pattern for the new mode bits.

The format of a symbolic mode is [**ugo**a...][[-+]=][*perms*...]. . .], where *perms* is either zero or more letters from the set **rwxXst**, or a single letter from the set **ugo**. Multiple symbolic modes can be given, separated by commas.

A combination of the letters **ugo**a controls which users' access to the file will be changed: the user who owns it (**u**), other users in the file's group (**g**), other users not in the file's group (**o**), or all users (**a**). If none of these are given, the effect is as if (**a**) were given, but bits that are set in the umask are not affected.

The operator + causes the selected file mode bits to be added to the existing file mode bits of each file; - causes them to be removed; and = causes them to be added and causes unmentioned bits to be removed except that a directory's unmentioned set user and group ID bits are not affected.

The letters **rwxXst** select file mode bits for the affected users: read (**r**), write (**w**), execute (or search for directories) (**x**), execute/search only if the file is a directory or already has execute permission for some user (**X**), set user or group ID on execution (**s**), restricted deletion flag or sticky bit (**t**). Instead of one or more of these letters, you can specify exactly one of the letters **ugo**: the permissions granted to the user who owns the file (**u**), the permissions granted to other users who are members of the file's group (**g**), and the permissions granted to users that are in neither of the two preceding categories (**o**).

A numeric mode is from one to four octal digits (0–7), derived by adding up the bits with values 4, 2, and 1. Omitted digits are assumed to be leading zeros. The first digit selects the set user ID (4) and set group ID (2) and restricted deletion or sticky (1) attributes. The second digit selects permissions for the user who owns the file: read (4), write (2), and execute (1); the third selects permissions for other users in the file's group, with the same values; and the fourth for other users not in the file's group, with the same values.

chmod never changes the permissions of symbolic links; the **chmod** system call cannot change their permissions. This is not a problem since the permissions of symbolic links are never used. However, for each symbolic link listed on the command line, **chmod** changes the permissions of the pointed-to file. In contrast, **chmod** ignores symbolic links encountered during recursive directory traversals.

SETUID AND SETGID BITS

chmod clears the set-group-ID bit of a regular file if the file's group ID does not match the user's effective group ID or one of the user's supplementary group IDs, unless the user has appropriate privileges. Additional restrictions may cause the set-user-ID and set-group-ID bits of *MODE* or *RFILE* to be ignored. This behavior depends on the policy and functionality of the underlying **chmod** system call. When in doubt, check the underlying system behavior.

For directories **chmod** preserves set-user-ID and set-group-ID bits unless you explicitly specify otherwise. You can set or clear the bits with symbolic modes like **u+s** and **g-s**. To clear these bits for directories with a numeric mode requires an additional leading zero, or leading = like **00755** , or **=755**

RESTRICTED DELETION FLAG OR STICKY BIT

The restricted deletion flag or sticky bit is a single bit, whose interpretation depends on the file type. For directories, it prevents unprivileged users from removing or renaming a file in the directory unless they own the file or the directory; this is called the *restricted deletion flag* for the directory, and is commonly found on world-writable directories like **/tmp**. For regular files on some older systems, the bit saves the program's text image on the swap device so it will load more quickly when run; this is called the *sticky bit*.

OPTIONS

Change the mode of each FILE to MODE. With **--reference**, change the mode of each FILE to that of RFILE.

-c, --changes

like verbose but report only when a change is made

-f, --silent, --quiet

suppress most error messages

-v, --verbose

output a diagnostic for every file processed

--no-preserve-root

do not treat '/' specially (the default)

--preserve-root

fail to operate recursively on '/'

--reference=RFILE

use RFILE's mode instead of MODE values

-R, --recursive

change files and directories recursively

--help display this help and exit

--version

output version information and exit

Each MODE is of the form '[ugoa]*([-=][[rwxXst]*|[ugo]]))|[-=][0-7]+'.

NAME

chmod, fchmod, fchmodat – change permissions of a file

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/stat.h>
int chmod(const char *pathname, mode_t mode);
int fchmod(int fd, mode_t mode);

#include <fcntl.h>      /* Definition of AT_* constants */
#include <sys/stat.h>

int fchmodat(int dirfd, const char *pathname, mode_t mode, int fla gs);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

fchmod():

Since glibc 2.24:

`_POSIX_C_SOURCE >= 199309L`

glibc 2.19 to glibc 2.23

`_POSIX_C_SOURCE`

glibc 2.16 to glibc 2.19:

`_BSD_SOURCE || _POSIX_C_SOURCE`

glibc 2.12 to glibc 2.16:

`_BSD_SOURCE || _XOPEN_SOURCE >= 500`

`|| _POSIX_C_SOURCE >= 200809L`

glibc 2.11 and earlier:

`_BSD_SOURCE || _XOPEN_SOURCE >= 500`

fchmodat():

Since glibc 2.10:

`_POSIX_C_SOURCE >= 200809L`

Before glibc 2.10:

`_ATFILE_SOURCE`

DESCRIPTION

The **chmod()** and **fchmod()** system calls change a file's mode bits. (The file mode consists of the file permission bits plus the set-user-ID, set-group-ID, and sticky bits.) These system calls differ only in how the file is specified:

- **chmod()** changes the mode of the file specified whose pathname is given in *pathname*, which is dereferenced if it is a symbolic link.
- **fchmod()** changes the mode of the file referred to by the open file descriptor *fd*.

The new file mode is specified in *mode*, which is a bit mask created by ORing together zero or more of the following:

S_ISUID (04000)	set-user-ID (set process effective user ID on execve(2))
S_ISGID (02000)	set-group-ID (set process effective group ID on execve(2) ; mandatory locking, as described in fcntl(2) ; take a new file's group from parent directory, as described in chown(2) and mkdir(2))
S_ISVTX (01000)	sticky bit (restricted deletion flag, as described in unlink(2))
S_IRUSR (00400)	read by owner
S_IWUSR (00200)	write by owner
S_IXUSR (00100)	execute/search by owner ("search" applies for directories, and means that entries within the directory can be accessed)

- S_IRGRP** (00040) read by group
- S_IWGRP** (00020) write by group
- S_IXGRP** (00010) execute/search by group
- S_IROTH** (00004) read by others
- S_IWOTH** (00002) write by others
- S_IXOTH** (00001) execute/search by others

The effective UID of the calling process must match the owner of the file, or the process must be privileged (Linux: it must have the **CAP_FOWNER** capability).

If the calling process is not privileged (Linux: does not have the **CAP_FSETID** capability), and the group of the file does not match the effective group ID of the process or one of its supplementary group IDs, the **S_ISGID** bit will be turned off, but this will not cause an error to be returned.

As a security measure, depending on the filesystem, the set-user-ID and set-group-ID execution bits may be turned off if a file is written. (On Linux, this occurs if the writing process does not have the **CAP_FSETID** capability.) On some filesystems, only the superuser can set the sticky bit, which may have a special meaning. For the sticky bit, and for set-user-ID and set-group-ID bits on directories, see **inode**(7).

On NFS filesystems, restricting the permissions will immediately influence already open files, because the access control is done on the server, but open files are maintained by the client. Widening the permissions may be delayed for other clients if attribute caching is enabled on them.

fchmodat()

The **fchmodat()** system call operates in exactly the same way as **chmod()**, except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **chmod()** for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like **chmod()**).

If *pathname* is absolute, then *dirfd* is ignored.

flags can either be 0, or include the following flag:

AT_SYMLINK_NOFOLLOW

If *pathname* is a symbolic link, do not dereference it: instead operate on the link itself. This flag is not currently implemented.

See **openat**(2) for an explanation of the need for **fchmodat()**.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, errors other than those listed below can be returned.

The more general errors for **chmod()** are listed below:

EACCES

Search permission is denied on a component of the path prefix. (See also **path_resolution**(7).)

EBADF

(**fchmod()**) The file descriptor *fd* is not valid.

EBADF

(**fchmodat()**) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT

pathname points outside your accessible address space.

EINVAL

(**fchmodat()**) Invalid flag specified in *flags*.

EIO An I/O error occurred.**ELOOP**

Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG

pathname is too long.

ENOENT

The file does not exist.

ENOMEM

Insufficient kernel memory was available.

ENOTDIR

A component of the path prefix is not a directory.

ENOTDIR

(**fchmodat()**) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

ENOTSUP

(**fchmodat()**) *flags* specified **AT_SYMLINK_NOFOLLOW**, which is not supported.

EPERM

The effective UID does not match the owner of the file, and the process is not privileged (Linux: it does not have the **CAP_FOWNER** capability).

EPERM

The file is marked immutable or append-only. (See **ioctl_iflags(2)**.)

EROFS

The named file resides on a read-only filesystem.

VERSIONS

fchmodat() was added in Linux 2.6.16; library support was added in glibc 2.4.

STANDARDS

chmod(), **fchmod()**: 4.4BSD, SVr4, POSIX.1-2001i, POSIX.1-2008.

fchmodat(): POSIX.1-2008.

NOTES**C library/kernel differences**

The GNU C library **fchmodat()** wrapper function implements the POSIX-specified interface described in this page. This interface differs from the underlying Linux system call, which does *not* have a *flags* argument.

glibc notes

On older kernels where **fchmodat()** is unavailable, the glibc wrapper function falls back to the use of **chmod()**. When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

NAME

chown – change file owner and group

SYNOPSIS

```
chown [OPTION]... [OWNER][:GROUP] FILE...
chown [OPTION]... --reference=RFILE FILE...
```

DESCRIPTION

This manual page documents the GNU version of **chown**. **chown** changes the user and/or group ownership of each given file. If only an owner (a user name or numeric user ID) is given, that user is made the owner of each given file, and the files' group is not changed. If the owner is followed by a colon and a group name (or numeric group ID), with no spaces between them, the group ownership of the files is changed as well. If a colon but no group name follows the user name, that user is made the owner of the files and the group of the files is changed to that user's login group. If the colon and group are given, but the owner is omitted, only the group of the files is changed; in this case, **chown** performs the same function as **chgrp**. If only a colon is given, or if the entire operand is empty, neither the owner nor the group is changed.

OPTIONS

Change the owner and/or group of each FILE to OWNER and/or GROUP. With **--reference**, change the owner and group of each FILE to those of RFILE.

-c, --changes

like verbose but report only when a change is made

-f, --silent, --quiet

suppress most error messages

-v, --verbose

output a diagnostic for every file processed

--dereference

affect the referent of each symbolic link (this is the default), rather than the symbolic link itself

-h, --no-dereference

affect symbolic links instead of any referenced file (useful only on systems that can change the ownership of a symlink)

--from=CURRENT_OWNER:CURRENT_GROUP

change the owner and/or group of each file only if its current owner and/or group match those specified here. Either may be omitted, in which case a match is not required for the omitted attribute

--no-preserve-root

do not treat '/' specially (the default)

--preserve-root

fail to operate recursively on '/'

--reference=RFILE

use RFILE's owner and group rather than specifying OWNER:GROUP values

-R, --recursive

operate on files and directories recursively

The following options modify how a hierarchy is traversed when the **-R** option is also specified. If more than one is specified, only the final one takes effect.

-H if a command line argument is a symbolic link to a directory, traverse it

-L traverse every symbolic link to a directory encountered

-P do not traverse any symbolic links (default)

--help display this help and exit

--version

output version information and exit

Owner is unchanged if missing. Group is unchanged if missing, but changed to login group if implied by a ':' following a symbolic OWNER. OWNER and GROUP may be numeric as well as symbolic.

EXAMPLES

chown root /u

Change the owner of /u to "root".

chown root:staff /u

Likewise, but also change its group to "staff".

chown -hR root /u

Change the owner of /u and subfiles to "root".

NAME

chown, fchown, lchown, fchownat – change ownership of a file

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <unistd.h>
int chown(const char *pathname, uid_t owner, gid_t group);
int fchown(int fd, uid_t owner, gid_t group);
int lchown(const char *pathname, uid_t owner, gid_t group);

#include <fcntl.h>      /* Definition of AT_* constants */
#include <unistd.h>

int fchownat(int dirfd, const char *pathname,
             uid_t owner, gid_t group, int flags);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
fchown(), lchown():
/* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L
|| _XOPEN_SOURCE >= 500
|| /* glibc <= 2.19: */ _BSD_SOURCE

fchownat():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_ATFILE_SOURCE
```

DESCRIPTION

These system calls change the owner and group of a file. The **chown()**, **fchown()**, and **lchown()** system calls differ only in how the file is specified:

- **chown()** changes the ownership of the file specified by *pathname*, which is dereferenced if it is a symbolic link.
- **fchown()** changes the ownership of the file referred to by the open file descriptor *fd*.
- **lchown()** is like **chown()**, but does not dereference symbolic links.

Only a privileged process (Linux: one with the **CAP_CHOWN** capability) may change the owner of a file. The owner of a file may change the group of the file to any group of which that owner is a member. A privileged process (Linux: with **CAP_CHOWN**) may change the group arbitrarily.

If the *owner* or *group* is specified as -1 , then that ID is not changed.

When the owner or group of an executable file is changed by an unprivileged user, the **S_ISUID** and **S_ISGID** mode bits are cleared. POSIX does not specify whether this also should happen when root does the **chown()**; the Linux behavior depends on the kernel version, and since Linux 2.2.13, root is treated like other users. In case of a non-group-executable file (i.e., one for which the **S_IXGRP** bit is not set) the **S_ISGID** bit indicates mandatory locking, and is not cleared by a **chown()**.

When the owner or group of an executable file is changed (by any user), all capability sets for the file are cleared.

fchownat()

The **fchownat()** system call operates in exactly the same way as **chown()**, except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **chown()** for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like **chown()**).

If *pathname* is absolute, then *dirfd* is ignored.

The *flags* argument is a bit mask created by ORing together 0 or more of the following values;

AT_EMPTY_PATH (since Linux 2.6.39)

If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the **open(2)** **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory. If *dirfd* is **AT_FDCWD**, the call operates on the current working directory. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_SYMLINK_NOFOLLOW

If *pathname* is a symbolic link, do not dereference it: instead operate on the link itself, like **lchown()**. (By default, **fchownat()** dereferences symbolic links, like **chown()**.)

See **openat(2)** for an explanation of the need for **fchownat()**.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, errors other than those listed below can be returned.

The more general errors for **chown()** are listed below.

EACCES

Search permission is denied on a component of the path prefix. (See also **path_resolution(7)**.)

EBADF

(**fchown()**) *fd* is not a valid open file descriptor.

EBADF

(**fchownat()**) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT

pathname points outside your accessible address space.

EINVAL

(**fchownat()**) Invalid flag specified in *flags*.

EIO

(**fchown()**) A low-level I/O error occurred while modifying the inode.

ELOOP

Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG

pathname is too long.

ENOENT

The file does not exist.

ENOMEM

Insufficient kernel memory was available.

ENOTDIR

A component of the path prefix is not a directory.

ENOTDIR

(**fchownat()**) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM

The calling process did not have the required permissions (see above) to change owner and/or group.

EPERM

The file is marked immutable or append-only. (See [ioctl_iflags\(2\)](#).)

EROFS

The named file resides on a read-only filesystem.

VERSIONS

fchownat() was added in Linux 2.6.16; library support was added in glibc 2.4.

STANDARDS

chown(), **fchown()**, **lchown()**: 4.4BSD, SVr4, POSIX.1-2001, POSIX.1-2008.

The 4.4BSD version can be used only by the superuser (that is, ordinary users cannot give away files).

fchownat(): POSIX.1-2008.

NOTES**Ownership of new files**

When a new file is created (by, for example, **open(2)** or **mkdir(2)**), its owner is made the same as the filesystem user ID of the creating process. The group of the file depends on a range of factors, including the type of filesystem, the options used to mount the filesystem, and whether or not the set-group-ID mode bit is enabled on the parent directory. If the filesystem supports the **-o gr pid** (or, synonymously **-o bsd-groups**) and **-o nogrpid** (or, synonymously **-o sysvgroups**) **mount(8)** options, then the rules are as follows:

- If the filesystem is mounted with **-o gr pid**, then the group of a new file is made the same as that of the parent directory.
- If the filesystem is mounted with **-o nogrpid** and the set-group-ID bit is disabled on the parent directory, then the group of a new file is made the same as the process's filesystem GID.
- If the filesystem is mounted with **-o nogrpid** and the set-group-ID bit is enabled on the parent directory, then the group of a new file is made the same as that of the parent directory.

As at Linux 4.12, the **-o gr pid** and **-o nogrpid** mount options are supported by ext2, ext3, ext4, and XFS. Filesystems that don't support these mount options follow the **-o nogrpid** rules.

glibc notes

On older kernels where **fchownat()** is unavailable, the glibc wrapper function falls back to the use of **chown()** and **lchown()**. When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

NFS

The **chown()** semantics are deliberately violated on NFS filesystems which have UID mapping enabled. Additionally, the semantics of all system calls which access the file contents are violated, because **chown()** may cause immediate access revocation on already open files. Client side caching may lead to a delay between the time where ownership have been changed to allow access for a user and the time where the file can actually be accessed by the user on other clients.

Historical details

The original Linux **chown()**, **fchown()**, and **lchown()** system calls supported only 16-bit user and group IDs. Subsequently, Linux 2.4 added **chown32()**, **fchown32()**, and **lchown32()**, supporting 32-bit IDs. The glibc **chown()**, **fchown()**, and **lchown()** wrapper functions transparently deal with the variations across kernel versions.

Before Linux 2.1.81 (except 2.1.46), **chown()** did not follow symbolic links. Since Linux 2.1.81, **chown()** does follow symbolic links, and there is a new system call **lchown()** that does not follow symbolic links. Since Linux 2.1.86, this new call (that has the same semantics as the old **chown()**) has got the same syscall number, and **chown()** got the newly introduced number.

EXAMPLES

The following program changes the ownership of the file named in its second command-line argument to the value specified in its first command-line argument. The new owner can be specified either as a numeric

user ID, or as a username (which is converted to a user ID by using **getpwnam(3)** to perform a lookup in the system password file).

Program source

```
#include <pwd.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    char             *endptr;
    uid_t            uid;
    struct passwd   *pwd;

    if (argc != 3 || argv[1][0] == '\0') {
        fprintf(stderr, "%s <owner> <file>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    uid = strtol(argv[1], &endptr, 10); /* Allow a numeric string */

    if (*endptr != '\0') {           /* Was not pure numeric string */
        pwd = getpwnam(argv[1]);    /* Try getting UID for username */
        if (pwd == NULL) {
            perror("getpwnam");
            exit(EXIT_FAILURE);
        }

        uid = pwd->pw_uid;
    }

    if (chown(argv[2], uid, -1) == -1) {
        perror("chown");
        exit(EXIT_FAILURE);
    }

    exit(EXIT_SUCCESS);
}
```

chown, fchown, lchown, fchownat – change ownership of a file

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <unistd.h>
int chown(const char *pathname, uid_t owner, gid_t group);
int fchown(int fd, uid_t owner, gid_t group);
int lchown(const char *pathname, uid_t owner, gid_t group);

#include <fcntl.h>      /* Definition of AT_* constants */
#include <unistd.h>

int fchownat(int dirfd, const char *pathname,
             uid_t owner, gid_t group, int flags);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
fchown(), lchown():
/* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L
|| _XOPEN_SOURCE >= 500
|| /* glibc <= 2.19: */ _BSD_SOURCE

fchownat():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_ATFILE_SOURCE
```

DESCRIPTION

These system calls change the owner and group of a file. The **chown()**, **fchown()**, and **lchown()** system calls differ only in how the file is specified:

- **chown()** changes the ownership of the file specified by *pathname*, which is dereferenced if it is a symbolic link.
- **fchown()** changes the ownership of the file referred to by the open file descriptor *fd*.
- **lchown()** is like **chown()**, but does not dereference symbolic links.

Only a privileged process (Linux: one with the **CAP_CHOWN** capability) may change the owner of a file. The owner of a file may change the group of the file to any group of which that owner is a member. A privileged process (Linux: with **CAP_CHOWN**) may change the group arbitrarily.

If the *owner* or *group* is specified as -1 , then that ID is not changed.

When the owner or group of an executable file is changed by an unprivileged user, the **S_ISUID** and **S_ISGID** mode bits are cleared. POSIX does not specify whether this also should happen when root does the **chown()**; the Linux behavior depends on the kernel version, and since Linux 2.2.13, root is treated like other users. In case of a non-group-executable file (i.e., one for which the **S_IXGRP** bit is not set) the **S_ISGID** bit indicates mandatory locking, and is not cleared by a **chown()**.

When the owner or group of an executable file is changed (by any user), all capability sets for the file are cleared.

fchownat()

The **fchownat()** system call operates in exactly the same way as **chown()**, except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **chown()** for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like **chown()**).

If *pathname* is absolute, then *dirfd* is ignored.

The *flags* argument is a bit mask created by ORing together 0 or more of the following values;

AT_EMPTY_PATH (since Linux 2.6.39)

If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the **open(2)** **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory. If *dirfd* is **AT_FDCWD**, the call operates on the current working directory. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_SYMLINK_NOFOLLOW

If *pathname* is a symbolic link, do not dereference it: instead operate on the link itself, like **lchown()**. (By default, **fchownat()** dereferences symbolic links, like **chown()**.)

See **openat(2)** for an explanation of the need for **fchownat()**.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, errors other than those listed below can be returned.

The more general errors for **chown()** are listed below.

EACCES

Search permission is denied on a component of the path prefix. (See also **path_resolution(7)**.)

EBADF

(**fchown()**) *fd* is not a valid open file descriptor.

EBADF

(**fchownat()**) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT

pathname points outside your accessible address space.

EINVAL

(**fchownat()**) Invalid flag specified in *flags*.

EIO

(**fchown()**) A low-level I/O error occurred while modifying the inode.

ELOOP

Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG

pathname is too long.

ENOENT

The file does not exist.

ENOMEM

Insufficient kernel memory was available.

ENOTDIR

A component of the path prefix is not a directory.

ENOTDIR

(**fchownat()**) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM

The calling process did not have the required permissions (see above) to change owner and/or group.

EPERM

The file is marked immutable or append-only. (See [ioctl_iflags\(2\)](#).)

EROFS

The named file resides on a read-only filesystem.

VERSIONS

fchownat() was added in Linux 2.6.16; library support was added in glibc 2.4.

STANDARDS

chown(), **fchown()**, **lchown()**: 4.4BSD, SVr4, POSIX.1-2001, POSIX.1-2008.

The 4.4BSD version can be used only by the superuser (that is, ordinary users cannot give away files).

fchownat(): POSIX.1-2008.

NOTES**Ownership of new files**

When a new file is created (by, for example, **open(2)** or **mkdir(2)**), its owner is made the same as the filesystem user ID of the creating process. The group of the file depends on a range of factors, including the type of filesystem, the options used to mount the filesystem, and whether or not the set-group-ID mode bit is enabled on the parent directory. If the filesystem supports the **-o gr pid** (or, synonymously **-o bsd-groups**) and **-o nogrpid** (or, synonymously **-o sysvgroups**) **mount(8)** options, then the rules are as follows:

- If the filesystem is mounted with **-o gr pid**, then the group of a new file is made the same as that of the parent directory.
- If the filesystem is mounted with **-o nogrpid** and the set-group-ID bit is disabled on the parent directory, then the group of a new file is made the same as the process's filesystem GID.
- If the filesystem is mounted with **-o nogrpid** and the set-group-ID bit is enabled on the parent directory, then the group of a new file is made the same as that of the parent directory.

As at Linux 4.12, the **-o gr pid** and **-o nogrpid** mount options are supported by ext2, ext3, ext4, and XFS. Filesystems that don't support these mount options follow the **-o nogrpid** rules.

glibc notes

On older kernels where **fchownat()** is unavailable, the glibc wrapper function falls back to the use of **chown()** and **lchown()**. When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

NFS

The **chown()** semantics are deliberately violated on NFS filesystems which have UID mapping enabled. Additionally, the semantics of all system calls which access the file contents are violated, because **chown()** may cause immediate access revocation on already open files. Client side caching may lead to a delay between the time where ownership have been changed to allow access for a user and the time where the file can actually be accessed by the user on other clients.

Historical details

The original Linux **chown()**, **fchown()**, and **lchown()** system calls supported only 16-bit user and group IDs. Subsequently, Linux 2.4 added **chown32()**, **fchown32()**, and **lchown32()**, supporting 32-bit IDs. The glibc **chown()**, **fchown()**, and **lchown()** wrapper functions transparently deal with the variations across kernel versions.

Before Linux 2.1.81 (except 2.1.46), **chown()** did not follow symbolic links. Since Linux 2.1.81, **chown()** does follow symbolic links, and there is a new system call **lchown()** that does not follow symbolic links. Since Linux 2.1.86, this new call (that has the same semantics as the old **chown()**) has got the same syscall number, and **chown()** got the newly introduced number.

EXAMPLES

The following program changes the ownership of the file named in its second command-line argument to the value specified in its first command-line argument. The new owner can be specified either as a numeric

user ID, or as a username (which is converted to a user ID by using **getpwnam(3)** to perform a lookup in the system password file).

Program source

```
#include <pwd.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    char             *endptr;
    uid_t            uid;
    struct passwd   *pwd;

    if (argc != 3 || argv[1][0] == '\0') {
        fprintf(stderr, "%s <owner> <file>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    uid = strtol(argv[1], &endptr, 10); /* Allow a numeric string */

    if (*endptr != '\0') {           /* Was not pure numeric string */
        pwd = getpwnam(argv[1]);    /* Try getting UID for username */
        if (pwd == NULL) {
            perror("getpwnam");
            exit(EXIT_FAILURE);
        }

        uid = pwd->pw_uid;
    }

    if (chown(argv[2], uid, -1) == -1) {
        perror("chown");
        exit(EXIT_FAILURE);
    }

    exit(EXIT_SUCCESS);
}
```

NAME

chpasswd – update passwords in batch mode

SYNOPSIS

chpasswd [*options*]

DESCRIPTION

The **chpasswd** command reads a list of user name and password pairs from standard input and uses this information to update a group of existing users. Each line is of the format:

user_name:password

By default the passwords must be supplied in clear-text, and are encrypted by **chpasswd**. Also the password age will be updated, if present.

By default, passwords are encrypted by PAM, but (even if not recommended) you can select a different encryption method with the **-e**, **-m**, or **-c** options.

Except when PAM is used to encrypt the passwords, **chpasswd** first updates all the passwords in memory, and then commits all the changes to disk if no errors occurred for any user.

When PAM is used to encrypt the passwords (and update the passwords in the system database) then if a password cannot be updated **chpasswd** continues updating the passwords of the next users, and will return an error code on exit.

This command is intended to be used in a large system environment where many accounts are created at a single time.

OPTIONS

The options which apply to the **chpasswd** command are:

-c, --crypt-method *METHOD*

Use the specified method to encrypt the passwords.

The available methods are DES, MD5, NONE, and SHA256 or SHA512 if your libc support these methods.

By default, PAM is used to encrypt the passwords.

-e, --encrypted

Supplied passwords are in encrypted form.

-h, --help

Display help message and exit.

-m, --md5

Use MD5 encryption instead of DES when the supplied passwords are not encrypted.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-s, --sha-rounds *ROUNDS*

Use the specified number of rounds to encrypt the passwords.

The value 0 means that the system will choose the default number of rounds for the crypt method (5000).

A minimal value of 1000 and a maximal value of 999,999,999 will be enforced.

You can only use this option with the SHA256 or SHA512 crypt method.

By default, the number of rounds is defined by the **SHA_CRYPT_MIN_ROUNDS** and

SHA_CRYPT_MAX_ROUNDS variables in /etc/login.defs.

CAVEATS

Remember to set permissions or umask to prevent readability of unencrypted files by other users.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

SHA_CRYPT_MIN_ROUNDS (number), **SHA_CRYPT_MAX_ROUNDS** (number)

When **ENCRYPT_METHOD** is set to *SHA256* or *SHA512*, this defines the number of SHA rounds used by the encryption algorithm by default (when the number of rounds is not specified on the command line).

With a lot of rounds, it is more difficult to brute forcing the password. But note also that more CPU resources will be needed to authenticate users.

If not specified, the libc will choose the default number of rounds (5000).

The values must be inside the 1000–999,999,999 range.

If only one of the **SHA_CRYPT_MIN_ROUNDS** or **SHA_CRYPT_MAX_ROUNDS** values is set, then this value will be used.

If **SHA_CRYPT_MIN_ROUNDS > SHA_CRYPT_MAX_ROUNDS**, the highest value will be used.

Note: This only affect the generation of group passwords. The generation of user passwords is done by PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

FILES

/etc/passwd

User account information.

/etc/shadow

Secure user account information.

/etc/login.defs

Shadow password suite configuration.

/etc/pam.d/chpasswd

PAM configuration for **chpasswd**.

NAME

chroot – change root directory

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <unistd.h>
int chroot(const char *path);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
chroot():
  Since glibc 2.2.2:
    _XOPEN_SOURCE && !(_POSIX_C_SOURCE >= 200112L)
    || /* Since glibc 2.20: */ _DEFAULT_SOURCE
    || /* glibc <= 2.19: */ _BSD_SOURCE
  Before glibc 2.2.2:
    none
```

DESCRIPTION

chroot() changes the root directory of the calling process to that specified in *path*. This directory will be used for pathnames beginning with */*. The root directory is inherited by all children of the calling process.

Only a privileged process (Linux: one with the **CAP_SYS_CHROOT** capability in its user namespace) may call **chroot()**.

This call changes an ingredient in the pathname resolution process and does nothing else. In particular, it is not intended to be used for any kind of security purpose, neither to fully sandbox a process nor to restrict filesystem system calls. In the past, **chroot()** has been used by daemons to restrict themselves prior to passing paths supplied by untrusted users to system calls such as **open(2)**. However, if a folder is moved out of the chroot directory, an attacker can exploit that to get out of the chroot directory as well. The easiest way to do that is to **chdir(2)** to the to-be-moved directory, wait for it to be moved out, then open a path like *../../../../etc/passwd*.

A slightly trickier variation also works under some circumstances if **chdir(2)** is not permitted. If a daemon allows a "chroot directory" to be specified, that usually means that if you want to prevent remote users from accessing files outside the chroot directory, you must ensure that folders are never moved out of it.

This call does not change the current working directory, so that after the call *'.'* can be outside the tree rooted at *'/'*. In particular, the superuser can escape from a "chroot jail" by doing:

```
mkdir foo; chroot foo; cd ..
```

This call does not close open file descriptors, and such file descriptors may allow access to files outside the chroot tree.

RETURN VALUE

On success, zero is returned. On error, *-1* is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, other errors can be returned. The more general errors are listed below:

EACCES

Search permission is denied on a component of the path prefix. (See also **path_resolution(7)**.)

EFAULT

path points outside your accessible address space.

EIO

An I/O error occurred.

ELOOP

Too many symbolic links were encountered in resolving *path*.

ENAMETOOLONG

path is too long.

ENOENT

The file does not exist.

ENOMEM

Insufficient kernel memory was available.

ENOTDIR

A component of *path* is not a directory.

EPERM

The caller has insufficient privilege.

STANDARDS

SVr4, 4.4BSD, SUSv2 (marked LEGACY). This function is not part of POSIX.1-2001.

NOTES

A child process created via **fork(2)** inherits its parent's root directory. The root directory is left unchanged by **execve(2)**.

The magic symbolic link, */proc/[pid]/root*, can be used to discover a process's root directory; see **proc(5)** for details.

FreeBSD has a stronger **jail()** system call.

SEE ALSO

chroot(1), **chdir(2)**, **pivot_root(2)**, **path_resolution(7)**, **switch_root(8)**

NAME

chroot – run command or interactive shell with special root directory

SYNOPSIS

chroot [*OPTION*] *NEWROOT* [*COMMAND* [*ARG*]...]
chroot *OPTION*

DESCRIPTION

Run *COMMAND* with root directory set to *NEWROOT*.

--groups=*G_LIST*
specify supplementary groups as g1,g2,...,gN
--userspec=*USER:GROUP*
specify user and group (ID or name) to use
--skip-chdir
do not change working directory to '/'
--help display this help and exit
--version
output version information and exit

If no command is given, run '\$SHELL' -i (default: '/bin/sh -i').

NAME

cron – daemon to execute scheduled commands (Vixie Cron)

SYNOPSIS

cron [**-f**] [**-l**] [**-L loglevel**]

DESCRIPTION

cron is started automatically from /etc/init.d on entering multi-user runlevels.

OPTIONS

- f** Stay in foreground mode, don't daemonize.
- P** Don't set PATH for child processes. Let it inherit instead.
- l** Enable LSB compliant names for /etc/cron.d files. This setting, however, does not affect the parsing of files under /etc/cron.hourly, /etc/cron.daily, /etc/cron.weekly or /etc/cron.monthly.
- n** Include the FQDN in the subject when sending mails. By default, cron will abbreviate the host-name.

-L loglevel

Tell cron what to log about **jobs** (errors are logged regardless of this value) as the sum of the following values:

- 1** will log the start of all cron jobs
- 2** will log the end of all cron jobs
- 4** will log all failed jobs (exit status != 0)
- 8** will log the process number of all cron jobs

The default is to log the start of all jobs (1). Logging will be disabled if *levels* is set to zero (0). A value of fifteen (15) will select all options.

NOTES

cron searches its spool area (/var/spool/cron/crontabs) for crontab files (which are named after accounts in /etc/passwd); crontabs found are loaded into memory. Note that crontabs in this directory should not be accessed directly - the *crontab* command should be used to access and update them.

cron also reads /etc/crontab, which is in a slightly different format (see *crontab(5)*). In Debian, the content of /etc/crontab is predefined to run programs under /etc/cron.hourly, /etc/cron.daily, /etc/cron.weekly and /etc/cron.monthly. This configuration is specific to Debian, see the note under **DEBIAN SPECIFIC** below.

Additionally, in Debian, *cron* reads the files in the /etc/cron.d directory. *cron* treats the files in /etc/cron.d as in the same way as the /etc/crontab file (they follow the special format of that file, i.e. they include the *user* field). However, they are independent of /etc/crontab: they do not, for example, inherit environment variable settings from it. This change is specific to Debian see the note under **DEBIAN SPECIFIC** below.

Like /etc/crontab, the files in the /etc/cron.d directory are monitored for changes. In general, the system administrator should not use /etc/cron.d/, but use the standard system crontab /etc/crontab.

/etc/crontab and the files in /etc/cron.d must be owned by root, and must not be group- or other-writable. In contrast to the spool area, the files under /etc/cron.d or the files under /etc/cron.hourly, /etc/cron.daily, /etc/cron.weekly and /etc/cron.monthly may also be symlinks, provided that both the symlink and the file it points to are owned by root. The files under /etc/cron.d do not need to be executable, while the files under /etc/cron.hourly, /etc/cron.daily, /etc/cron.weekly and /etc/cron.monthly do, as they are run by *run-parts* (see *run-parts(8)* for more information).

cron then wakes up every minute, examining all stored crontabs, checking each command to see if it should be run in the current minute. When executing commands, any output is mailed to the owner of the crontab (or to the user named in the MAILTO environment variable in the crontab, if such exists) from the owner of

the crontab (or from the email address given in the MAILFROM environment variable in the crontab, if such exists). The children copies of cron running these processes have their name coerced to uppercase, as will be seen in the syslog and ps output.

Additionally, *cron* checks each minute to see if its spool directory's modtime (or the modtime on the */etc/crontab* file) has changed, and if it has, *cron* will then examine the modtime on all crontabs and reload those which have changed. Thus *cron* need not be restarted whenever a crontab file is modified. Note that the *crontab(1)* command updates the modtime of the spool directory whenever it changes a crontab.

Special considerations exist when the clock is changed by less than 3 hours, for example at the beginning and end of daylight savings time. If the time has moved forwards, those jobs which would have run in the time that was skipped will be run soon after the change. Conversely, if the time has moved backwards by less than 3 hours, those jobs that fall into the repeated time will not be re-run.

Only jobs that run at a particular time (not specified as @hourly, nor with '*' in the hour or minute specifier) are affected. Jobs which are specified with wildcards are run based on the new time immediately.

Clock changes of more than 3 hours are considered to be corrections to the clock, and the new time is used immediately.

cron logs its action to the syslog facility 'cron', and logging may be controlled using the standard *syslogd(8)* facility.

ENVIRONMENT

If configured in */etc/default/cron* in Debian systems, the *cron* daemon localisation settings environment can be managed through the use of */etc/environment* or through the use of */etc/default/locale* with values from the latter overriding values from the former. These files are read and they will be used to setup the LANG, LC_ALL, and LC_CTYPE environment variables. These variables are then used to set the charset of mails, which defaults to 'C'.

This does **NOT** affect the environment of tasks running under cron. For more information on how to modify the environment of tasks, consult *crontab(5)*.

The daemon will use, if present, the definition from */etc/timezone* for the timezone.

The environment can be redefined in user's crontab definitions but *cron* will only handle tasks in a single timezone.

DEBIAN SPECIFIC

Debian introduces some changes to *cron* that were not originally available upstream. The most significant changes introduced are:

- Support for */etc/cron.{hourly,daily,weekly,monthly}* via */etc/crontab*,
- Support for */etc/cron.d* (drop-in dir for package crontabs),
- PAM support,
- SELinux support,
- auditlog support,
- DST and other time-related changes/fixes,
- SGID *crontab(1)* instead of SUID root,
- Debian-specific file locations and commands,
- Debian-specific configuration (*/etc/default/cron*),
- numerous other smaller features and fixes.

Support for */etc/cron.hourly*, */etc/cron.daily*, */etc/cron.weekly* and */etc/cron.monthly* is provided in Debian through the default setting of the */etc/crontab* file (see the system-wide example in *crontab(5)*). The default

system-wide crontab contains four tasks: run every hour, every day, every week and every month. Each of these tasks will execute **run-parts** providing each one of the directories as an argument. These tasks are disabled if **anacron** is installed (except for the hourly task) to prevent conflicts between both daemons.

As described above, the files under these directories have to pass some sanity checks including the following: be executable, be owned by root, not be writable by group or other and, if symlinks, point to files owned by root. Additionally, the file names must conform to the filename requirements of **run-parts**: they must be entirely made up of letters, digits and can only contain the special signs underscores ('_') and hyphens ('-'). Any file that does not conform to these requirements will not be executed by **run-parts**. For example, any file containing dots will be ignored. This is done to prevent cron from running any of the files that are left by the Debian package management system when handling files in /etc/cron.d/ as configuration files (i.e. files ending in .dpkg-dist, .dpkg-orig, .dpkg-old, and .dpkg-new).

This feature can be used by system administrators and packages to include tasks that will be run at defined intervals. Files created by packages in these directories should be named after the package that supplies them.

Support for /etc/cron.d is included in the *cron* daemon itself, which handles this location as the system-wide crontab spool. This directory can contain any file defining tasks following the format used in /etc/crontab, i.e. unlike the user cron spool, these files must provide the username to run the task as in the task definition.

Files in this directory have to be owned by root, do not need to be executable (they are configuration files, just like /etc/crontab) and must conform to the same naming convention as used by *run-parts*(8) : they must consist solely of upper- and lower-case letters, digits, underscores, and hyphens. This means that they **cannot** contain any dots. If the **-I** option is specified to *cron* (this option can be setup through /etc/default/cron, see below), then they must conform to the LSB namespace specification, exactly as in the **--lsb-sysinit** option in *run-parts*.

The intended purpose of this feature is to allow packages that require finer control of their scheduling than the /etc/cron.{hourly,daily,weekly,monthly} directories to add a crontab file to /etc/cron.d. Such files should be named after the package that supplies them.

Also, the default configuration of *cron* is controlled by /etc/default/cron which is read by the init.d script that launches the *cron* daemon. This file determines whether *cron* will read the system's environment variables and makes it possible to add additional options to the *cron* program before it is executed, either to configure its logging or to define how it will treat the files under /etc/cron.d.

crontab(1), crontab(5), run-parts(8)

AUTHOR

Paul Vixie <paul@vix.com> is the author of *cron* and original creator of this manual page. This page has also been modified for Debian by Steve Greenland, Javier Fernandez-Sanguino and Christian Kastner.

NAME

`crontab` – maintain crontab files for individual users (Vixie Cron)

SYNOPSIS

```
crontab [ -u user ] file
crontab [ -u user ] [ -i ] { -e | -l | -r }
```

DESCRIPTION

crontab is the program used to install, deinstall or list the tables used to drive the *cron*(8) daemon in Vixie Cron. Each user can have their own crontab, and though these are files in */var/spool/cron/crontabs*, they are not intended to be edited directly.

If the */etc/cron.allow* file exists, then you must be listed (one user per line) therein in order to be allowed to use this command. If the */etc/cron.allow* file does not exist but the */etc/cron.deny* file does exist, then you must **not** be listed in the */etc/cron.deny* file in order to use this command.

If neither of these files exists, then depending on site-dependent configuration parameters, only the super user will be allowed to use this command, or all users will be able to use this command.

If both files exist then */etc/cron.allow* takes precedence. Which means that */etc/cron.deny* is not considered and your user must be listed in */etc/cron.allow* in order to be able to use the crontab.

Regardless of the existence of any of these files, the root administrative user is always allowed to setup a crontab. For standard Debian systems, all users may use this command.

If the *-u* option is given, it specifies the name of the user whose crontab is to be used (when listing) or modified (when editing). If this option is not given, *crontab* examines "your" crontab, i.e., the crontab of the person executing the command. Note that *su*(8) can confuse *crontab* and that if you are running inside of *su*(8) you should always use the *-u* option for safety's sake.

The first form of this command is used to install a new crontab from some named file or standard input if the pseudo-filename “*-*” is given.

The *-l* option causes the current crontab to be displayed on standard output. See the note under **DEBIAN SPECIFIC** below.

The *-r* option causes the current crontab to be removed.

The *-e* option is used to edit the current crontab using the editor specified by the *VISUAL* or *EDITOR* environment variables. After you exit from the editor, the modified crontab will be installed automatically. If neither of the environment variables is defined, then the default editor */usr/bin/editor* is used.

The *-i* option modifies the *-r* option to prompt the user for a 'y/Y' response before actually removing the crontab.

DEBIAN SPECIFIC

The "out-of-the-box" behaviour for *crontab -l* is to display the three line "DO NOT EDIT THIS FILE" header that is placed at the beginning of the crontab when it is installed. The problem is that it makes the sequence

```
crontab -l | crontab -
```

non-idempotent — you keep adding copies of the header. This causes pain to scripts that use sed to edit a crontab. Therefore, the default behaviour of the *-l* option has been changed to not output such header. You may obtain the original behaviour by setting the environment variable **CRONTAB_NOHEADER** to 'N', which will cause the *crontab -l* command to emit the extraneous header.

SEE ALSO

crontab(5), *cron*(8)

FILES

```
/etc/cron.allow
/etc/cron.deny
/var/spool/cron/crontabs
```

The files */etc/cron.allow* and */etc/cron.deny* if, they exist, must be either world-readable, or readable by group “*crontab*”. If they are not, then cron will deny access to all users until the permissions are fixed.

There is one file for each user’s crontab under the */var/spool/cron/crontabs* directory. Users are not allowed to edit the files under that directory directly to ensure that only users allowed by the system to run periodic tasks can add them, and only syntactically correct crontabs will be written there. This is enforced by having the directory writable only by the *crontab* group and configuring *crontab* command with the setgid bit set for that specific group.

STANDARDS

The *crontab* command conforms to IEEE Std1003.2-1992 (“POSIX”). This new command syntax differs from previous versions of Vixie Cron, as well as from the classic SVR3 syntax.

DIAGNOSTICS

A fairly informative usage message appears if you run it with a bad command line.

cron requires that each entry in a crontab end in a newline character. If the last entry in a crontab is missing the newline, cron will consider the crontab (at least partially) broken and refuse to install it.

The files under */var/spool/cron/crontabs* are named based on the user’s account name. Crontab jobs will not be run for users whose accounts have been renamed either due to changes in the local system or because they are managed through a central user database (external to the system, for example an LDAP directory).

AUTHOR

Paul Vixie <paul@vix.com> is the author of *cron* and original creator of this manual page. This page has also been modified for Debian by Steve Greenland, Javier Fernandez-Sanguino and Christian Kastner.

NAME

`crontab` – tables for driving cron

DESCRIPTION

A `crontab` file contains instructions to the `cron(8)` daemon of the general form: “run this command at this time on this date”. Each user has their own crontab, and commands in any given crontab will be executed as the user who owns the crontab. Uucp and News will usually have their own crontabs, eliminating the need for explicitly running `su(1)` as part of a cron command.

Blank lines and leading spaces and tabs are ignored. Lines whose first non-space character is a hash-sign (#) are comments, and are ignored. Note that comments are not allowed on the same line as cron commands, since they will be taken to be part of the command. Similarly, comments are not allowed on the same line as environment variable settings.

An active line in a crontab will be either an environment setting or a cron command. The crontab file is parsed from top to bottom, so any environment settings will affect only the cron commands below them in the file. An environment setting is of the form,

```
name = value
```

where the spaces around the equal-sign (=) are optional, and any subsequent non-leading spaces in *value* will be part of the value assigned to *name*. The *value* string may be placed in quotes (single or double, but matching) to preserve leading or trailing blanks. To define an empty variable, quotes **must** be used.

The *value* string is **not** parsed for environmental substitutions or replacement of variables or tilde(~) expansion, thus lines like

```
PATH = $HOME/bin:$PATH
PATH = ~/bin:/usr/bin:/bin
```

will not work as you might expect. And neither will this work

```
A=1
B=2
C=$A $B
```

There will not be any substitution for the defined variables in the last value.

Several environment variables are set up automatically by the `cron(8)` daemon. SHELL is set to /bin/sh, and LOGNAME and HOME are set from the /etc/passwd line of the crontab’s owner. PATH is inherited from the environment. HOME, SHELL, and PATH may be overridden by settings in the crontab; LOGNAME is the user that the job is running from, and may not be changed.

(Another note: the LOGNAME variable is sometimes called USER on BSD systems... on these systems, USER will be set also.)

In addition to LOGNAME, HOME, and SHELL, `cron(8)` will look at MAILTO and MAILFROM if it has any reason to send mail as a result of running commands in “this” crontab.

If MAILTO is defined (and non-empty), mail is sent to the user so named. MAILTO may also be used to direct mail to multiple recipients by separating recipient users with a comma. If MAILTO is defined but empty (MAILTO=""), no mail will be sent. Otherwise mail is sent to the owner of the crontab.

If MAILFROM is defined, the sender email address is set to MAILFROM. Otherwise mail is sent as "root (Cron Daemon)".

On the Debian GNU/Linux system, cron supports the **pam_env** module, and loads the environment specified by /etc/environment and /etc/security/pam_env.conf. It also reads locale information from /etc/default/locale. However, the PAM settings do **NOT** override the settings described above nor any settings in the `crontab` file itself.

By default, cron will send mail using the mail "Content-Type:" header of "text/plain" with the "charset=" parameter set to the charmap / codeset of the locale in which `crond(8)` is started up – i.e. either the default system locale, if no LC_* environment variables are set, or the locale specified by the LC_* environment variables (see `locale(7)`). You can use different character encodings for mailed cron job output by setting

the CONTENT_TYPE and CONTENT_TRANSFER_ENCODING variables in crontabs, to the correct values of the mail headers of those names.

The format of a cron command is very much the V7 standard, with a number of upward-compatible extensions. Each line has five time and date fields, followed by a command, followed by a newline character ('\n'). The system crontab (/etc/crontab) uses the same format, except that the username for the command is specified after the time and date fields and before the command. The fields may be separated by spaces or tabs. The maximum permitted length for the command field is 998 characters.

Commands are executed by *cron*(8) when the minute, hour, and month of year fields match the current time, *and* when at least one of the two day fields (day of month, or day of week) match the current time (see "Note" below). *cron*(8) examines cron entries once every minute. The time and date fields are:

field	allowed values
-----	-----
minute	0–59
hour	0–23
day of month	1–31
month	1–12 (or names, see below)
day of week	0–7 (0 or 7 is Sun, or use names)

A field may be an asterisk (*), which always stands for "first–last".

Ranges of numbers are allowed. Ranges are two numbers separated with a hyphen. The specified range is inclusive. For example, 8–11 for an "hours" entry specifies execution at hours 8, 9, 10 and 11.

Lists are allowed. A list is a set of numbers (or ranges) separated by commas. Examples: "1,2,5,9", "0–4,8–12".

Step values can be used in conjunction with ranges. Following a range with "/<number>" specifies skips of the number's value through the range. For example, "0–23/2" can be used in the hours field to specify command execution every other hour (the alternative in the V7 standard is "0,2,4,6,8,10,12,14,16,18,20,22"). Steps are also permitted after an asterisk, so if you want to say "every two hours", just use "*/2".

Names can also be used for the "month" and "day of week" fields. Use the first three letters of the particular day or month (case doesn't matter). Ranges or lists of names are not allowed.

The "sixth" field (the rest of the line) specifies the command to be run. The entire command portion of the line, up to a newline or % character, will be executed by /bin/sh or by the shell specified in the SHELL variable of the crontab file. Percent-signs (%) in the command, unless escaped with backslash (\), will be changed into newline characters, and all data after the first % will be sent to the command as standard input. There is no way to split a single command line onto multiple lines, like the shell's trailing "\".

Note: The day of a command's execution can be specified by two fields — day of month, and day of week. If both fields are restricted (i.e., don't start with *), the command will be run when *either* field matches the current time. For example,

"30 4 1,15 * 5" would cause a command to be run at 4:30 am on the 1st and 15th of each month, plus every Friday. One can, however, achieve the desired result by adding a test to the command (see the last example in EXAMPLE CRON FILE below).

Instead of the first five fields, one of eight special strings may appear:

string	meaning
-----	-----
@reboot	Run once, at startup.
@yearly	Run once a year, "0 0 1 1 *".
@annually	(same as @yearly)
@monthly	Run once a month, "0 0 1 * *".
@weekly	Run once a week, "0 0 * * 0".
@daily	Run once a day, "0 0 * * *".
@midnight	(same as @daily)

@hourly	Run once an hour, "0 * * * *".
---------	--------------------------------

Please note that startup, as far as @reboot is concerned, is the time when the *cron(8)* daemon startup. In particular, it may be before some system daemons, or other facilities, were startup. This is due to the boot order sequence of the machine.

EXAMPLE CRON FILE

The following lists an example of a user crontab file.

```
# use /bin/bash to run commands, instead of the default /bin/sh
SHELL=/bin/bash
# mail any output to 'paul', no matter whose crontab this is
MAILTO=paul
#
# run five minutes after midnight, every day
5 0 * * *    $HOME/bin/daily.job >> $HOME/tmp/out 2>&1
# run at 2:15pm on the first of every month — output mailed to paul
15 14 1 * *    $HOME/bin/monthly
# run at 10 pm on weekdays, annoy Joe
0 22 * * 1-5   mail -s "It's 10pm" joe%Joe,%%Where are your kids?%
23 0-23/2 * * * echo "run 23 minutes after midn, 2am, 4am ..., everyday"
5 4 * * sun    echo "run at 5 after 4 every Sunday"
0 */4 1 * mon  echo "run every 4th hour on the 1st and on every Monday"
0 0 */2 * sun  echo "run at midn on every Sunday that's an uneven date"
# Run on every second Saturday of the month
0 4 8-14 * *   test $(date +\%u) -eq 6 && echo "2nd Saturday"
```

All the above examples run non-interactive programs. If you wish to run a program that interacts with the user's desktop you have to make sure the proper environment variable *DISPLAY* is set.

```
# Execute a program and run a notification every day at 10:00 am
0 10 * * * $HOME/bin/program | DISPLAY=:0 notify-send "Program run" "$(cat)"
```

EXAMPLE SYSTEM CRON FILE

The following lists the content of a regular system-wide crontab file. Unlike a user's crontab, this file has the username field, as used by */etc/crontab*.

```
# /etc/crontab: system-wide crontab
# Unlike any other crontab you don't have to run the 'crontab'
# command to install the new version when you edit this file
# and files in /etc/cron.d. These files also have username fields,
# that none of the other crontabs do.
```

```
SHELL=/bin/sh
# You can also override PATH, but by default, newer versions inherit it from the environment
#PATH=/usr/local/sbin:/usr/local/bin:/sbin:/bin:/usr/sbin:/usr/bin

# Example of job definition:
# .----- minute (0 - 59)
# | .----- hour (0 - 23)
# | | .----- day of month (1 - 31)
# | | | .---- month (1 - 12) OR jan,feb,mar,apr ...
# | | | | .--- day of week (0 - 6) (Sunday=0 or 7) OR sun,mon,tue,wed,thu,fri,sat
```

```
# | | | |
# m h dom mon dow user  command
17 * * * * root cd / && run-parts --report /etc/cron.hourly
25 6 * * * root test -x /usr/sbin/anacron || ( cd / && run-parts --report /etc/cron.daily )
47 6 * * 7 root test -x /usr/sbin/anacron || ( cd / && run-parts --report /etc/cron.weekly )
52 6 1 * * root test -x /usr/sbin/anacron || ( cd / && run-parts --report /etc/cron.monthly )
#
```

Note that all the system-wide tasks will run, by default, from 6 am to 7 am. In the case of systems that are not powered on during that period of time, only the hourly tasks will be executed unless the defaults above are changed.

SEE ALSO

[cron\(8\)](#), [crontab\(1\)](#)

EXTENSIONS

When specifying day of week, both day 0 and day 7 will be considered Sunday. BSD and AT&T seem to disagree about this.

Lists and ranges are allowed to co-exist in the same field. "1-3,7-9" would be rejected by AT&T or BSD cron — they want to see "1-3" or "7,8,9" ONLY.

Ranges can include "steps", so "1-9/2" is the same as "1,3,5,7,9".

Months or days of the week can be specified by name.

Environment variables can be set in the crontab. In BSD or AT&T, the environment handed to child processes is basically the one from /etc/rc.

Command output is mailed to the crontab owner (BSD can't do this), can be mailed to a person other than the crontab owner (SysV can't do this), or the feature can be turned off and no mail will be sent at all (SysV can't do this either).

All of the '@' commands that can appear in place of the first five fields are extensions.

LIMITATIONS

The *cron* daemon runs with a defined timezone. It currently does not support per-user timezones. All the tasks: system's and user's will be run based on the configured timezone. Even if a user specifies the *TZ* environment variable in his *crontab* this will affect only the commands executed in the crontab, not the execution of the crontab tasks themselves.

POSIX specifies that the day of month and the day of week fields both need to match the current time if either of them is a *. However, this implementation only checks if the *first character* is a *. This is why "0 0 */2 * sun" runs every Sunday that's an uneven date while the POSIX standard would have it run every Sunday and on every uneven date.

The *crontab* syntax does not make it possible to define all possible periods one can imagine. For example, it is not straightforward to define the last weekday of a month. To have a task run in a time period that cannot be defined using *crontab* syntax, the best approach would be to have the program itself check the date and time information and continue execution only if the period matches the desired one.

If the program itself cannot do the checks then a wrapper script would be required. Useful tools that could be used for date analysis are *ncal* or *calendar*. For example, to run a program the last Saturday of every month you could use the following wrapper code:

```
0 4 * * Sat [ "$(date +\%e)" = "$(LANG=C ncal | sed -n 's/^Sa .* \([0-9]\)\+\)\ *$/\1/p'" ] && echo "Last Saturday" &&
```

DIAGNOSTICS

cron requires that each entry in a crontab end in a newline character. If the last entry in a crontab is missing a newline (i.e. terminated by EOF), cron will consider the crontab (at least partially) broken. A warning will be written to syslog.

NAME

cut – remove sections from each line of files

SYNOPSIS

cut *OPTION...* [*FILE*]...

DESCRIPTION

Print selected parts of lines from each FILE to standard output.

With no FILE, or when FILE is **-**, read standard input.

Mandatory arguments to long options are mandatory for short options too.

-b, --bytes=LIST

select only these bytes

-c, --characters=LIST

select only these characters

-d, --delimiter=DELIM

use DELIM instead of TAB for field delimiter

-f, --fields=LIST

select only these fields; also print any line that contains no delimiter character, unless the **-s** option is specified

-n (ignored)

--complement

complement the set of selected bytes, characters or fields

-s, --only-delimited

do not print lines not containing delimiters

--output-delimiter=STRING

use STRING as the output delimiter the default is to use the input delimiter

-z, --zero-terminated

line delimiter is NUL, not newline

--help display this help and exit

--version

output version information and exit

Use one, and only one of **-b**, **-c** or **-f**. Each LIST is made up of one range, or many ranges separated by commas. Selected input is written in the same order that it is read, and is written exactly once. Each range is one of:

N N'th byte, character or field, counted from 1

N- from N'th byte, character or field, to end of line

N-M from N'th to M'th (included) byte, character or field

-M from first to M'th (included) byte, character or field

NAME

date – print or set the system date and time

SYNOPSIS

```
date [OPTION]... [+FORMAT]
date [-u/--utc/--universal] [MMDDhhmm[[CC]YY][.ss]]
```

DESCRIPTION

Display the current time in the given FORMAT, or set the system date.

Mandatory arguments to long options are mandatory for short options too.

-d, --date=STRING

display time described by STRING, not 'now'

--debug

annotate the parsed date, and warn about questionable usage to stderr

-f, --file=DATEFILE

like **--date**; once for each line of DATEFILE

-I[FMT], --iso-8601[=FMT]

output date/time in ISO 8601 format. FMT='date' for date only (the default), 'hours', 'minutes', 'seconds', or 'ns' for date and time to the indicated precision. Example: 2006-08-14T02:34:56-06:00

-R, --rfc-email

output date and time in RFC 5322 format. Example: Mon, 14 Aug 2006 02:34:56 -0600

--rfc-3339=FMT

output date/time in RFC 3339 format. FMT='date', 'seconds', or 'ns' for date and time to the indicated precision. Example: 2006-08-14 02:34:56-06:00

-r, --reference=FILE

display the last modification time of FILE

-s, --set=STRING

set time described by STRING

-u, --utc, --universal

print or set Coordinated Universal Time (UTC)

--help display this help and exit

--version

output version information and exit

FORMAT controls the output. Interpreted sequences are:

%%	a literal %
%a	locale's abbreviated weekday name (e.g., Sun)
%A	locale's full weekday name (e.g., Sunday)
%b	locale's abbreviated month name (e.g., Jan)
%B	locale's full month name (e.g., January)
%c	locale's date and time (e.g., Thu Mar 3 23:05:25 2005)
%C	century; like %Y, except omit last two digits (e.g., 20)
%d	day of month (e.g., 01)
%D	date; same as %m/%d/%y
%e	day of month, space padded; same as %_d

%F	full date; like %+4Y-%m-%d
%g	last two digits of year of ISO week number (see %G)
%G	year of ISO week number (see %V); normally useful only with %V
%h	same as %b
%H	hour (00..23)
%I	hour (01..12)
%j	day of year (001..366)
%k	hour, space padded (0..23); same as %_H
%l	hour, space padded (1..12); same as %_I
%m	month (01..12)
%M	minute (00..59)
%n	a newline
%N	nanoseconds (00000000..99999999)
%p	locale's equivalent of either AM or PM; blank if not known
%P	like %p, but lower case
%q	quarter of year (1..4)
%r	locale's 12-hour clock time (e.g., 11:11:04 PM)
%R	24-hour hour and minute; same as %H:%M
%s	seconds since 1970-01-01 00:00:00 UTC
%S	second (00..60)
%t	a tab
%T	time; same as %H:%M:%S
%u	day of week (1..7); 1 is Monday
%U	week number of year, with Sunday as first day of week (00..53)
%V	ISO week number, with Monday as first day of week (01..53)
%w	day of week (0..6); 0 is Sunday
%W	week number of year, with Monday as first day of week (00..53)
%x	locale's date representation (e.g., 12/31/99)
%X	locale's time representation (e.g., 23:13:48)
%y	last two digits of year (00..99)
%Y	year
%z	+hhmm numeric time zone (e.g., -0400)
%:z	+hh:mm numeric time zone (e.g., -04:00)
%::z	+hh:mm:ss numeric time zone (e.g., -04:00:00)
%:::z	numeric time zone with : to necessary precision (e.g., -04, +05:30)
%Z	alphabetic time zone abbreviation (e.g., EDT)

By default, date pads numeric fields with zeroes. The following optional flags may follow '%':

– (hyphen) do not pad the field

- (underscore) pad with spaces
- 0 (zero) pad with zeros
- + pad with zeros, and put '+' before future years with >4 digits
- ^ use upper case if possible
- # use opposite case if possible

After any flags comes an optional field width, as a decimal number; then an optional modifier, which is either E to use the locale's alternate representations if available, or O to use the locale's alternate numeric symbols if available.

EXAMPLES

Convert seconds since the epoch (1970-01-01 UTC) to a date

```
$ date --date='@2147483647'
```

Show the time on the west coast of the US (use tzselect(1) to find TZ)

```
$ TZ='America/Los_Angeles' date
```

Show the local time for 9AM next Friday on the west coast of the US

```
$ date --date='TZ="America/Los_Angeles" 09:00 next Fri'
```

DATE STRING

The --date=STRING is a mostly free format human readable date string such as "Sun, 29 Feb 2004 16:21:42 -0800" or "2004-02-29 16:21:42" or even "next Thursday". A date string may contain items indicating calendar date, time of day, time zone, day of week, relative time, relative date, and numbers. An empty string indicates the beginning of the day. The date string format is more complex than is easily documented here but is fully described in the info documentation.

NAME

dd – convert and copy a file

SYNOPSIS

dd [*OPERAND*]...
dd *OPTION*

DESCRIPTION

Copy a file, converting and formatting according to the operands.

bs=BYTES

read and write up to BYTES bytes at a time (default: 512); overrides ibs and obs

cbs=BYTES

convert BYTES bytes at a time

conv=CONVS

convert the file as per the comma separated symbol list

count=N

copy only N input blocks

ibs=BYTES

read up to BYTES bytes at a time (default: 512)

if=FILE

read from FILE instead of stdin

iflag=FLAGS

read as per the comma separated symbol list

obs=BYTES

write BYTES bytes at a time (default: 512)

of=FILE

write to FILE instead of stdout

oflag=FLAGS

write as per the comma separated symbol list

seek=N skip N obs-sized blocks at start of output

skip=N skip N ibs-sized blocks at start of input

status=LEVEL

The LEVEL of information to print to stderr; 'none' suppresses everything but error messages, 'noxfer' suppresses the final transfer statistics, 'progress' shows periodic transfer statistics

N and BYTES may be followed by the following multiplicative suffixes: c=1, w=2, b=512, kB=1000, K=1024, MB=1000*1000, M=1024*1024, xM=M, GB=1000*1000*1000, G=1024*1024*1024, and so on for T, P, E, Z, Y. Binary prefixes can be used, too: KiB=K, MiB=M, and so on.

Each CONV symbol may be:

ascii from EBCDIC to ASCII

ebcdic from ASCII to EBCDIC

ibm from ASCII to alternate EBCDIC

block pad newline-terminated records with spaces to cbs-size

unblock

replace trailing spaces in cbs-size records with newline

lcase change upper case to lower case

ucase change lower case to upper case

sparse try to seek rather than write all-NUL output blocks
swab swap every pair of input bytes
sync pad every input block with NULs to ibs-size; when used with block or unblock, pad with spaces rather than NULs
excl fail if the output file already exists
nocreat do not create the output file
notrunc do not truncate the output file
noerror continue after read errors
fdatasync physically write output file data before finishing
fsync likewise, but also write metadata

Each FLAG symbol may be:

append append mode (makes sense only for output; conv=notrunc suggested)
direct use direct I/O for data
directory fail unless a directory
dsync use synchronized I/O for data
sync likewise, but also for metadata
fullblock accumulate full blocks of input (iflag only)
nonblock use non-blocking I/O
noatime do not update access time
nocache Request to drop cache. See also oflag=sync
noctty do not assign controlling terminal from file
nofollow do not follow symlinks
count_bytes treat 'count=N' as a byte count (iflag only)
skip_bytes treat 'skip=N' as a byte count (iflag only)
seek_bytes treat 'seek=N' as a byte count (oflag only)

Sending a USR1 signal to a running 'dd' process makes it print I/O statistics to standard error and then resume copying.

Options are:

--help display this help and exit
--version output version information and exit

NAME

deluser, **delgroup** – remove a user or group from the system

SYNOPSIS

```
deluser [options] [--force] [--remove-home] [--remove-all-files] [--backup] [--backup-to DIR] user
deluser --group [options] group
delgroup [options] [--only-if-empty] group
deluser [options] user group
```

COMMON OPTIONS

```
[--quiet] [--system] [--help] [--version] [--conf FILE]
```

DESCRIPTION

deluser and **delgroup** remove users and groups from the system according to command line options and configuration information in */etc/deluser.conf* and */etc/adduser.conf*. They are friendlier front ends to the **userdel** and **groupdel** programs, removing the home directory as option or even all files on the system owned by the user to be removed, running a custom script, and other features. **deluser** and **delgroup** can be run in one of three modes:

Remove a normal user

If called with one non-option argument and without the **--group** option, **deluser** will remove a normal user.

By default, **deluser** will remove the user without removing the home directory, the mail spool or any other files on the system owned by the user. Removing the home directory and mail spool can be achieved using the **--remove-home** option.

The **--remove-all-files** option removes all files on the system owned by the user. Note that if you activate both options **--remove-home** will have no effect because all files including the home directory and mail spool are already covered by the **--remove-all-files** option.

If you want to backup all files before deleting them you can activate the **--backup** option which will create a file *username.tar(.gz|.bz2)* in the directory specified by the **--backup-to** option (defaulting to the current working directory). Both the remove and backup options can also be activated for default in the configuration file */etc/deluser.conf*. See **deluser.conf(5)** for details.

If you want to remove the root account (uid 0), then use the **--force** parameter; this may prevent to remove the root user by accident.

If the file **/usr/local/sbin/deluser.local** exists, it will be executed after the user account has been removed in order to do any local cleanup. The arguments passed to **deluser.local** are:
username uid gid home-directory

Remove a group

If **deluser** is called with the **--group** option, or **delgroup** is called, a group will be removed.

Warning: The primary group of an existing user cannot be removed.

If the option **--only-if-empty** is given, the group won't be removed if it has any members left.

Remove a user from a specific group

If called with two non-option arguments, **deluser** will remove a user from a specific group.

OPTIONS

--conf FILE

Use FILE instead of the default files */etc/deluser.conf* and */etc/adduser.conf*

--group

Remove a group. This is the default action if the program is invoked as *delgroup*.

--help Display brief instructions.**--quiet**

Suppress progress messages.

--system

Only delete if user/group is a system user/group. This avoids accidentally deleting non-system users/groups. Additionally, if the user does not exist, no error value is returned. This option is mainly for use in Debian package maintainer scripts.

--only-if-empty

Only remove if no members are left.

--backup

Backup all files contained in the userhome and the mailspool-file to a file named */\$user.tar.bz2* or */\$user.tar.gz*.

--backup-to

Place the backup files not in / but in the directory specified by this parameter. This implicitly sets --backup also.

--remove-home

Remove the home directory of the user and its mailspool. If --backup is specified, the files are deleted after having performed the backup.

--remove-all-files

Remove all files from the system owned by this user. Note: --remove-home does not have an effect any more. If --backup is specified, the files are deleted after having performed the backup.

--version

Display version and copyright information.

RETURN VALUE

- 0** The action was successfully executed.
- 1** The user to delete was not a system account. No action was performed.
- 2** There is no such user. No action was performed.
- 3** There is no such group. No action was performed.
- 4** Internal error. No action was performed.
- 5** The group to delete is not empty. No action was performed.
- 6** The user does not belong to the specified group. No action was performed.
- 7** You cannot remove a user from its primary group. No action was performed.
- 8** The required perl-package 'perl modules' is not installed. This package is required to perform the requested actions. No action was performed.
- 9** For removing the root account the parameter "--force" is required. No action was performed.

FILES

/etc/deluser.conf Default configuration file for deluser and delgroup

/usr/local/sbin/deluser.local

Optional custom add-ons.

NAME

depmod – Generate modules.dep and map files.

SYNOPSIS

```
depmod [-b basedir] [-e] [-E Module.symvers] [-F System.map] [-n] [-v] [-A] [-P prefix] [-w] [version]
depmod [-e] [-E Module.symvers] [-F System.map] [-n] [-v] [-P prefix] [-w] [version] [filename...]
```

DESCRIPTION

Linux kernel modules can provide services (called "symbols") for other modules to use (using one of the EXPORT_SYMBOL variants in the code). If a second module uses this symbol, that second module clearly depends on the first module. These dependencies can get quite complex.

depmod creates a list of module dependencies by reading each module under /lib/modules/*version* and determining what symbols it exports and what symbols it needs. By default, this list is written to modules.dep, and a binary hashed version named modules.dep.bin, in the same directory. If filenames are given on the command line, only those modules are examined (which is rarely useful unless all modules are listed). **depmod** also creates a list of symbols provided by modules in the file named modules.symbols and its binary hashed version, modules.symbols.bin. Finally, **depmod** will output a file named modules.devname if modules supply special device names (devname) that should be populated in /dev on boot (by a utility such as systemd-tmpfiles).

If a *version* is provided, then that kernel version's module directory is used rather than the current kernel version (as returned by **uname -r**).

OPTIONS**-a, --all**

Probe all modules. This option is enabled by default if no file names are given in the command-line.

-A, --quick

This option scans to see if any modules are newer than the modules.dep file before any work is done: if not, it silently exits rather than regenerating the files.

-b *basedir*, --basedir *basedir*

If your modules are not currently in the (normal) directory /lib/modules/*version*, but in a staging area, you can specify a *basedir* which is prepended to the directory name. This *basedir* is stripped from the resulting modules.dep file, so it is ready to be moved into the normal location. Use this option if you are a distribution vendor who needs to pre-generate the meta-data files rather than running depmod again later.

-C, --config *file or directory*

This option overrides the default configuration directory at /etc/depmod.d/.

-e, --errsyms

When combined with the **-F** option, this reports any symbols which a module needs which are not supplied by other modules or the kernel. Normally, any symbols not provided by modules are assumed to be provided by the kernel (which should be true in a perfect world), but this assumption can break especially when additionally updated third party drivers are not correctly installed or were built incorrectly.

-E, --symvers

When combined with the **-e** option, this reports any symbol versions supplied by modules that do not match with the symbol versions provided by the kernel in its Module.symvers. This option is mutually incompatible with **-F**.

-F, --filesyms *System.map*

Supplied with the System.map produced when the kernel was built, this allows the **-e** option to report unresolved symbols. This option is mutually incompatible with **-E**.

-h, --help

Print the help message and exit.

-n, --show, --dry-run

This sends the resulting modules.dep and the various map files to standard output rather than writing them into the module directory.

-P

Some architectures prefix symbols with an extraneous character. This specifies a prefix character (for example '_') to ignore.

-v, --verbose

In verbose mode, **depmod** will print (to stdout) all the symbols each module depends on and the module's file name which provides that symbol.

-V, --version

Show version of program and exit. See below for caveats when run on older kernels.

-w

Warn on duplicate dependencies, aliases, symbol versions, etc.

NAME

df – report file system disk space usage

SYNOPSIS

df [*OPTION*]... [*FILE*]...

DESCRIPTION

This manual page documents the GNU version of **df**. **df** displays the amount of disk space available on the file system containing each file name argument. If no file name is given, the space available on all currently mounted file systems is shown. Disk space is shown in 1K blocks by default, unless the environment variable `POSIXLY_CORRECT` is set, in which case 512-byte blocks are used.

If an argument is the absolute file name of a disk device node containing a mounted file system, **df** shows the space available on that file system rather than on the file system containing the device node. This version of **df** cannot show the space available on unmounted file systems, because on most kinds of systems doing so requires very nonportable intimate knowledge of file system structures.

OPTIONS

Show information about the file system on which each FILE resides, or all file systems by default.

Mandatory arguments to long options are mandatory for short options too.

-a, --all

include pseudo, duplicate, inaccessible file systems

-B, --block-size=SIZE

scale sizes by SIZE before printing them; e.g., '-BM' prints sizes in units of 1,048,576 bytes; see SIZE format below

-h, --human-readable

print sizes in powers of 1024 (e.g., 1023M)

-H, --si

print sizes in powers of 1000 (e.g., 1.1G)

-i, --inodes

list inode information instead of block usage

-k like --block-size=1K

-l, --local

limit listing to local file systems

--no-sync

do not invoke sync before getting usage info (default)

--output=[FIELD_LIST]

use the output format defined by FIELD_LIST, or print all fields if FIELD_LIST is omitted.

-P, --portability

use the POSIX output format

--sync invoke sync before getting usage info

--total elide all entries insignificant to available space, and produce a grand total

-t, --type=TYPE

limit listing to file systems of type TYPE

-T, --print-type

print file system type

-x, --exclude-type=TYPE

limit listing to file systems not of type TYPE

-v (ignored)

--help display this help and exit

--version

output version information and exit

Display values are in units of the first available SIZE from **--block-size**, and the DF_BLOCK_SIZE, BLOCK_SIZE and BLOCKSIZE environment variables. Otherwise, units default to 1024 bytes (or 512 if POSIXLY_CORRECT is set).

The SIZE argument is an integer and optional unit (example: 10K is 10*1024). Units are K,M,G,T,P,E,Z,Y (powers of 1024) or KB,MB,... (powers of 1000). Binary prefixes can be used, too: KiB=K, MiB=M, and so on.

FIELD_LIST is a comma-separated list of columns to be included. Valid field names are: 'source', 'fstype', 'itotal', 'iused', 'iavail', 'ipcent', 'size', 'used', 'avail', 'pcent', 'file' and 'target' (see info page).

NAME

diff – compare files line by line

SYNOPSIS

diff [*OPTION*]... *FILES*

DESCRIPTION

Compare *FILES* line by line.

Mandatory arguments to long options are mandatory for short options too.

--normal

output a normal diff (the default)

-q, --brief

report only when files differ

-s, --report-identical-files

report when two files are the same

-c, -C NUM, --context[=NUM]

output NUM (default 3) lines of copied context

-u, -U NUM, --unified[=NUM]

output NUM (default 3) lines of unified context

-e, --ed

output an ed script

-n, --rcs

output an RCS format diff

-y, --side-by-side

output in two columns

-W, --width=NUM

output at most NUM (default 130) print columns

--left-column

output only the left column of common lines

--suppress-common-lines

do not output common lines

-p, --show-c-function

show which C function each change is in

-F, --show-function-line=RE

show the most recent line matching RE

--label LABEL

use LABEL instead of file name and timestamp (can be repeated)

-t, --expand-tabs

expand tabs to spaces in output

-T, --initial-tab

make tabs line up by prepending a tab

--tabsize=NUM

tab stops every NUM (default 8) print columns

--suppress-blank-empty

suppress space or tab before empty output lines

-l, --paginate

pass output through 'pr' to paginate it

-r, --recursive
recursively compare any subdirectories found

--no-dereference
don't follow symbolic links

-N, --new-file
treat absent files as empty

--unidirectional-new-file
treat absent first files as empty

--ignore-file-name-case
ignore case when comparing file names

--no-ignore-file-name-case
consider case when comparing file names

-x, --exclude=PAT
exclude files that match PAT

-X, --exclude-from=FILE
exclude files that match any pattern in FILE

-S, --starting-file=FILE
start with FILE when comparing directories

--from-file=FILE1
compare FILE1 to all operands; FILE1 can be a directory

--to-file=FILE2
compare all operands to FILE2; FILE2 can be a directory

-i, --ignore-case
ignore case differences in file contents

-E, --ignore-tab-expansion
ignore changes due to tab expansion

-Z, --ignore-trailing-space
ignore white space at line end

-b, --ignore-space-change
ignore changes in the amount of white space

-w, --ignore-all-space
ignore all white space

-B, --ignore-blank-lines
ignore changes where lines are all blank

-I, --ignore-matching-lines=RE
ignore changes where all lines match RE

-a, --text
treat all files as text

--strip-trailing-cr
strip trailing carriage return on input

-D, --ifdef=NAME
output merged file with '#ifdef NAME' diffs

--GTYPE-group-format=GFMT
format GTYPE input groups with GFMT

--line-format=LFMT

format all input lines with LFMT

--LTYPE-line-format=LFMT

format LTYPE input lines with LFMT

These format options provide fine-grained control over the output
of diff, generalizing **-D**/**--ifdef**.

LTYPE is 'old', 'new', or 'unchanged'.

GTYPE is LTYPE or 'changed'.

GFMT (only) may contain:

%< lines from FILE1

%> lines from FILE2

%= lines common to FILE1 and FILE2

%[-][WIDTH][.[PREC]]{doX}LETTER
printf-style spec for LETTER

LETTERS are as follows for new group, lower case for old group:

F first line number

L last line number

N number of lines = L-F+1

E F-1

M L+1

%**(A=B?T:E)**

if A equals B then T else E

LFMT (only) may contain:

%L contents of line

%l contents of line, excluding any trailing newline

%[-][WIDTH][.[PREC]]{doX}n
printf-style spec for input line number

Both GFMT and LFMT may contain:

%% %

%c'C' the single character C

%c'\OOO'
the character with octal code OOO

C the character C (other characters represent themselves)

-d, --minimal

try hard to find a smaller set of changes

--horizon-lines=NUM

keep NUM lines of the common prefix and suffix

--speed-large-files

assume large files and many scattered small changes

--color[=WHEN]

color output; WHEN is 'never', 'always', or 'auto'; plain **--color** means **--color='auto'**

--palette=PALETTE

the colors to use when **--color** is active; PALETTE is a colon-separated list of terminfo capabilities

--help display this help and exit**-v, --version**

output version information and exit

FILES are 'FILE1 FILE2' or 'DIR1 DIR2' or 'DIR FILE' or 'FILE DIR'. If **--from-file** or **--to-file** is given, there are no restrictions on FILE(s). If a FILE is '−', read standard input. Exit status is 0 if inputs are the same, 1 if different, 2 if trouble.

info diff

should give you access to the complete manual.

NAME

diff3 – compare three files line by line

SYNOPSIS

diff3 [*OPTION*]... *MYFILE OLDFILE YOURFILE*

DESCRIPTION

Compare three files line by line.

Mandatory arguments to long options are mandatory for short options too.

-A, --show-all

output all changes, bracketing conflicts

-e, --ed

output ed script incorporating changes from *OLDFILE* to *YOURFILE* into *MYFILE*

-E, --show-overlap

like **-e**, but bracket conflicts

-3, --easy-only

like **-e**, but incorporate only nonoverlapping changes

-x, --overlap-only

like **-e**, but incorporate only overlapping changes

-X like **-x**, but bracket conflicts

-i append 'w' and 'q' commands to ed scripts

-m, --merge

output actual merged file, according to **-A** if no other options are given

-a, --text

treat all files as text

--strip-trailing-cr

strip trailing carriage return on input

-T, --initial-tab

make tabs line up by prepending a tab

--diff-program=PROGRAM

use *PROGRAM* to compare files

-L, --label=LABEL

use *LABEL* instead of file name (can be repeated up to three times)

--help display this help and exit

-v, --version

output version information and exit

The default output format is a somewhat human-readable representation of the changes.

The **-e**, **-E**, **-x**, **-X** (and corresponding long) options cause an ed script to be output instead of the default.

Finally, the **-m** (**--merge**) option causes diff3 to do the merge internally and output the actual merged file. For unusual input, this is more robust than using ed.

If a FILE is '–', read standard input. Exit status is 0 if successful, 1 if conflicts, 2 if trouble.

NAME

Dislocate – disconnect and reconnect processes

SYNOPSIS

dislocate [*program args...*]

INTRODUCTION

Dislocate allows processes to be disconnected and reconnected to the terminal. Possible uses:

- You can disconnect a process from a terminal at work and reconnect from home, to continue working.
- After having your line be dropped due to noise, you can get back to your process without having to restart it from scratch.
- If you have a problem that you would like to show someone, you can set up the scenario at your own terminal, disconnect, walk down the hall, and reconnect on another terminal.
- If you are in the middle of a great game (or whatever) that does not allow you to save, and someone else kicks you off the terminal, you can disconnect, and reconnect later.

USAGE

When run with no arguments, **Dislocate** tells you about your disconnected processes and lets you reconnect to one. Otherwise, **Dislocate** runs the named program along with any arguments.

By default, ^] is an escape that lets you talk to **Dislocate** itself. At that point, you can disconnect (by pressing ^D) or suspend **Dislocate** (by pressing ^Z).

Any Tcl or Expect command is also acceptable at this point. For example, to insert the contents of a the file /etc/motd as if you had typed it, say:

```
send -i $out [exec cat /etc/motd]
```

To send the numbers 1 to 100 in response to the prompt "next #", say:

```
for {set i 0} {$i<100} {incr i} {
    expect -i $in "next #"
    send -i $out "$i\r"
}
```

Scripts can also be prepared and sourced in so that you don't have to type them on the spot.

Dislocate is actually just a simple **Expect** script. Feel free to make it do what you want it to do or just use **Expect** directly, without going through **Dislocate**. **Dislocate** understands a few special arguments. These should appear before any program name. Each should be separated by whitespace. If the arguments themselves takes arguments, these should also be separated by whitespace.

The **-escape** flag sets the escape to whatever follows. The default escape is ^].

CAVEATS

This program was written by the author as an exercise to show that communicating with disconnected processes is easy. There are many features that could be added, but that is not the intent of this program.

NAME

dmesg – print or control the kernel ring buffer

SYNOPSIS

dmesg [options]

dmesg --clear

dmesg --read-clear [options]

dmesg --console-level *level*

dmesg --console-on

dmesg --console-off

DESCRIPTION

dmesg is used to examine or control the kernel ring buffer.

The default action is to display all messages from the kernel ring buffer.

OPTIONS

The **--clear**, **--read-clear**, **--console-on**, **--console-off**, and **--console-level** options are mutually exclusive.

-C, --clear

Clear the ring buffer.

-c, --read-clear

Clear the ring buffer after first printing its contents.

-D, --console-off

Disable the printing of messages to the console.

-d, --show-delta

Display the timestamp and the time delta spent between messages. If used together with **--notime** then only the time delta without the timestamp is printed.

-E, --console-on

Enable printing messages to the console.

-e, --reltime

Display the local time and the delta in human-readable format. Be aware that conversion to the local time could be inaccurate (see **-T** for more details).

-F, --file *file*

Read the syslog messages from the given *file*. Note that **-F** does not support messages in kmsg format. The old syslog format is supported only.

-f, --facility *list*

Restrict output to the given (comma-separated) *list* of facilities. For example:

dmesg --facility=daemon

will print messages from system daemons only. For all supported facilities see the **--help** output.

-H, --human

Enable human-readable output. See also **--color**, **--reltime** and **--nopager**.

-J, --json

Use JSON output format. The time output format is in "sec.usec" format only, log priority level is not decoded by default (use **--decode** to split into facility and priority), the other options to control the output format or time format are silently ignored.

-k, --kernel

Print kernel messages.

-L, --color[=when]

Colorize the output. The optional argument *when* can be **auto**, **never** or **always**. If the *when* argument is omitted, it defaults to **auto**. The colors can be disabled; for the current built-in default see the **--help** output. See also the **COLORS** section below.

-l, --level list

Restrict output to the given (comma-separated) *list* of levels. For example:

```
dmesg --level=err,warn
```

will print error and warning messages only. For all supported levels see the **--help** output.

-n, --console-level level

Set the *level* at which printing of messages is done to the console. The *level* is a level number or abbreviation of the level name. For all supported levels see the **--help** output.

For example, **-n 1** or **-n emerg** prevents all messages, except emergency (panic) messages, from appearing on the console. All levels of messages are still written to */proc/kmsg*, so **syslogd(8)** can still be used to control exactly where kernel messages appear. When the **-n** option is used, **dmesg** will *not* print or clear the kernel ring buffer.

--noescape

The unprintable and potentially unsafe characters (e.g., broken multi-byte sequences, terminal controlling chars, etc.) are escaped in format **\x<hex>** for security reason by default. This option disables this feature at all. It's usable for example for debugging purpose together with **--raw**. Be careful and don't use it by default.

-P, --nopager

Do not pipe output into a pager. A pager is enabled by default for **--human** output.

-p, --force-prefix

Add facility, level or timestamp information to each line of a multi-line message.

-r, --raw

Print the raw message buffer, i.e., do not strip the log-level prefixes, but all unprintable characters are still escaped (see also **--noescape**).

Note that the real raw format depends on the method how **dmesg** reads kernel messages. The */dev/kmsg* device uses a different format than **syslog(2)**. For backward compatibility, **dmesg** returns data always in the **syslog(2)** format. It is possible to read the real raw data from */dev/kmsg* by, for example, the command 'dd if=/dev/kmsg iflag=nonblock'.

-S, --syslog

Force **dmesg** to use the **syslog(2)** kernel interface to read kernel messages. The default is to use **/dev/kmsg** rather than **syslog(2)** since kernel 3.5.0.

-s, --buffer-size *size*

Use a buffer of *size* to query the kernel ring buffer. This is 16392 by default. (The default kernel syslog buffer size was 4096 at first, 8192 since 1.3.54, 16384 since 2.1.113.) If you have set the kernel buffer to be larger than the default, then this option can be used to view the entire buffer.

-T, --ctime

Print human-readable timestamps.

Be aware that the timestamp could be inaccurate! The **time** source used for the logs is **not updated after system SUSPEND/RESUME**. Timestamps are adjusted according to current delta between boottime and monotonic clocks, this works only for messages printed after last resume.

--since *time*

Display record since the specified time. The time is possible to specify in absolute way as well as by relative notation (e.g. '1 hour ago'). Be aware that the timestamp could be inaccurate and see **--ctime** for more details.

--until *time*

Display record until the specified time. The time is possible to specify in absolute way as well as by relative notation (e.g. '1 hour ago'). Be aware that the timestamp could be inaccurate and see **--ctime** for more details.

-t, --notime

Do not print kernel's timestamps.

--time-format *format*

Print timestamps using the given *format*, which can be **ctime**, **reltime**, **delta** or **iso**. The first three formats are aliases of the time-format-specific options. The **iso** format is a **dmesg** implementation of the ISO-8601 timestamp format. The purpose of this format is to make the comparing of timestamps between two systems, and any other parsing, easy. The definition of the **iso** timestamp is:
YYYY-MM-DD<T>HH:MM:SS,<microseconds><+><timezone offset from UTC>.

The **iso** format has the same issue as **ctime**: the time may be inaccurate when a system is suspended and resumed.

-u, --userspace

Print userspace messages.

-w, --follow

Wait for new messages. This feature is supported only on systems with a readable **/dev/kmsg** (since kernel 3.5.0).

-W, --follow-new

Wait and print only new messages.

-x, --decode

Decode facility and level (priority) numbers to human-readable prefixes.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

COLORS

The output colorization is implemented by **terminal-colors.d(5)** functionality. Implicit coloring can be disabled by an empty file

/etc/terminal-colors.d/dmesg.disable

for the **dmesg** command or for all tools by

/etc/terminal-colors.d/disable

The user-specific *\$XDG_CONFIG_HOME/terminal-colors.d* or *\$HOME/.config/terminal-colors.d* overrides the global setting.

Note that the output colorization may be enabled by default, and in this case *terminal-colors.d* directories do not have to exist yet.

The logical color names supported by **dmesg** are:

subsys

The message sub-system prefix (e.g., "ACPI:").

time

The message timestamp.

timebreak

The message timestamp in short ctime format in **--reltime** or **--human** output.

alert

The text of the message with the alert log priority.

crit

The text of the message with the critical log priority.

err

The text of the message with the error log priority.

warn

The text of the message with the warning log priority.

segfault

The text of the message that inform about segmentation fault.

EXIT STATUS

dmesg can fail reporting permission denied error. This is usually caused by **dmesg_restrict** kernel setting, please see **syslog(2)** for more details.

[--separator SEPARATOR]
[RAID-set...]

dmraid {-V|--version}

Description

dmraid discovers block and software RAID devices (eg, ATARAID) by using multiple different metadata format handlers which support various formats (eg, Highpoint 37x series). It offers activating RAID sets made up by 2 or more discovered RAID devices, display properties of devices and sets (see option **-I** for supported metadata formats). Block device access to activated RAID sets occurs via device-mapper nodes /dev/mapper/RaidSetName. RaidSetName starts with the format name (see **-I** option) which can be used to access all RAID sets of a specific format easily with certain options (eg, **-a** below).

Options

-a, **--activate** {y|n} [RAID set...]

Activates or deactivates all or particular software RAID set. In case metadata format handlers are chosen with **-f**, only RAID sets with such **format(s)** can be activated or

deactivated. Useful if devices have multiple metadata signatures. When activating RAID sets, **-p** disables the activation of partitions on them, and **-Z** will make dmraid tell the kernel to remove the partitions from the disks underlying the set, ie if sda is part of the set, remove sda1, sda2, etc. This prevents applications from directly accessing the disks bypassing dmraid. RAID set names given on command line don't need to be fully specified (eg, "dmraid -ay sil" would activate all discovered Silicon Image Medley RAID sets).

{-b|--block_devices} [device-path...]

List all or particular discovered block devices with their properties (size, serial number). Add **-c** to display block device names only and **-cc** for CSV column output of block device properties. See description of **-c** below for FIELD identifiers.

{-d|--debug}...

Enable debugging output. Option can be given multiple times increasing the debug output level.

{-c|--display_columns}[FIELD[,FIELD...]]...

Display properties of block devices, RAID sets and devices in **column**(s). Optional list specifying which FIELDS to display.

For **-b**:

d[evpath]|p[ath], sec[tors]|si[ze], ser[ialnumber].

For **-r**:

de[vpath]|p[ath], f[ormat], r[aidname], t[ype], st[atus], se[ctors]|si[ze], da[taoffset]|o[ffset].

For **-s**:

f[ormat], r[aidname], t[ype], sta[tus], str[ide], se[ctors]|si[ze], su[bsets], d[evices], sp[ares].

{-f|--format FORMAT[,FORMAT...]]

Use metadata format **handler**(s) to discover RAID devices. See **-I** for a list of supported format handler names. This is useful to select particular formats in case multiple metadata signatures are found on a device. A comma separated list of format names can be specified which may not contain white space.

{-h|--help}

Display help text.

{-i|--ignorelocking}

Don't take out any locks. Useful in early boot where no read/write access to /var is available.

{-l|--list_formats}

List all available metadata format handlers with their names and descriptions.

Supported RAID levels are listed in parenthesis:

S: Span (concatination)

0: RAID0 (stripe)

1: RAID1 (mirror)

10: RAID10 (mirror on top of stripes)

01: RAID10 (stripe on top of mirrors) Note: Intel OROM displays this as RAID10

{-n|--native_log} [device-path...]

Display metadata in native, vendor-specific format. In case a metadata format handler is chosen with **-f** only RAID devices with such format will be displayed in native format. If **device-path(s)** is/are given on the command line, native metadata output is restricted to those listed.

[{-P|--partchar} CHAR]

Use CHAR as the separator between the device name and the partition number.

{-R|--rebuild} RAID-set [device-path]

Rebuild raid array after a drive has failed and a new drive is added. For Intel chipset based systems, there are two methods in which a new drive is added to the system.

1. Using OROM to identify a new drive During system reboot, enter OROM and mark the new drive as the rebuild drive.

After booting to the OS, use the dmraid command to rebuild.

Example: dmraid -R raid_set

2. Using dmraid to identify a new drive Boot to the OS and use the dmraid command with the new drive as the second parameter.

Example: dmraid -R raid_set /dev/sdc

3. Using hot spare drive Mark a drive as hot spare using the "dmraid -f isw -S" command. Then use the dmraid command to start the rebuild.

Example: dmraid -R raid_set

{-x|--remove} [RAID-set]

Delete one or all existing software RAID devices from the metadata.

-f FORMAT-handler **{-C|--create}** --type raidlevel [--size=setsize --strip=stripsize] --disk "device-path, device-path [,device-path]"

Delete one or all existing Configure a software RAID device and store the configuration data in a group of hard drive devices consisting of this array. This command requires the following options:

-f FORMAT-handler

metadata format (see "dmraid -l")

--type digit[digit...]

specify the raid level of the software RAID set.

0: raid0

1: raid1

5: raid5

01: raid01 (isw raid10)

--size: [digits[k|K|m|M|g|G][b|B]]

specify the size of the RAID set. The number is an integer followed by [kKmMgG] and/or [bB].

b: byte (default)

B: block (512 bytes)

K or k: on the base of 1024

m or M: on the base of 1024*1024

g or G: on the base of 1024*1024*1024

If this option is missing, it's set to the default value pre-configured by the vendor.

Note that different vendors may apply different constraints on the granularity of the size or the minimal value.

--strip: [digits[k|K|m|M|g|G][b|B]]

specify the strip size of a RAID1, RAID5, and RAID10 RAID set (as above)

--disk: device-path[{| }device-path...]

specify the array of the hard drives, e.g. /dev/sda.

-f FORMAT-handler -S -M device-path

-S -M device-path

This command adds hot spare support for one or more RAID sets.

1. When used with a format handler, which supports hot spare sets (e.g. isw), a hot spare is marked to be used when rebuilding any RAID set of that format. 2. When used when specifying a RAID set, the drive is added to that RAID set and will be used only to rebuild that set. Note: If the specified name does not match an existing RAID-set, a set with the new name will be created.

{-r|--raid_devices} [device-path...]

List all discovered RAID devices with format, RAID level, sectors used and data offset into the device. In case a metadata format handler is chosen with **-f**, only RAID devices with such format can be discovered. Useful if devices have multiple metadata signatures. If **-D** is added to **-r** the RAID metadata gets dumped into a subdirectory named dmraid.format_name (eg. format_name = isw) in files named devicename.dat. The byte offset where the metadata is located on the device is written into files named devicename.offset and the size of the device in sectors into files named devicename.size.

If **-E** is added to **-r** the RAID metadata on the devices gets conditionally erased.

Useful to erase old metadata after new one of different type has been stored on a device in order to avoid discovering both. If you enter **-E** option **-D** will be enforced in order to have a fallback in case the wrong metadata got erased. Manual copying back onto the device is needed to recover from erasing the wrong metadata using the

dumped files devicename_formatname.dat and devicename_formatname.offset. Eg, to restore all *.dat files in the working directory to the respective devices:

```
for f in *.dat
do
dd if=$f of=/dev/${f%%.dat} \
seek='cat ${f%%dat}offset' bs=1

done
```

If **device-path**(s) is/are given on the command line, the above actions are restricted to those listed. Add **-c** to display RAID device names only and **-cc** for CSV column output of RAID device properties. See description of **-c** above for FIELD identifiers.

--separator SEPARATOR

Use SEPARATOR as a delimiter for all options taking or displaying lists.

-s... [a|i] [RAID-set...]

Display properties of RAID sets. Multiple RAID set names can be given on the command line which don't need to be fully specified (eg, "dmraid -s hpt" would display all discovered Highpoint RAID sets). Enter **-s** twice to display RAID subsets too. Add **-c** to display names of RAID sets only, **-cc** for CSV column output of RAID set properties and **-ccc** for inclusion of block devices in the listing. Doesn't imply **-s -s** to show RAID subsets (implied for group sets, e.g. isw). Add **-g** to include information about group RAID sets (as with Intel Software RAID) in the listing. See description of **-c** above for FIELD identifiers. Note: Size is given in sectors (not bytes).

[-v|--verbose]...

Enable verbose runtime information output. Option can be given multiple times increasing the verbosity level.

Examples

"dmraid -l" lists all supported metadata formats with their names along with some descriptive information, eg:

```
hpt37x : (+) Highpoint HPT37X
hpt45x : (+) Highpoint HPT45X
isw : (+) Intel Software RAID
lsi : (0) LSI Logic MegaRAID
nvidia : (+) NVidia RAID
pdc : (+) Promise FastTrack
sil : (+) Silicon Image(tm) Medley(tm)
via : (+) VIA Software RAID
dos : (+) DOS partitions on SW RAIDs
(0): Discover, (+): Discover+Activate
"dmraid -ay" activates all software RAID sets discovered.
"dmraid -an" deactivates all active software RAID sets which are not open (eg, mounted
```

filesystem on them).

"dmraid -ay -f pdc" (pdc looked up from "dmraid -l") activates all software RAID sets with Promise format discovered and ignores all other supported formats.

"dmraid -r" discovers all software RAID devices supported on your system, eg:

```
/dev/dm-46: hpt45x, "hpt45x_chidjhaiaa-0", striped, ok, 320172928 sectors, data@ 0  
/dev/dm-50: hpt45x, "hpt45x_chidjhaiaa-0", striped, ok, 320172928 sectors, data@ 0  
/dev/dm-54: hpt45x, "hpt45x_chidjhaiaa-1", striped, ok, 320172928 sectors, data@ 0  
/dev/dm-58: hpt45x, "hpt45x_chidjhaiaa-1", striped, ok, 320172928 sectors, data@ 0
```

"dmraid -s -s hpt45x_chidjhaiaa" displays properties of set "hpt45x_chidjhaiaa", eg:

*** Superset

```
name : hpt45x_chidjhaiaa  
size : 640345856  
stride : 128  
type : raid10  
status : ok  
subsets: 2  
dev : 4  
spare : 0  
---> Subset  
name : hpt45x_chidjhaiaa-0  
size : 640345856  
stride : 128  
type : stripe  
status : ok  
subsets: 0  
dev : 2  
spare : 0  
---> Subset  
name : hpt45x_chidjhaiaa-1  
size : 640345856  
stride : 128  
type : stripe  
status : ok  
subsets: 0  
dev : 2  
spare : 0
```

"dmraid -s -ccs hpt45" displays properties in column format of all sets and subsets with hpt45* format, eg:

```
hpt45x_chidjhaiaa,640345856,128,raid10,ok,4,0  
hpt45x_chidjhaiaa-a,640345856,128,stripe,ok,2,0  
hpt45x_chidjhaiaa-b,640345856,128,stripe,ok,2,0
```

"dmraid -r --sep : -cpath:size" display paths and sizes in sectors for RAID devices in

column format using ':' as a delimiter, eg:

```
/dev/dm-8:320173055  
/dev/dm-12:320173055  
/dev/dm-22:320173055  
/dev/dm-26:320173055  
/dev/dm-30:586114703  
/dev/dm-34:586114703  
/dev/dm-38:586114703  
/dev/dm-42:586114703  
/dev/dm-46:156301487  
/dev/dm-50:156301487  
/dev/dm-54:390624896  
/dev/dm-58:390624896  
/dev/dm-62:390624896  
/dev/dm-66:390624896
```

"dmraid -f isw -C Raid0 --type 0 --strip 8k --size 20g --disk "/dev/sdb /dev/sdc"" creates an ISW volume with a name of "Raid0", 20Gig bytes in total, and 8kilo bytes strip size on two disks.

"dmraid -f isw -C Test0 --type 0 --disk "/dev/sdd /dev/sde"" creates an ISW volume with the default size and strip size.

"dmraid -f isw -C Test10 --type 01 --strip 128B --disk "/dev/sda /dev/sdb /dev/sdc /dev/sdd" creates a stacked RAID device, RAID10 (isw format), with a name of "Test10", 128 blocks (512bytes) strip size , and the default volume size on 4 disks.

"dmraid -f isw -S -M /dev/sde" marks the device /dev/sde as a hot spare for rebuild

"dmraid -R isw_djaggchdde_RAID1 /dev/sde" starts rebuild of the RAID volume on device /dev/sde

Diagnostics

dmraid returns an exit code of 0 for success or 1 for error.

DNF(8)

DNF

DNF(8)

NAME top

`dnf` – DNF Command Reference

SYNOPSIS top

`dnf [options] <command> [<args>...]`

DESCRIPTION top

DNF is the next upcoming major version of **YUM**, a package manager for RPM-based Linux distributions. It roughly maintains CLI compatibility with YUM and defines a strict API for extensions and plugins.

Plugins can modify or extend features of DNF or provide additional CLI commands on top of those mentioned below. If you know the name of such a command (including commands mentioned below), you may find/install the package which provides it using the appropriate virtual provide in the form of `dnf-command(<alias>)`, where `<alias>` is the name of the command; e.g. ```dnf install 'dnf-command(versionlock)'``` installs a `versionlock` plugin. This approach also applies to specifying dependencies of packages that require a particular DNF command.

Return values:

- **0** : Operation was successful.
- **1** : An error occurred, which was handled by dnf.
- **3** : An unknown unhandled error occurred during operation.
- **100**: See `check-update`
- **200**: There was a problem with acquiring or releasing of locks.

Available commands:

- `alias`
- `autoremove`
- `check`
- `check-update`
- `clean`
- `deplist`
- `distro-sync`
- `downgrade`
- `group`
- `help`
- `history`

OPTIONS

[top](#)

- 4** Resolve to IPv4 addresses only.
- 6** Resolve to IPv6 addresses only.
- advisory=<advisory>, --advisories=<advisory>**
Include packages corresponding to the advisory ID, Eg.
FEDORA-2021-123. Applicable for the **install**, **repoquery**,
updateinfo, **upgrade** and **offline-upgrade** (`dnf-plugins-core`)
commands.
- allowerasing**
Allow erasing of installed packages to resolve
dependencies. This option could be used as an alternative
to the **yum swap** command where packages to remove are not
explicitly defined.
- assumeno**

Automatically answer no for all questions.

-b, --best

Try the best available package versions in transactions. Specifically during `dnf upgrade`, which by default skips over updates that can not be installed for dependency reasons, this switch forces DNF to only consider the latest packages. When running into packages with broken dependencies, DNF will fail giving a reason why the latest version can not be installed.

Note that the use of the newest available version is only guaranteed for the packages directly requested (e.g. as a command line arguments), and the solver may use older versions of dependencies to meet their requirements.

--bugfix

Include packages that fix a bugfix issue. Applicable for the `install`, `repoquery`, `updateinfo`, `upgrade` and `offline-upgrade` (`dnf-plugins-core`) commands.

--bz=<bugzilla>, --bzs=<bugzilla>

Include packages that fix a Bugzilla ID, Eg. 123123. Applicable for the `install`, `repoquery`, `updateinfo`, `upgrade` and `offline-upgrade` (`dnf-plugins-core`) commands.

-C, --cacheonly

Run entirely from system cache, don't update the cache and use it even in case it is expired.

DNF uses a separate cache for each user under which it executes. The cache for the root user is called the system cache. This switch allows a regular user read-only access to the system cache, which usually is more fresh than the user's and thus he does not have to wait for metadata sync.

--color=<color>

Control whether color is used in terminal output. Valid values are `always`, `never` and `auto` (default).

--comment=<comment>

Add a comment to the transaction history.

-c <config file>, --config=<config file>

Configuration file location.

--cve=<cves>, --cves=<cves>

Include packages that fix a CVE (Common Vulnerabilities and Exposures) ID (<http://cve.mitre.org/about/>), Eg. CVE-2021-0123. Applicable for the `install`, `repoquery`, `updateinfo`, `upgrade` and `offline-upgrade` (`dnf-plugins-core`) commands.

-d <debug level>, --debuglevel=<debug level>

Debugging output level. This is an integer value between 0 (no additional information strings) and 10 (shows all debugging information, even that not understandable to the user), default is 2. Deprecated, use `-v` instead.

--debugsolver

Dump data aiding in dependency solver debugging into `./debugdata`.

--disableexcludes=[all|main|<repoid>],

--disableexcludepkgs=[all|main|<repoid>]

Disable the configuration file excludes. Takes one of the following three options:

- `all`, disables all configuration file excludes
- `main`, disables excludes defined in the `[main]` section
- `repoid`, disables excludes defined for the given repository

--disable, --set-disabled

Disable specified repositories (automatically saves). The option has to be used together with the `config-manager` command (`dnf-plugins-core`).

--disableplugin=<plugin names>

Disable the listed plugins specified by names or globs.

--disablerepo=<repoid>

Temporarily disable active repositories for the purpose of the current dnf command. Accepts an id, a comma-separated list of ids, or a glob of ids. This option can be specified multiple times, but is mutually exclusive with **--repo**.

--downloaddir=<path>, --destdir=<path>

Redirect downloaded packages to provided directory. The option has to be used together with the **--downloadonly** command line option, with the **download**, **modulesync**, **reposync** or **system-upgrade** commands (dnf-plugins-core).

--downloadonly

Download the resolved package set without performing any rpm transaction (install/upgrade/erase).

Packages are removed after the next successful transaction. This applies also when used together with **--destdir** option as the directory is considered as a part of the DNF cache. To persist the packages, use the **download** command instead.

-e <error level>, --errorlevel=<error level>

Error output level. This is an integer value between 0 (no error output) and 10 (shows all error messages), default is 3. Deprecated, use **-v** instead.

--enable, --set-enabled

Enable specified repositories (automatically saves). The option has to be used together with the **config-manager** command (dnf-plugins-core).

--enableplugin=<plugin names>

Enable the listed plugins specified by names or globs.

--enablerepo=<repoid>

Temporarily enable additional repositories for the purpose of the current dnf command. Accepts an id, a comma-separated list of ids, or a glob of ids. This option can be specified multiple times.

--enhancement

Include enhancement relevant packages. Applicable for the **install**, **repoquery**, **updateinfo**, **upgrade** and **offline-upgrade** (dnf-plugins-core) commands.

-x <package-file-spec>, --exclude=<package-file-spec>

Exclude packages specified by **<package-file-spec>** from the operation.

--excludepkgs=<package-file-spec>

Deprecated option. It was replaced by the **--exclude** option.

--forcearch=<arch>

Force the use of an architecture. Any architecture can be specified. However, use of an architecture not supported natively by your CPU will require emulation of some kind. This is usually through QEMU. The behavior of **--forcearch** can be configured by using the **arch** and **ignorearch** configuration options with values **<arch>** and **True** respectively.

-h, --help, --help-cmd

Show the help.

--installroot=<path>

Specifies an alternative installroot, relative to where all packages will be installed. Think of this like doing **chroot <root> dnf**, except using **--installroot** allows dnf to work before the chroot is created. It requires absolute path.

- **cachedir**, **log files**, **releasever**, and **gpgkey** are taken from or stored in the installroot. **Gpgkeys** are imported into the installroot from a path relative to the host which can be specified in the repository section of configuration files.

- *configuration file* and *reposdir* are searched inside the installroot first. If they are not present, they are taken from the host system. Note: When a path is specified within a command line argument (`--config=<config file>` in case of *configuration file* and `--setopt=reposdir=<reposdir>` for *reposdir*) then this path is always relative to the host with no exceptions.
- *vars* are taken from the host system or installroot according to *reposdir*. When *reposdir* path is specified within a command line argument, vars are taken from the installroot. When *varsdir* paths are specified within a command line argument (`--setopt=varsdir=<reposdir>`) then those path are always relative to the host with no exceptions.
- The *pluginpath* and *pluginconfpath* are relative to the host. Note: You may also want to use the command-line option `--releasever=<release>` when creating the installroot, otherwise the *\$releasever* value is taken from the rpmdb within the installroot (and thus it is empty at the time of creation and the transaction will fail). If `--releasever=/` is used, the releasever will be detected from the host (/) system. The new installroot path at the time of creation does not contain the *repository*, *releasever* and *dnf.conf* files.

On a modular system you may also want to use the `--setopt=module_platform_id=<module_platform_name:stream>` command-line option when creating the installroot, otherwise the *module_platform_id* value will be taken from the */etc/os-release* file within the installroot (and thus it will be empty at the time of creation, the modular dependency could be unsatisfied and modules content could be excluded).

Installroot examples:

```
dnf --installroot=<installroot> --releasever=<release> install
system-release
    Permanently sets the releasever of the system in the
    <installroot> directory to <release>.

dnf --installroot=<installroot> --setopt=reposdir=<path>
--config /path/dnf.conf upgrade
    Upgrades packages inside the installroot from a
    repository described by --setopt using configuration
    from /path/dnf.conf.
```

--newpackage
Include newpackage relevant packages. Applicable for the **install**, **repoquery**, **updateinfo**, **upgrade** and **offline-upgrade** (dnf-plugins-core) commands.

--noautoremove
Disable removal of dependencies that are no longer used.
It sets *clean_requirements_on_remove* configuration option to **False**.

--nobest
Set best option to **False**, so that transactions are not limited to best candidates only.

--nodocs
Do not install documentation. Sets the rpm flag '**RPMTRANS_FLAG_NODOCS**'.

--nogpgcheck
Skip checking GPG signatures on packages (if RPM policy allows).

--nopugins
Disable all plugins.

--obsoletes
This option has an effect on an install/update, it enables dnf's obsoletes processing logic. For more information see the *obsoletes* option.

This option also displays capabilities that the package obsoletes when used together with the *repoquery* command.

Configuration Option: *obsoletes*

-q, --quiet
 In combination with a non-interactive command, shows just the relevant content. Suppresses messages notifying about the current state or actions of DNF.

-R <minutes>, --randomwait=<minutes>
 Maximum command wait time.

--refresh
 Set metadata as expired before running the command.

--releasever=<release>
 Configure DNF as if the distribution release was <release>. This can affect cache paths, values in configuration files and mirrorlist URLs.

--repofrompath <repo>,<path/url>
 Specify a repository to add to the repositories for this query. This option can be used multiple times.

- The repository label is specified by <repo>.
- The path or url to the repository is specified by <path/url>. It is the same path as a baseurl and can be also enriched by the *repo variables*.
- The configuration for the repository can be adjusted using --
`-setopt=<repo>.<option>=<value>`.
- If you want to view only packages from this repository, combine this with the `--repo=<repo>` or `--disablerepo="*"` switches.

--repo=<repoid>, --repoid=<repoid>
 Enable just specific repositories by an id or a glob. Can be used multiple times with accumulative effect. It is basically a shortcut for `--disablerepo="*"`
`--enablerepo=<repoid>` and is mutually exclusive with the `--disablerepo` option.

--rpmverbosity=<name>
 RPM debug scriptlet output level. Sets the debug level to <name> for RPM scriptlets. For available levels, see the `rpmverbosity` configuration option.

--sec-severity=<severity>, --secseverity=<severity>
 Includes packages that provide a fix for an issue of the specified severity. Applicable for the `install`, `repoquery`, `updateinfo`, `upgrade` and `offline-upgrade` (`dnf-plugins-core`) commands.

--security
 Includes packages that provide a fix for a security issue. Applicable for the `install`, `repoquery`, `updateinfo`, `upgrade` and `offline-upgrade` (`dnf-plugins-core`) commands.

--setopt=<option>=<value>
 Override a configuration option from the configuration file. To override configuration options for repositories, use `repoid.option` for the <option>. Values for configuration options like `excludepkgs`, `includepkgs`, `installonlypkgs` and `tsflags` are appended to the original value, they do not override it. However, specifying an empty value (e.g. `--setopt=tsflags=`) will clear the option.

--skip-broken
 Resolve depsolve problems by removing packages that are causing problems from the transaction. It is an alias for the `strict` configuration option with value `False`. Additionally, with the `enable` and `disable` module subcommands it allows one to perform an action even in case of broken modular dependencies.

--showduplicates
 Show duplicate packages in repositories. Applicable for the list and search commands.

-v, --verbose
 Verbose operation, show debug messages.

--version

Show DNF version and exit.

-y, --assumeyes

Automatically answer yes for all questions.

List options are comma-separated. Command-line options override respective settings from configuration files.

COMMANDS

[top](#)

For an explanation of **<package-spec>**, **<package-file-spec>** and **<package-name-spec>** see *Specifying Packages*.

For an explanation of **<provide-spec>** see *Specifying Provides*.

For an explanation of **<group-spec>** see *Specifying Groups*.

For an explanation of **<module-spec>** see *Specifying Modules*.

For an explanation of **<transaction-spec>** see *Specifying Transactions*.

Alias Command

Command: **alias**

Allows the user to define and manage a list of aliases (in the form **<name=value>**), which can be then used as dnf commands to abbreviate longer command sequences. For examples on using the alias command, see *Alias Examples*. For examples on the alias processing, see *Alias Processing Examples*.

To use an alias (**name=value**), the name must be placed as the first "command" (e.g. the first argument that is not an option). It is then replaced by its value and the resulting sequence is again searched for aliases. The alias processing stops when the first found command is not a name of any alias.

In case the processing would result in an infinite recursion, the original arguments are used instead.

Also, like in shell aliases, if the result starts with a ****, the alias processing will stop.

All aliases are defined in configuration files in the **/etc/dnf/aliases.d/** directory in the **[aliases]** section, and aliases created by the alias command are written to the **USER.conf** file. In case of conflicts, the **USER.conf** has the highest priority, and alphabetical ordering is used for the rest of the configuration files.

Optionally, there is the **enabled** option in the **[main]** section defaulting to True. This can be set for each file separately in the respective file, or globally for all aliases in the **ALIASES.conf** file.

```
dnf alias [options] [list] [<name>...]
List aliases with their final result. The [<alias>...]
parameter further limits the result to only those aliases
matching it.
```

```
dnf alias [options] add <name=value>...
Create new aliases.
```

```
dnf alias [options] delete <name>...
Delete aliases.
```

Alias Examples

dnf alias list

Lists all defined aliases.

dnf alias add rm=remove

Adds a new command alias called **rm** which works the same as the **remove** command.

**dnf alias add upgrade="\\upgrade --skip-broken
--disableexcludes-all --obsoletes"**

Adds a new command alias called **upgrade** which works the same as the **upgrade** command, with additional options. Note that the original **upgrade** command is prefixed with a **** to prevent an infinite loop in alias processing.

Alias Processing Examples

If there are defined aliases `in=install` and `FORCE="--skip-broken --disableexcludes=all"`:

- `dnf FORCE in` will be replaced with `dnf --skip-broken --disableexcludes=all install`
- `dnf in FORCE` will be replaced with `dnf install FORCE` (which will fail)

If there is defined alias `in=install`:

- `dnf in` will be replaced with `dnf install`
- `dnf --repo updates in` will be replaced with `dnf --repo updates in` (which will fail)

Autoremove Command

Command: `autoremove`

Aliases for `explicit NEVRA matching`: `autoremove-n`, `autoremove-na`, `autoremove-nevra`

dnf [options] autoremove

Removes all "leaf" packages from the system that were originally installed as dependencies of user-installed packages, but which are no longer required by any such package.

Packages listed in `installyonlypkgs` are never automatically removed by this command.

dnf [options] autoremove <spec>...

This is an alias for the `Remove Command` command with `clean_requirements_on_remove` set to `True`. It removes the specified packages from the system along with any packages depending on the packages being removed. Each `<spec>` can be either a `<package-spec>`, which specifies a package directly, or a `@<group-spec>`, which specifies an (environment) group which contains it. It also removes any dependencies that are no longer needed.

There are also a few specific autoremove commands `autoremove-n`, `autoremove-na` and `autoremove-nevra` that allow the specification of an exact argument in the NEVRA (`name-epoch:version-release.architecture`) format.

This command by default does not force a sync of expired metadata. See also `Metadata Synchronization`.

Check Command

Command: `check`

dnf [options] check [--dependencies] [--duplicates] [--obsoleted] [--provides]

Checks the local packagedb and produces information on any problems it finds. You can limit the checks to be performed by using the `--dependencies`, `--duplicates`, `--obsoleted` and `--provides` options (the default is to check everything).

Check-Update Command

Command: `check-update`
Aliases: `check-upgrade`

dnf [options] check-update [--changelogs]

[<package-file-spec>...]

Non-interactively checks if updates of the specified packages are available. If no `<package-file-spec>` is given, checks whether any updates at all are available for your system. DNF exit code will be 100 when there are updates available and a list of the updates will be printed, 0 if not and 1 if an error occurs. If `--changelogs` option is specified, also changelog delta of packages about to be updated is printed.

Please note that having a specific newer version available for an installed package (and reported by `check-update`) does not imply that subsequent `dnf upgrade` will install it. The difference is that `dnf upgrade` has restrictions (like package dependencies being satisfied) to take into account.

The output is affected by the `autocheck_running_kernel` configuration option.

Clean CommandCommand: **clean**

Performs cleanup of temporary files kept for repositories. This includes any such data left behind from disabled or removed repositories as well as for different distribution release versions.

dnf clean dbcache

Removes cache files generated from the repository metadata. This forces DNF to regenerate the cache files the next time it is run.

dnf clean expire-cache

Marks the repository metadata expired. DNF will re-validate the cache for each repository the next time it is used.

dnf clean metadata

Removes repository metadata. Those are the files which DNF uses to determine the remote availability of packages. Using this option will make DNF download all the metadata the next time it is run.

dnf clean packages

Removes any cached packages from the system.

dnf clean all

Does all of the above.

Deplist Command

```
dnf [options] deplist [<select-options>] [<query-options>]
[<package-spec>]
```

Deprecated alias for `dnf repoquery --deplist`.

Distro-Sync CommandCommand: **distro-sync**Aliases: **dsync**

Deprecated aliases: **distrosync**, **distribution-synchronization**

dnf distro-sync [<package-spec>...]

As necessary upgrades, downgrades or keeps selected installed packages to match the latest version available from any enabled repository. If no package is given, all installed packages are considered.

See also *Configuration Files Replacement Policy*.

Downgrade CommandCommand: **downgrade**Aliases: **dg****dnf [options] downgrade <package-spec>...**

Downgrades the specified packages to the highest installable package of all known lower versions if possible. When version is given and is lower than version of installed package then it downgrades to target version.

Group CommandCommand: **group**Aliases: **grp**

Deprecated aliases: **groups**, **grouplist**, **groupinstall**, **groupupdate**, **groupremove**, **grouperase**, **groupinfo**

Groups are virtual collections of packages. DNF keeps track of groups that the user selected ("marked") installed and can manipulate the comprising packages with simple commands.

dnf [options] group [summary] <group-spec>

Display overview of how many groups are installed and available. With a spec, limit the output to the matching groups. **summary** is the default groups subcommand.

dnf [options] group info <group-spec>

Display package lists of a group. Shows which packages are installed or available from a repository when **-v** is used.

dnf [options] group install [--with-optional] <group-spec>...

Mark the specified group installed and install packages it contains. Also include **optional** packages of the group if **--with-optional** is specified. All **mandatory** and **Default**

packages will be installed whenever possible. Conditional packages are installed if they meet their requirement. If the group is already (partially) installed, the command installs the missing packages from the group. Depending on the value of *obsoletes configuration option* group installation takes obsoletes into account.

dnf [options] group list <group-spec>...
 List all matching groups, either among installed or available groups. If nothing is specified, list all known groups. **--installed** and **--available** options narrow down the requested list. Records are ordered by the *display_order* tag defined in comps.xml file. Provides a list of all hidden groups by using option **--hidden**. Provides group IDs when the **-v** or **--ids** options are used.

dnf [options] group remove <group-spec>...
 Mark the group removed and remove those packages in the group from the system which do not belong to another installed group and were not installed explicitly by the user.

dnf [options] group upgrade <group-spec>...
 Upgrades the packages from the group and upgrades the group itself. The latter comprises of installing packages that were added to the group by the distribution and removing packages that got removed from the group as far as they were not installed explicitly by the user.

Groups can also be marked installed or removed without physically manipulating any packages:

dnf [options] group mark install <group-spec>...
 Mark the specified group installed. No packages will be installed by this command, but the group is then considered installed.

dnf [options] group mark remove <group-spec>...
 Mark the specified group removed. No packages will be removed by this command.

See also *Configuration Files Replacement Policy*.

Help Command

Command: **help**

dnf help [<command>]
 Displays the help text for all commands. If given a command name then only displays help for that particular command.

History Command

Command: **history**

Aliases: **hist**

The history command allows the user to view what has happened in past transactions and act according to this information (assuming the *history_record* configuration option is set).

dnf history [list] [--reverse] [<spec>...]
 The default history action is listing information about given transactions in a table. Each *<spec>* can be either a *<transaction-spec>*, which specifies a transaction directly, or a *<transaction-spec>..<transaction-spec>*, which specifies a range of transactions, or a *<package-name-spec>*, which specifies a transaction by a package which it manipulated. When no transaction is specified, list all known transactions.

--reverse
 The order of **history list** output is printed in reverse order.

dnf history info [<spec>...]
 Describe the given transactions. The meaning of *<spec>* is the same as in the *History List Command*. When no transaction is specified, describe what happened during the latest transaction.

dnf history redo <transaction-spec>|<package-file-spec>
 Repeat the specified transaction. Uses the last

transaction (with the highest ID) if more than one transaction for given <package-file-spec> is found. If it is not possible to redo some operations due to the current state of RPMDB, it will not redo the transaction.

```
dnf history replay [--ignore-installed] [--ignore-extras]
[--skip-unavailable] <filename>
    Replay a transaction stored in file <filename> by History Store Command. The replay will perform the exact same operations on the packages as in the original transaction and will return with an error if case of any differences in installed packages or their versions. See also the Transaction JSON Format specification of the file format.
```

--ignore-installed

Don't check for the installed packages being in the same state as those recorded in the transaction.
E.g. in case there is an upgrade **foo-1.0** → **foo-2.0** stored in the transaction, but there is **foo-1.1** installed on the target system.

--ignore-extras

Don't check for extra packages pulled into the transaction on the target system. E.g. the target system may not have some dependency, which was installed on the source system. The replay errors out on this by default, as the transaction would not be the same.

--skip-unavailable

In case some packages stored in the transaction are not available on the target system, skip them instead of erroring out.

```
dnf history rollback <transaction-spec>|<package-file-spec>
    Undo all transactions performed after the specified transaction. Uses the last transaction (with the highest ID) if more than one transaction for given <package-file-spec> is found. If it is not possible to undo some transactions due to the current state of RPMDB, it will not undo any transaction.
```

```
dnf history store [--output <output-file>] <transaction-spec>
    Store a transaction specified by <transaction-spec>. The transaction can later be replayed by the History Replay Command.
```

Warning: The stored transaction format is considered unstable and may change at any time. It will work if the same version of dnf is used to store and replay (or between versions as long as it stays the same).

```
-o <output-file>, --output=<output-file> Store the serialized transaction into <output-file>. Default is transaction.json.
```

```
dnf history undo <transaction-spec>|<package-file-spec>
    Perform the opposite operation to all operations performed in the specified transaction. Uses the last transaction (with the highest ID) if more than one transaction for given <package-file-spec> is found. If it is not possible to undo some operations due to the current state of RPMDB, it will not undo the transaction.
```

dnf history userinstalled

Show all installonly packages, packages installed outside of DNF and packages not installed as dependency. I.e. it lists packages that will stay on the system when *Autoremove Command* or *Remove Command* along with *clean_requirements_on_remove* configuration option set to True is executed. Note the same results can be accomplished with **dnf repoquery --userinstalled**, and the repoquery command is more powerful in formatting of the output.

This command by default does not force a sync of expired metadata, except for the redo, rollback, and undo subcommands. See also *Metadata Synchronization* and *Configuration Files Replacement Policy*.

Info Command

Command: **info**
 Aliases: **if**

dnf [options] info [<package-file-spec>...]
 Lists description and summary information about installed
 and available packages.

The **info** command limits the displayed packages the same way as
 the *list command*.

This command by default does not force a sync of expired
 metadata. See also *Metadata Synchronization*.

Install Command

Command: **install**

Aliases: **in**

Aliases for *explicit NEVRA matching*: **install-n**, **install-na**, **install-nevra**
 Deprecated aliases: **localinstall**

dnf [options] install <spec>...

Makes sure that the given packages and their dependencies
 are installed on the system. Each **<spec>** can be either a
<package-spec>, or a **@<module-spec>**, or a **@<group-spec>**.
 See *Install Examples*. If a given package or provide
 cannot be (and is not already) installed, the exit code
 will be non-zero. If the **<spec>** matches both a **@-**
<module-spec> and a **@<group-spec>**, only the module is
 installed.

When **<package-spec>** to specify the exact version of the
 package is given, DNF will install the desired version, no
 matter which version of the package is already installed.
 The former version of the package will be removed in the
 case of non-installonly package.

On the other hand if **<package-spec>** specifies only a name,
 DNF also takes into account packages obsoleting it when
 picking which package to install. This behaviour is
 specific to the install command. Note that this can lead
 to seemingly unexpected results if a package has multiple
 versions and some older version is being obsoleted. It
 creates a split in the upgrade-path and both ways are
 considered correct, the resulting package is picked simply
 by lexicographical order.

There are also a few specific install commands **install-n**,
install-na and **install-nevra** that allow the specification
 of an exact argument in the NEVRA format.

See also *Configuration Files Replacement Policy*.

Install Examples

dnf install tito

Install the **tito** package (tito is the package name).

dnf install ~/Downloads/tito-0.6.2-1.fc22.noarch.rpm

Install a local rpm file tito-0.6.2-1.fc22.noarch.rpm from
 the **~/Downloads/** directory.

dnf install tito-0.5.6-1.fc22

Install the package with a specific version. If the
 package is already installed it will automatically try to
 downgrade or upgrade to the specific version.

dnf --best install tito

Install the latest available version of the package. If
 the package is already installed it will try to
 automatically upgrade to the latest version. If the latest
 version of the package cannot be installed, the
 installation will fail.

dnf install vim

DNF will automatically recognize that vim is not a package
 name, but will look up and install a package that provides
 vim with all the required dependencies. Note: Package name
 match has precedence over package provides match.

dnf install

<https://kojipkgs.fedoraproject.org//packages/tito/0.6.0/1.fc22/noarch/tito-0.6.0-1.fc22.noarch.rpm>
 Install a package directly from a URL.

```
dnf install '@docker'
    Install all default profiles of module 'docker' and their
    RPMs. Module streams get enabled accordingly.

dnf install '@Web Server'
    Install the 'Web Server' environmental group.

dnf install /usr/bin/rpmsign
    Install a package that provides the /usr/bin/rpmsign file.

dnf -y install tito --setopt=install_weak_deps=False
    Install the tito package (tito is the package name)
    without weak deps. Weak deps are not required for core
    functionality of the package, but they enhance the
    original package (like extended documentation, plugins,
    additional functions, etc.).

dnf install --advisory=FEDORA-2018-b7b99fe852 \*
    Install all packages that belong to the
    "FEDORA-2018-b7b99fe852" advisory.
```

List Command

Command: **list**
 Aliases: **ls**

Prints lists of packages depending on the packages' relation to the system. A package is **installed** if it is present in the RPMDB, and it is **available** if it is not installed but is present in a repository that DNF knows about.

The list command also limits the displayed packages according to specific criteria, e.g. to only those that update an installed package (respecting the repository **priority**). The **exclude** option in the configuration file can influence the result, but if the **--disableexcludes** command line option is used, it ensures that all installed packages will be listed.

```
dnf [options] list [--all] [<package-file-spec>...]
    Lists all packages, present in the RPMDB, in a repository
    or both.

dnf [options] list --installed [<package-file-spec>...]
    Lists installed packages.

dnf [options] list --available [<package-file-spec>...]
    Lists available packages.

dnf [options] list --extras [<package-file-spec>...]
    Lists extras, that is packages installed on the system
    that are not available in any known repository.

dnf [options] list --obsoletes [<package-file-spec>...]
    List packages installed on the system that are obsoleted
    by packages in any known repository.

dnf [options] list --recent [<package-file-spec>...]
    List packages recently added into the repositories.

dnf [options] list --upgrades [<package-file-spec>...]
    List upgrades available for the installed packages.

dnf [options] list --autoremove
    List packages which will be removed by the dnf autoremove
    command.
```

This command by default does not force a sync of expired metadata. See also **Metadata Synchronization**.

Makecache Command

Command: **makecache**
 Aliases: **mc**

```
dnf [options] makecache
    Downloads and caches metadata for enabled repositories.
    Tries to avoid downloading whenever possible (e.g. when
    the local metadata hasn't expired yet or when the metadata
    timestamp hasn't changed).

dnf [options] makecache --timer
    Like plain makecache, but instructs DNF to be more
    resource-aware, meaning it will not do anything if running
```

on battery power and will terminate immediately if it's too soon after the last successful `makecache` run (see `dnf.conf(5)`, `metadata_timer_sync`).

Mark Command

Command: `mark`

dnf mark install <package-spec>...

Marks the specified packages as installed by user. This can be useful if any package was installed as a dependency and is desired to stay on the system when `Autoremove Command` or `Remove Command` along with `clean_requirements_on_remove` configuration option set to `True` is executed.

dnf mark remove <package-spec>...

Unmarks the specified packages as installed by user. Whenever you as a user don't need a specific package you can mark it for removal. The package stays installed on the system but will be removed when `Autoremove Command` or `Remove Command` along with `clean_requirements_on_remove` configuration option set to `True` is executed. You should use this operation instead of `Remove Command` if you're not sure whether the package is a requirement of other user installed packages on the system.

dnf mark group <package-spec>...

Marks the specified packages as installed by group. This can be useful if any package was installed as a dependency or a user and is desired to be protected and handled as a group member like during group remove.

Module Command

Command: `module`

Modularity overview is available at [man page `dnf.modularity\(7\)`](#). Module subcommands take `<module-spec>...` arguments that specify modules or profiles.

dnf [options] module install <module-spec>...

Install module profiles, including their packages. In case no profile was provided, all default profiles get installed. Module streams get enabled accordingly.

This command cannot be used for switching module streams. Use the `dnf module switch-to` command for that.

dnf [options] module update <module-spec>...

Update packages associated with an active module stream, optionally restricted to a profile. If the `profile_name` is provided, only the packages referenced by that profile will be updated.

dnf [options] module switch-to <module-spec>...

Switch to or enable a module stream, change versions of installed packages to versions provided by the new stream, and remove packages from the old stream that are no longer available. It also updates installed profiles if they are available for the new stream. When a profile was provided, it installs that profile and does not update any already installed profiles.

This command can be used as a stronger version of the `dnf module enable` command, which not only enables modules, but also does a `distroSync` to all modular packages in the enabled modules.

It can also be used as a stronger version of the `dnf module install` command, but it requires to specify profiles that are supposed to be installed, because `switch-to` command does not use `default profiles`. The `switch-to` command doesn't only install profiles, it also makes a `distroSync` to all modular packages in the installed module.

dnf [options] module remove <module-spec>...

Remove installed module profiles, including packages that were installed with the `dnf module install` command. Will not remove packages required by other installed module profiles or by other user-installed packages. In case no profile was provided, all installed profiles get removed.

```
dnf [options] module remove --all <module-spec>...
    Remove installed module profiles, including packages that
    were installed with the dnf module install command. With
    --all option it additionally removes all packages whose
    names are provided by specified modules. Packages required
    by other installed module profiles and packages whose
    names are also provided by any other module are not
    removed.

dnf [options] module enable <module-spec>...
    Enable a module stream and make the stream RPMs available
    in the package set.

    Modular dependencies are resolved, dependencies checked
    and also recursively enabled. In case of modular
    dependency issue the operation will be rejected. To
    perform the action anyway please use --skip-broken option.

    This command cannot be used for switching module streams.
    Use the dnf module switch-to command for that.

dnf [options] module disable <module-name>...
    Disable a module. All related module streams will become
    unavailable. Consequently, all installed profiles will be
    removed and the module RPMs will become unavailable in the
    package set. In case of modular dependency issue the
    operation will be rejected. To perform the action anyway
    please use --skip-broken option.

dnf [options] module reset <module-name>...
    Reset module state so it's no longer enabled or disabled.
    Consequently, all installed profiles will be removed and
    only RPMs from the default stream will be available in the
    package set.

dnf [options] module provides <package-name-spec>...
    Lists all modular packages matching <package-name-spec>
    from all modules (including disabled), along with the
    modules and streams they belong to.

dnf [options] module list [--all] [module_name...]
    Lists all module streams, their profiles and states
    (enabled, disabled, default).

dnf [options] module list --enabled [module_name...]
    Lists module streams that are enabled.

dnf [options] module list --disabled [module_name...]
    Lists module streams that are disabled.

dnf [options] module list --installed [module_name...]
    List module streams with installed profiles.

dnf [options] module info <module-spec>...
    Print detailed information about given module stream.

dnf [options] module info --profile <module-spec>...
    Print detailed information about given module profiles.

dnf [options] module repoquery <module-spec>...
    List all available packages belonging to selected modules.

dnf [options] module repoquery --available <module-spec>...
    List all available packages belonging to selected modules.

dnf [options] module repoquery --installed <module-spec>...
    List all installed packages with same name like packages
    belonging to selected modules.
```

Provides Command

Command: **provides**
 Aliases: **prov**, **whatprovides**, **wp**

```
dnf [options] provides <provide-spec>
    Finds the packages providing the given <provide-spec>.
    This is useful when one knows a filename and wants to find
    what package (installed or not) provides this file. The
    <provide-spec> is gradually looked for at following
    locations:
```

1. The **<provide-spec>** is matched with all file provides of any available package:

```
$ dnf provides /usr/bin/gzip
gzip-1.9-9.fc29.x86_64 : The GNU data compression program
Matched from:
Filename      : /usr/bin/gzip
```

2. Then all provides of all available packages are searched:

```
$ dnf provides "gzip(x86-64)"
gzip-1.9-9.fc29.x86_64 : The GNU data compression program
Matched from:
Provide      : gzip(x86-64) = 1.9-9.fc29
```

3. DNF assumes that the **<provide-spec>** is a system command, prepends it with **/usr/bin/**, **/usr/sbin/** prefixes (one at a time) and does the file provides search again. For legacy reasons (packages that didn't do `UsrMove`) also **/bin** and **/sbin** prefixes are being searched:

```
$ dnf provides zless
gzip-1.9-9.fc29.x86_64 : The GNU data compression program
Matched from:
Filename      : /usr/bin/zless
```

4. If this last step also fails, DNF returns "Error: No Matches found".

This command by default does not force a sync of expired metadata. See also [Metadata Synchronization](#).

Reinstall Command

Command: **reinstall**
Aliases: **rei**

```
dnf [options] reinstall <package-spec>...
Installs the specified packages, fails if some of the
packages are either not installed or not available (i.e.
there is no repository where to download the same RPM).
```

Remove Command

Command: **remove**
Aliases: **rm**
Aliases for [explicit NEVRA matching](#): **remove-n**, **remove-na**, **remove-nevra**
Deprecated aliases: **erase**, **erase-n**, **erase-na**, **erase-nevra**

```
dnf [options] remove <package-spec>...
Removes the specified packages from the system along with
any packages depending on the packages being removed. Each
<spec> can be either a <package-spec>, which specifies a
package directly, or a @<group-spec>, which specifies an
(environment) group which contains it. If
clean_requirements_on_remove is enabled (the default),
also removes any dependencies that are no longer needed.
```

```
dnf [options] remove --duplicates
Removes older versions of duplicate packages. To ensure
the integrity of the system it reinstalls the newest
package. In some cases the command cannot resolve
conflicts. In such cases the dnf shell command with remove
--duplicates and upgrade dnf-shell sub-commands could
help.
```

```
dnf [options] remove --oldinstallonly
Removes old installonly packages, keeping only latest
versions and version of running kernel.
```

There are also a few specific remove commands **remove-n**, **remove-na** and **remove-nevra** that allow the specification of an exact argument in the NEVRA format.

Remove Examples

```
dnf remove acpi tito
Remove the acpi and tito packages.
```

```
dnf remove $(dnf repoquery --extras --exclude=tito,acpi)
Remove packages not present in any repository, but don't
remove the tito and acpi packages (they still might be
```

removed if they depend on some of the removed packages).

Remove older versions of duplicated packages (an equivalent of yum's **package-cleanup --cleandups**):

```
dnf remove --duplicates
```

Repoinfo Command

Command: **repoinfo**

An alias for the **repolist** command that provides more detailed information like **dnf repolist -v**.

Repolist Command

Command: **repolist**

```
dnf [options] repolist [--enabled|--disabled|--all]
```

Depending on the exact command lists enabled, disabled or all known repositories. Lists all enabled repositories by default. Provides more detailed information when **-v** option is used.

This command by default does not force a sync of expired metadata. See also [Metadata Synchronization](#).

Repoquery Command

Command: **repoquery**

Aliases: **rq**

Aliases for [explicit NEVRA matching](#): **repoquery-n**, **repoquery-na**, **repoquery-nevra**

```
dnf [options] repoquery [<select-options>] [<query-options>]  
[<package-file-spec>]
```

Searches available DNF repositories for selected packages and displays the requested information about them. It is an equivalent of **rpm -q** for remote repositories.

```
dnf [options] repoquery --groupmember <package-spec>...  
List groups that contain <package-spec>.
```

```
dnf [options] repoquery --querytags
```

Provides the list of tags recognized by the [--queryformat](#) **repoquery** option.

There are also a few specific repoquery commands **repoquery-n**, **repoquery-na** and **repoquery-nevra** that allow the specification of an exact argument in the NEVRA format (does not affect arguments of options like **--whatprovides <arg>**, ...).

Select Options

Together with **<package-file-spec>**, control what packages are displayed in the output. If **<package-file-spec>** is given, limits the resulting set of packages to those matching the specification. All packages are considered if no **<package-file-spec>** is specified.

<package-file-spec>

Package specification in the NEVRA format (name[-epoch:]version[-release]][.arch]), a package provide or a file provide. See [Specifying Packages](#).

-a, --all

Query all packages (for rpmquery compatibility, also a shorthand for **repoquery '*' or repoquery without arguments**).

--arch <arch>[,<arch>...], --archlist <arch>[,<arch>...]

Limit the resulting set only to packages of selected architectures (default is all architectures). In some cases the result is affected by the basearch of the running system, therefore to run **repoquery** for an arch incompatible with your system use the **--forcearch=<arch>** option to change the basearch.

--duplicates

Limit the resulting set to installed duplicate packages (i.e. more package versions for the same name and architecture). Installonly packages are excluded from this set.

--unneeded

Limit the resulting set to leaves packages that were installed as dependencies so they are no longer needed. This switch lists packages that are going to be removed after executing the **dnf autoremove** command.

--available

Limit the resulting set to available packages only (set by default).

--disable-modular-filtering

Disables filtering of modular packages, so that packages of inactive module streams are included in the result.

--extras

Limit the resulting set to packages that are not present in any of the available repositories.

-f <file>, --file <file>

Limit the resulting set only to the package that owns <file>.

--installed

Limit the resulting set to installed packages only. The **exclude** option in the configuration file might influence the result, but if the command line option **--disableexcludes** is used, it ensures that all installed packages will be listed.

--installonly

Limit the resulting set to installed installonly packages.

--latest-limit <number>

Limit the resulting set to <number> of latest packages for every package name and architecture. If <number> is negative, skip <number> of latest packages. For a negative <number> use the **--latest-limit=<number>** syntax.

--recent

Limit the resulting set to packages that were recently edited.

--repo <repoid>

Limit the resulting set only to packages from a repository identified by <repoid>. Can be used multiple times with accumulative effect.

--unsatisfied

Report unsatisfied dependencies among installed packages (i.e. missing requires and existing conflicts).

--upgrades

Limit the resulting set to packages that provide an upgrade for some already installed package.

--userinstalled

Limit the resulting set to packages installed by the user. The **exclude** option in the configuration file might influence the result, but if the command line option **--disableexcludes** is used, it ensures that all installed packages will be listed.

--whatdepends <capability>[,<capability>...]

Limit the resulting set only to packages that require, enhance, recommend, suggest or supplement any of <capabilities>.

--whatconflicts <capability>[,<capability>...]

Limit the resulting set only to packages that conflict with any of <capabilities>.

--whatenhances <capability>[,<capability>...]

Limit the resulting set only to packages that enhance any of <capabilities>. Use **--whatdepends** if you want to list all depending packages.

--whatobsoletes <capability>[,<capability>...]

Limit the resulting set only to packages that obsolete any of <capabilities>.

--whatprovides <capability>[,<capability>...]

Limit the resulting set only to packages that provide any

```

of <capabilities>.

--whatrecommends <capability>[,<capability>...]
    Limit the resulting set only to packages that recommend
    any of <capabilities>. Use --whatdepends if you want to
    list all depending packages.

--whatrequires <capability>[,<capability>...]
    Limit the resulting set only to packages that require any
    of <capabilities>. Use --whatdepends if you want to list
    all depending packages.

--whatsuggests <capability>[,<capability>...]
    Limit the resulting set only to packages that suggest any
    of <capabilities>. Use --whatdepends if you want to list
    all depending packages.

--whatsupplements <capability>[,<capability>...]
    Limit the resulting set only to packages that supplement
    any of <capabilities>. Use --whatdepends if you want to
    list all depending packages.

--alldeps
    This option is stackable with --whatrequires or --
    --whatdepends only. Additionally it adds all packages
    requiring the package features to the result set (used as
    default).

--exactdeps
    This option is stackable with --whatrequires or --
    --whatdepends only. Limit the resulting set only to
    packages that require <capability> specified by
    --whatrequires.

--srpm Operate on the corresponding source RPM.

Query Options
Set what information is displayed about each package.

The following are mutually exclusive, i.e. at most one can be
specified. If no query option is given, matching packages are
displayed in the standard NEVRA notation.

-i, --info
    Show detailed information about the package.

-l, --list
    Show the list of files in the package.

-s, --source
    Show the package source RPM name.

--changelogs
    Print the package changelogs.

--conflicts
    Display capabilities that the package conflicts with. Same
    as --qf "%{conflicts}".

--depends
    Display capabilities that the package depends on,
    enhances, recommends, suggests or supplements.

--enhances
    Display capabilities enhanced by the package. Same as --qf
    "%{enhances}".

--location
    Show a location where the package could be downloaded
    from.

--obsoletes
    Display capabilities that the package obsoletes. Same as
    --qf "%{obsoletes}".

--provides
    Display capabilities provided by the package. Same as --qf
    "%{provides}".

--recommends
    Display capabilities recommended by the package. Same as

```

```
--qf "%{recommends}".

--requires
    Display capabilities that the package depends on. Same as
    --qf "%{requires}".

--requires-pre
    Display capabilities that the package depends on for
    running a %pre script. Same as --qf "%{requires-pre}".

--suggests
    Display capabilities suggested by the package. Same as
    --qf "%{suggests}".

--supplements
    Display capabilities supplemented by the package. Same as
    --qf "%{supplements}".

--tree Display a recursive tree of packages with capabilities
        specified by one of the following supplementary options:
        --whatrequires, --requires, --conflicts, --enhances,
        --suggests, --provides, --supplements, --recommends.

--deplist
    Produce a list of all direct dependencies and what
    packages provide those dependencies for the given
    packages. The result only shows the newest providers
    (which can be changed by using --verbose).

--nvr Show found packages in the name-version-release format.
    Same as --qf "%{name}-%{version}-%{release}".

--nevra
    Show found packages in the
    name-epoch:version-release.architecture format. Same as
    --qf "%{name}-%{epoch}: %{version}-%{release}.%{arch}"
    (default).

--envra
    Show found packages in the
    epoch:name-version-release.architecture format. Same as
    --qf "%{epoch}: %{name}-%{version}-%{release}.%{arch}"

--qf <format>, --queryformat <format>
    Custom display format. <format> is the string to output
    for each matched package. Every occurrence of %{<tag>}
    within is replaced by the corresponding attribute of the
    package. The list of recognized tags can be displayed by
    running dnf repoquery --querytags.

--recursive
    Query packages recursively. Has to be used with
    --whatrequires <REQ> (optionally with --alldeps, but not
    with --exactdeps) or with --requires <REQ> --resolve.

--resolve
    resolve capabilities to originating package(s).
```

Examples

Display NEVRAs of all available packages matching **light***:

```
dnf repoquery 'light*'
```

Display NEVRAs of all available packages matching name **light*** and
 architecture **noarch** (accepts only arguments in the
 "<name>.arch" format):

```
dnf repoquery-na 'light*.noarch'
```

Display requires of all lighttpd packages:

```
dnf repoquery --requires lighttpd
```

Display packages providing the requires of python packages:

```
dnf repoquery --requires python --resolve
```

Display source rpm of lighttpd package:

```
dnf repoquery --source lighttpd
```

Display package name that owns the given file:

```
dnf repoquery --file /etc/lighttpd/lighttpd.conf
```

Display name, architecture and the containing repository of all lighttpd packages:

```
dnf repoquery --queryformat '%{name}.%{arch} : %{reponame}' lighttpd
```

Display all available packages providing "webserver":

```
dnf repoquery --whatprovides webserver
```

Display all available packages providing "webserver" but only for "i686" architecture:

```
dnf repoquery --whatprovides webserver --arch i686
```

Display duplicate packages:

```
dnf repoquery --duplicates
```

Display source packages that require a <provide> for a build:

```
dnf repoquery --disablerepo="*" --enablerepo="*-source" --arch=src --whatrequires <provide>
```

Repository-Packages Command

Command: **repository-packages**

Deprecated aliases: **repo-pkgs**, **repo-packages**, **repository-pkgs**

The repository-packages command allows the user to run commands on top of all packages in the repository named <repoid>. However, any dependency resolution takes into account packages from all enabled repositories. The <package-file-spec> and <package-spec> specifications further limit the candidates to only those packages matching at least one of them.

The **info** subcommand lists description and summary information about packages depending on the packages' relation to the repository. The **list** subcommand just prints lists of those packages.

```
dnf [options] repository-packages <repoid> check-update
[<package-file-spec>...]
    Non-interactively checks if updates of the specified
    packages in the repository are available. DNF exit code
    will be 100 when there are updates available and a list of
    the updates will be printed.
```

```
dnf [options] repository-packages <repoid> info [--all]
[<package-file-spec>...]
    List all related packages.
```

```
dnf [options] repository-packages <repoid> info --installed
[<package-file-spec>...]
    List packages installed from the repository.
```

```
dnf [options] repository-packages <repoid> info --available
[<package-file-spec>...]
    List packages available in the repository but not
    currently installed on the system.
```

```
dnf [options] repository-packages <repoid> info --extras
[<package-file-specs>...]
    List packages installed from the repository that are not
    available in any repository.
```

```
dnf [options] repository-packages <repoid> info --obsoletes
[<package-file-spec>...]
    List packages in the repository that obsolete packages
    installed on the system.
```

```
dnf [options] repository-packages <repoid> info --recent
[<package-file-spec>...]
    List packages recently added into the repository.
```

```
dnf [options] repository-packages <repoid> info --upgrades
[<package-file-spec>...]
    List packages in the repository that upgrade packages
    installed on the system.
```

```

dnf [options] repository-packages <repoid> install
[<package-spec>...]
    Install packages matching <package-spec> from the
    repository. If <package-spec> isn't specified at all,
    install all packages from the repository.

dnf [options] repository-packages <repoid> list [--all]
[<package-file-spec>...]
    List all related packages.

dnf [options] repository-packages <repoid> list --installed
[<package-file-spec>...]
    List packages installed from the repository.

dnf [options] repository-packages <repoid> list --available
[<package-file-spec>...]
    List packages available in the repository but not
    currently installed on the system.

dnf [options] repository-packages <repoid> list --extras
[<package-file-spec>...]
    List packages installed from the repository that are not
    available in any repository.

dnf [options] repository-packages <repoid> list --obsoletes
[<package-file-spec>...]
    List packages in the repository that obsolete packages
    installed on the system.

dnf [options] repository-packages <repoid> list --recent
[<package-file-spec>...]
    List packages recently added into the repository.

dnf [options] repository-packages <repoid> list --upgrades
[<package-file-spec>...]
    List packages in the repository that upgrade packages
    installed on the system.

dnf [options] repository-packages <repoid> move-to
[<package-spec>...]
    Reinstall all those packages that are available in the
    repository.

dnf [options] repository-packages <repoid> reinstall
[<package-spec>...]
    Run the reinstall-old subcommand. If it fails, run the
    move-to subcommand.

dnf [options] repository-packages <repoid> reinstall-old
[<package-spec>...]
    Reinstall all those packages that were installed from the
    repository and simultaneously are available in the
    repository.

dnf [options] repository-packages <repoid> remove
[<package-spec>...]
    Remove all packages installed from the repository along
    with any packages depending on the packages being removed.
    If clean_requirements_on_remove is enabled (the default)
    also removes any dependencies that are no longer needed.

dnf [options] repository-packages <repoid> remove-or-distro-sync
[<package-spec>...]
    Select all packages installed from the repository.
    Upgrade, downgrade or keep those of them that are
    available in another repository to match the latest
    version available there and remove the others along with
    any packages depending on the packages being removed. If
    clean_requirements_on_remove is enabled (the default) also
    removes any dependencies that are no longer needed.

dnf [options] repository-packages <repoid> remove-or-reinstall
[<package-spec>...]
    Select all packages installed from the repository.
    Reinstall those of them that are available in another
    repository and remove the others along with any packages
    depending on the packages being removed. If
    clean_requirements_on_remove is enabled (the default) also
    removes any dependencies that are no longer needed.

dnf [options] repository-packages <repoid> upgrade

```

[<package-spec>...]
 Update all packages to the highest resolvable version available in the repository. When versions are specified in the **<package-spec>**, update to these versions.

dnf [options] repository-packages <repoid> upgrade-to [<package-specs>...]
 A deprecated alias for the upgrade subcommand.

Search Command

Command: **search**
 Aliases: **se**

dnf [options] search [--all] <keywords>...
 Search package metadata for keywords. Keywords are matched as case-insensitive substrings, globbing is supported. By default lists packages that match all requested keys (AND operation). Keys are searched in package names and summaries. If the "--all" option is used, lists packages that match at least one of the keys (an OR operation). In addition the keys are searched in the package descriptions and URLs. The result is sorted from the most relevant results to the least.

This command by default does not force a sync of expired metadata. See also *Metadata Synchronization*.

Shell Command

Command: **shell**
 Aliases: **sh**

dnf [options] shell [filename]
 Open an interactive shell for conducting multiple commands during a single execution of DNF. These commands can be issued manually or passed to DNF from a file. The commands are much the same as the normal DNF command line options. There are a few additional commands documented below.

config [conf-option] [value]

- Set a configuration option to a requested value.
 If no value is given it prints the current value.

repo [list|enable|disable] [repo-id]

- list: list repositories and their status
- enable: enable repository
- disable: disable repository

transaction [list|reset|solve|run]

- list: resolve and list the content of the transaction
- reset: reset the transaction
- run: resolve and run the transaction

Note that all local packages must be used in the first shell transaction subcommand (e.g. **install /tmp/nodejs-1.1.x86_64.rpm /tmp/acpi-1-1.noarch.rpm**) otherwise an error will occur. Any **disable**, **enable**, and **reset** module operations (e.g. **module enable nodejs**) must also be performed before any other shell transaction subcommand is used.

Swap Command

Command: **swap**

dnf [options] swap <remove-spec> <install-spec>
 Remove spec and install spec in one transaction. Each **<spec>** can be either a **<package-spec>**, which specifies a package directly, or a **@<group-spec>**, which specifies an (environment) group which contains it. Automatic conflict solving is provided in DNF by the --allowerasing option that provides the functionality of the swap command automatically.

Updateinfo Command

Command: **updateinfo**

```

Aliases: upif
Deprecated aliases: list-updateinfo, list-security, list-sec, info-updateinfo, info-security, info-sec, summ

dnf [options] updateinfo [--summary|--list|--info]
[<availability>] [<spec>...]
    Display information about update advisories.

Depending on the output type, DNF displays just counts of
advisory types (omitted or --summary), list of advisories
(--list) or detailed information (--info). The -v option
extends the output. When used with --info, the information
is even more detailed. When used with --list, an
additional column with date of the last advisory update is
added.

<availability> specifies whether advisories about newer
versions of installed packages (omitted or --available),
advisories about equal and older versions of installed
packages (--installed), advisories about newer versions of
those installed packages for which a newer version is
available (--updates) or advisories about any versions of
installed packages (--all) are taken into account. Most of
the time, --available and --updates displays the same
output. The outputs differ only in the cases when an
advisory refers to a newer version but there is no enabled
repository which contains any newer version.

Note, that --available takes only the latest installed
versions of packages into account. In case of the kernel
packages (when multiple version could be installed
simultaneously) also packages of the currently running
version of kernel are added.

To print only advisories referencing a CVE or a bugzilla
use --with-cve or --with-bz options. When these switches
are used also the output of the --list is altered - the ID
of the CVE or the bugzilla is printed instead of the one
of the advisory.

If given and if neither ID, type (bugfix, enhancement,
security/sec) nor a package name of an advisory matches
<spec>, the advisory is not taken into account. The
matching is case-sensitive and in the case of advisory IDs
and package names, globbing is supported.

Output of the --summary option is affected by the
autocheck\_running\_kernel configuration option.

```

Upgrade Command

```

Command: upgrade
Aliases: up
Deprecated aliases: update, upgrade-to, update-to, localupdate

```

```

dnf [options] upgrade
    Updates each package to the latest version that is both
    available and resolvable.

```

```

dnf [options] upgrade <package-spec>...
    Updates each specified package to the latest available
    version. Updates dependencies as necessary. When versions
    are specified in the <package-spec>, update to these
    versions.

```

```

dnf [options] upgrade @<spec>...
    Alias for the dnf module update command.

```

If the main **obsoletes** configure option is true or the **--obsoletes** flag is present, dnf will include package obsoletes in its calculations. For more information see **obsoletes**.

See also [Configuration Files Replacement Policy](#).

Upgrade-Minimal Command

```

Command: upgrade-minimal
Aliases: up-min
Deprecated aliases: update-minimal

```

```

dnf [options] upgrade-minimal
    Updates each package to the latest available version that
    provides a bugfix, enhancement or a fix for a security
    issue (security).

```

```
dnf [options] upgrade-minimal <package-spec>...
    Updates each specified package to the latest available
    version that provides a bugfix, enhancement or a fix for
    security issue (security). Updates dependencies as
    necessary.
```

SPECIFYING PACKAGES [top](#)

Many commands take a **<package-spec>** parameter that selects a package for the operation. The **<package-spec>** argument is matched against package NEVRAs, provides and file provides.

<package-file-spec> is similar to **<package-spec>**, except provides matching is not performed. Therefore, **<package-file-spec>** is matched only against NEVRAs and file provides.

<package-name-spec> is matched against NEVRAs only.

Globs

Package specification supports the same glob pattern matching that shell does, in all three above mentioned packages it matches against (NEVRAs, provides and file provides).

The following patterns are supported:

- * Matches any number of characters.
- ? Matches any single character.
- [] Matches any one of the enclosed characters. A pair of characters separated by a hyphen denotes a range expression; any character that falls between those two characters, inclusive, is matched. If the first character following the [is a ! or a ^ then any character not enclosed is matched.

Note: Curly brackets ({}) are not supported. You can still use them in shells that support them and let the shell do the expansion, but if quoted or escaped, dnf will not expand them.

NEVRA Matching

When matching against NEVRAs, partial matching is supported. DNF tries to match the spec against the following list of NEVRA forms (in decreasing order of priority):

- **name-[epoch:]version-release.arch**
- **name.arch**
- **name**
- **name-[epoch:]version-release**
- **name-[epoch:]version**

Note that **name** can in general contain dashes (e.g. **package-with-dashes**).

The first form that matches any packages is used and the remaining forms are not tried. If none of the forms match any packages, an attempt is made to match the **<package-spec>** against full package NEVRAs. This is only relevant if globs are present in the **<package-spec>**.

<package-spec> matches NEVRAs the same way **<package-name-spec>** does, but in case matching NEVRAs fails, it attempts to match against provides and file provides of packages as well.

You can specify globs as part of any of the five NEVRA components. You can also specify a glob pattern to match over multiple NEVRA components (in other words, to match across the NEVRA separators). In that case, however, you need to write the spec to match against full package NEVRAs, as it is not possible to split such spec into NEVRA forms.

Specifying NEVRA Matching Explicitly

Some commands (**autoremove**, **install**, **remove** and **repoquery**) also have aliases with suffixes **-n**, **-na** and **-nevra** that allow to explicitly specify how to parse the arguments:

- Command `install-n` only matches against `name`.
- Command `install-na` only matches against `name.arch`.
- Command `install-nevra` only matches against
`name-[epoch:]version-release.arch`.

SPECIFYING PROVIDES[top](#)

`<provide-spec>` in command descriptions means the command operates on packages providing the given spec. This can either be an explicit provide, an implicit provide (i.e. name of the package) or a file provide. The selection is case-sensitive and globbing is supported.

Specifying File Provides

If a spec starts with either `/` or `*/`, it is considered as a potential file provide.

SPECIFYING GROUPS[top](#)

`<group-spec>` allows one to select (environment) groups a particular operation should work on. It is a case insensitive string (supporting globbing characters) that is matched against a group's ID, canonical name and name translated into the current `LC_MESSAGES` locale (if possible).

SPECIFYING MODULES[top](#)

`<module-spec>` allows one to select modules or profiles a particular operation should work on.

It is in the form of `NAME:STREAM:VERSION:CONTEXT:ARCH/PROFILE` and supported partial forms are the following:

- `NAME`
- `NAME:STREAM`
- `NAME:STREAM:VERSION`
- `NAME:STREAM:VERSION:CONTEXT`
- all above combinations with `::ARCH` (e.g. `NAME::ARCH`)
- `NAME:STREAM:VERSION:CONTEXT:ARCH`
- all above combinations with `/PROFILE` (e.g. `NAME/PROFILE`)

In case stream is not specified, the enabled or the default stream is used, in this order. In case profile is not specified, the system default profile or the 'default' profile is used.

SPECIFYING TRANSACTIONS[top](#)

`<transaction-spec>` can be in one of several forms. If it is an integer, it specifies a transaction ID. Specifying `last` is the same as specifying the ID of the most recent transaction. The last form is `last-<offset>`, where `<offset>` is a positive integer. It specifies offset-th transaction preceding the most recent transaction.

PACKAGE FILTERING[top](#)

Package filtering filters packages out from the available package set, making them invisible to most of dnf commands. They cannot be used in a transaction. Packages can be filtered out by either Exclude Filtering or Modular Filtering.

Exclude Filtering

Exclude Filtering is a mechanism used by a user or by a DNF plugin to modify the set of available packages. Exclude Filtering can be modified by either `includepkgs` or `excludepkgs` configuration options in `configuration files`. The `--disableexcludes` command line option can be used to override

excludes from configuration files. In addition to user-configured excludes, plugins can also extend the set of excluded packages. To disable excludes from a DNF plugin you can use the `--disableplugin` command line option.

To disable all excludes for e.g. the `install` command you can use the following combination of command line options:

```
dnf --disableexcludes=all --disableplugin="*" install bash
```

Modular Filtering

Please see [the modularity documentation](#) for details on how Modular Filtering works.

With modularity, only RPM packages from **active** module streams are included in the available package set. RPM packages from **inactive** module streams, as well as non-modular packages with the same name or provides as a package from an **active** module stream, are filtered out. Modular filtering is not applied to packages added from the command line, installed packages, or packages from repositories with `module_hotfixes=true` in their `.repo` file.

Disabling of modular filtering is not recommended, because it could cause the system to get into a broken state. To disable modular filtering for a particular repository, specify `module_hotfixes=true` in the `.repo` file or use `--setopt=<repo_id>.module_hotfixes=true`.

To discover the module which contains an excluded package use `dnf module provides`.

METADATA SYNCHRONIZATION

[top](#)

Correct operation of DNF depends on having access to up-to-date data from all enabled repositories but contacting remote mirrors on every operation considerably slows it down and costs bandwidth for both the client and the repository provider. The `metadata_expire` (see [dnf.conf\(5\)](#)) repository configuration option is used by DNF to determine whether a particular local copy of repository data is due to be re-synced. It is crucial that the repository providers set the option well, namely to a value where it is guaranteed that if particular metadata was available in time **T** on the server, then all packages it references will still be available for download from the server in time **T** + `metadata_expire`.

To further reduce the bandwidth load, some of the commands where having up-to-date metadata is not critical (e.g. the `list` command) do not look at whether a repository is expired and whenever any version of it is locally available to the user's account, it will be used. For non-root use, see also the `--cacheonly` switch. Note that in all situations the user can force synchronization of all enabled repositories with the `--refresh` switch.

CONFIGURATION FILES REPLACEMENT POLICY

[top](#)

The updated packages could replace the old modified configuration files with the new ones or keep the older files. Neither of the files are actually replaced. To the conflicting ones RPM gives additional suffix to the origin name. Which file should maintain the true name after transaction is not controlled by package manager but is specified by each package itself, following packaging guideline.

FILES

[top](#)

Cache Files
`/var/cache/dnf`

Main Configuration
`/etc/dnf/dnf.conf`

Repository
`/etc/yum.repos.d/`

NAME

do-release-upgrade – upgrade operating system to latest release

SYNOPSIS

do-release-upgrade [*options*]

DESCRIPTION

Upgrade the operating system to the latest release from the command-line. This is the preferred command if the machine has no graphic environment or if the machine is to be upgraded over a remote connection.

OPTIONS

-h, --help

show help message and exit

-d, --devel-release

If using the latest supported release, upgrade to the development release

-p, --proposed

Try upgrading to the latest release using the upgrader from Ubuntu-proposed

-m MODE, --mode=MODE

Run in a special upgrade mode. Currently "desktop" for regular upgrades of a desktop system and "server" for server systems are supported.

-f FRONTEND, --frontend=FRONTEND

Run the specified frontend

update-manager(8), apt-get(8)

NAME

fsck.fat – check and repair MS-DOS FAT filesystems

SYNOPSIS

fsck.fat [*OPTIONS*] *DEVICE*

DESCRIPTION

fsck.fat verifies the consistency of MS-DOS filesystems and optionally tries to repair them.

The following filesystem problems can be corrected (in this order):

- FAT contains invalid cluster numbers. Cluster is changed to EOF.
- File's cluster chain contains a loop. The loop is broken.
- Bad clusters (read errors). The clusters are marked bad and they are removed from files owning them. This check is optional.
- Directories with a large number of bad entries (probably corrupt). The directory can be deleted.
- Files . and .. are non-directories. They can be deleted or renamed.
- Directories . and .. in root directory. They are deleted.
- Bad filenames. They can be renamed.
- Duplicate directory entries. They can be deleted or renamed.
- Directories with non-zero size field. Size is set to zero.
- Directory . does not point to parent directory. The start pointer is adjusted.
- Directory .. does not point to parent of parent directory. The start pointer is adjusted.
- . and .. are not the two first entries in a non-root directory. The entries are created, moving occupied slots if necessary.
- Start cluster number of a file is invalid. The file is truncated.
- File contains bad or free clusters. The file is truncated.
- File's cluster chain is longer than indicated by the size fields. The file is truncated.
- Two or more files share the same cluster(s). All but one of the files are truncated. If the file being truncated is a directory file that has already been read, the filesystem check is restarted after truncation.
- File's cluster chain is shorter than indicated by the size fields. The file is truncated.
- Volume label in root directory or label in boot sector is invalid. Invalid labels are removed.
- Volume label in root directory and label in boot sector are different. Volume label from root directory is copied to boot sector.
- Clusters are marked as used but are not owned by a file. They are marked as free.

Additionally, the following problems are detected, but not repaired:

- Invalid parameters in boot sector

When **fsck.fat** checks a filesystem, it accumulates all changes in memory and performs them only after all checks are complete. This can be disabled with the **-w** option.

Two different variants of the FAT filesystem are supported. Standard is the FAT12, FAT16 and FAT32 filesystems as defined by Microsoft and widely used on hard disks and removable media like USB sticks and SD cards. The other is the legacy Atari variant used on Atari ST.

There are some minor differences in Atari format: Some boot sector fields are interpreted slightly different, and the special FAT entries for end-of-file and bad cluster can be different. Under MS-DOS 0xffff8 is used for EOF and Atari employs 0xffff by default, but both systems recognize all values from 0xffff8–0xffff as end-of-file. MS-DOS uses only 0xffff7 for bad clusters, where on Atari values 0xffff0–0xffff7 are for this

purpose (but the standard value is still 0xffff7).

OPTIONS

-a Automatically repair the filesystem. No user intervention is necessary. Whenever there is more than one method to solve a problem, the least destructive approach is used.

-A Select using the Atari variation of the FAT filesystem if that isn't active already, otherwise select standard FAT filesystem. This is selected by default if **mkfs.fat** is run on 68k Atari Linux.

-b Make read-only boot sector check.

-c PAGE

Use DOS codepage *PAGE* to decode short file names. By default codepage 850 is used.

-d PATH

Delete the specified file. If more than one file with that name exist, the first one is deleted. This option can be given more than once.

-f Salvage unused cluster chains to files. By default, unused clusters are added to the free disk space except in auto mode (**-a**).

-F NUM

Specify FAT table *NUM* for filesystem access. By default value 0 is assumed and then the first uncorrupted FAT table is chosen. Uncorrupted means that FAT table has valid first cluster. If default value 0 is used and all FAT tables are corrupted then **fsck.fat** gives up and does not try to repair FAT filesystem. If non-zero *NUM* value is specified then **fsck.fat** uses FAT table *NUM* for repairing FAT filesystem. If FAT table *NUM* has corrupted first cluster then **fsck.fat** will repair it. In any case, if FAT filesystem has more FAT tables then repaired content of chosen FAT table is copied to other FAT tables. To repair corrupted first cluster it is required to call **fsck.fat** with non-zero *NUM* value.

-l List path names of files being processed.

-n No-operation mode: non-interactively check for errors, but don't write anything to the filesystem.

-p Same as **-a**, for compatibility with other *fsck.

-r Interactively repair the filesystem. The user is asked for advice whenever there is more than one approach to fix an inconsistency. This is the default mode and the option is only retained for backwards compatibility.

-S Consider short (8.3) file names with spaces in the middle to be invalid, like previous versions of this program did. While such file names are not forbidden by the FAT specification, and were never treated as errors by Microsoft file system checking tools, many DOS programs are unable to handle files with such names. Using this option can make them accessible to these programs.

Short file names which *start* with a space are considered invalid regardless of this option's setting.

Previous versions of this program exceptionally treated *EA DATA. SF* and *WP ROOT. SF* as valid short names; using this option does not preserve that exception.

-t Mark unreadable clusters as bad.

-u PATH

Try to undelete the specified file. **fsck.fat** tries to allocate a chain of contiguous unallocated clusters beginning with the start cluster of the undeleted file. This option can be given more than once.

-U Consider lowercase volume and boot label as invalid and allow only uppercase characters. Such labels are forbidden by the FAT specification, but they are widely used by Linux tools. Moreover MS-DOS and Windows systems do not have problems to read them. Therefore volume and boot labels with lowercase characters are by default permitted.

-v Verbose mode. Generates slightly more output.

-V Perform a verification pass. The filesystem check is repeated after the first run. The second pass should never report any fixable errors. It may take considerably longer than the first pass, because the first pass may have generated long list of modifications that have to be scanned for each disk read.

--variant *TYPE*

Create a filesystem of variant *TYPE*. Acceptable values are *standard* and *atari* (in any combination of upper/lower case). See above under DESCRIPTION for the differences.

-w Write changes to disk immediately.

-y Same as **-a** (automatically repair filesystem) for compatibility with other fsck tools.

--help

Display help message describing usage and options then exit.

EXIT STATUS

0 No recoverable errors have been detected.

1 Recoverable errors have been detected or **fsck.fat** has discovered an internal inconsistency.

2 Usage error. **fsck.fat** did not access the filesystem.

FILES

fsck0000.rec, *fsck0001.rec*, ...

When recovering from a corrupted filesystem, **fsck.fat** dumps recovered data into files named *fsckNNNN.rec* in the top level directory of the filesystem.

BUGS

- Does not remove entirely empty directories.
- Should give more diagnostic messages.
- Undeleting files should use a more sophisticated algorithm.

HOMEPAGE

The home for the **dosfstools** project is its GitHub project page (<https://github.com/dosfstools/dosfstools>).

AUTHORS

dosfstools were written by Werner Almesberger <werner.almesberger@lrc.di.epfl.ch>, Roman Hodek <Roman.Hodek@informatik.uni-erlangen.de>, and others. Current maintainers are Andreas Bombe <aeb@debian.org> and Pali Rohár <pali.rohar@gmail.com>.

NAME

dpkg – package manager for Debian

SYNOPSIS

dpkg [*option...*] *action*

WARNING

This manual is intended for users wishing to understand **dpkg**'s command line options and package states in more detail than that provided by **dpkg --help**.

It should *not* be used by package maintainers wishing to understand how **dpkg** will install their packages. The descriptions of what **dpkg** does when installing and removing packages are particularly inadequate.

DESCRIPTION

dpkg is a medium-level tool to install, build, remove and manage Debian packages. The primary and more user-friendly front-end for **dpkg** as a CLI (command-line interface) is **apt(8)** and as a TUI (terminal user interface) is **aptitude(8)**. **dpkg** itself is controlled entirely via command line parameters, which consist of exactly one action and zero or more options. The action-parameter tells **dpkg** what to do and options control the behavior of the action in some way.

dpkg can also be used as a front-end to **dpkg-deb(1)** and **dpkg-query(1)**. The list of supported actions can be found later on in the ACTIONS section. If any such action is encountered **dpkg** just runs **dpkg-deb** or **dpkg-query** with the parameters given to it, but no specific options are currently passed to them, to use any such option the back-ends need to be called directly.

INFORMATION ABOUT PACKAGES

dpkg maintains some usable information about available packages. The information is divided in three classes: **states**, **selection states** and **flags**. These values are intended to be changed mainly with **dselect**.

Package states

not-installed

The package is not installed on your system.

config-files

Only the configuration files or the **postrm** script and the data it needs to remove of the package exist on the system.

half-installed

The installation of the package has been started, but not completed for some reason.

unpacked

The package is unpacked, but not configured.

half-configured

The package is unpacked and configuration has been started, but not yet completed for some reason.

triggers-awaited

The package awaits trigger processing by another package.

triggers-pending

The package has been triggered.

installed

The package is correctly unpacked and configured.

Package selection states

install

The package is selected for installation.

hold

A package marked to be on **hold** is kept on the same version, that is, no automatic new installs, upgrades or removals will be performed on them, unless these actions are requested explicitly, or are permitted to be done automatically with the **--force-hold** option.

deinstall

The package is selected for deinstallation (i.e. we want to remove all files, except configuration files).

purge

The package is selected to be purged (i.e. we want to remove everything from system directories, even configuration files).

unknown

The package selection is unknown. A package that is also in **not-installed** state, and with an **ok** flag will be forgotten in the next database store.

Package flags

ok A package marked **ok** is in a known state, but might need further processing.

reinstreq

A package marked **reinstreq** is broken and requires reinstallation. These packages cannot be removed, unless forced with option **--force-remove-reinstreq**.

ACTIONS**-i, --install package-file...**

Install the package. If **--recursive** or **-R** option is specified, *package-file* must refer to a directory instead.

Installation consists of the following steps:

1. Extract the control files of the new package.
2. If another version of the same package was installed before the new installation, execute *prerm* script of the old package.
3. Run *preinst* script, if provided by the package.
4. Unpack the new files, and at the same time back up the old files, so that if something goes wrong, they can be restored.
5. If another version of the same package was installed before the new installation, execute the *postrm* script of the old package. Note that this script is executed after the *preinst* script of the new package, because new files are written at the same time old files are removed.
6. Configure the package. See **--configure** for detailed information about how this is done.

--unpack package-file...

Unpack the package, but don't configure it. If **--recursive** or **-R** option is specified, *package-file* must refer to a directory instead.

--configure package...|-a|--pending

Configure a package which has been unpacked but not yet configured. If **-a** or **--pending** is given instead of *package*, all unpacked but unconfigured packages are configured.

To reconfigure a package which has already been configured, try the **dpkg-reconfigure(8)** command instead.

Configuring consists of the following steps:

1. Unpack the conffiles, and at the same time back up the old conffiles, so that they can be restored if something goes wrong.
2. Run *postinst* script, if provided by the package.

--triggers-only package...|-a|--pending

Processes only triggers (since dpkg 1.14.17). All pending triggers will be processed. If package names are supplied only those packages' triggers will be processed, exactly once each where necessary. Use of this option may leave packages in the improper **triggers-awaited** and **triggers-pending** states. This can be fixed later by running: **dpkg --configure --pending**.

-r, --remove package...|-a|--pending

Remove an installed package. This removes everything except conffiles and other data cleaned up by the *postrm* script, which may avoid having to reconfigure the package if it is reinstalled later (conffiles are configuration files that are listed in the *DEBIAN/conffiles* control file). If there is no *DEBIAN/conffiles* control file nor *DEBIAN/postrm* script, this command is equivalent to calling **--purge**. If **-a** or **--pending** is given instead of a package name, then all packages unpacked, but marked to be removed in file */var/lib/dpkg/status*, are removed.

Removing of a package consists of the following steps:

- 1.** Run *prerm* script
- 2.** Remove the installed files
- 3.** Run *postrm* script

-P, --purge package...|-a|--pending

Purge an installed or already removed package. This removes everything, including conffiles, and anything else cleaned up from *postrm*. If **-a** or **--pending** is given instead of a package name, then all packages unpacked or removed, but marked to be purged in file */var/lib/dpkg/status*, are purged.

Note: Some configuration files might be unknown to **dpkg** because they are created and handled separately through the configuration scripts. In that case, **dpkg** won't remove them by itself, but the package's *postrm* script (which is called by **dpkg**), has to take care of their removal during purge. Of course, this only applies to files in system directories, not configuration files written to individual users' home directories.

Purging of a package consists of the following steps:

- 1.** Remove the package, if not already removed. See **--remove** for detailed information about how this is done.
- 2.** Run *postrm* script.

-V, --verify [package-name...]

Verifies the integrity of *package-name* or all packages if omitted, by comparing information from the files installed by a package with the files metadata information stored in the **dpkg** database (since *dpkg* 1.17.2). The origin of the files metadata information in the database is the binary packages themselves. That metadata gets collected at package unpack time during the installation process.

Currently the only functional check performed is an md5sum verification of the file contents against the stored value in the files database. It will only get checked if the database contains the file md5sum. To check for any missing metadata in the database, the **--audit** command can be used.

The output format is selectable with the **--verify-format** option, which by default uses the **rpm** format, but that might change in the future, and as such, programs parsing this command output should be explicit about the format they expect.

-C, --audit [package-name...]

Performs database sanity and consistency checks for *package-name* or all packages if omitted (per package checks since *dpkg* 1.17.10). For example, searches for packages that have been installed only partially on your system or that have missing, wrong or obsolete control data or files. **dpkg** will suggest what to do with them to get them fixed.

--update-avail [Packages-file]**--merge-avail [Packages-file]**

Update **dpkg**'s and **dselect**'s idea of which packages are available. With action **--merge-avail**, old information is combined with information from *Packages-file*. With action **--update-avail**, old information is replaced with the information in the *Packages-file*. The *Packages-file* distributed with Debian is simply named «*Packages*». If the *Packages-file* argument is missing or named «--» then it will be read from standard input (since *dpkg* 1.17.7). **dpkg** keeps its record of available packages in */var/lib/dpkg/available*.

A simpler one-shot command to retrieve and update the *available* file is **dselect update**. Note that this file is mostly useless if you don't use **dselect** but an APT-based frontend: APT has its own system to keep track of available packages.

-A, --record-avail *package-file...*

Update **dpkg** and **dselect**'s idea of which packages are available with information from the package *package-file*. If **--recursive** or **-R** option is specified, *package-file* must refer to a directory instead.

--forget-old-unavail

Now **obsolete** and a no-op as **dpkg** will automatically forget uninstalled unavailable packages (since **dpkg** 1.15.4), but only those that do not contain user information such as package selections.

--clear-avail

Erase the existing information about what packages are available.

--get-selections [*package-name-pattern...*]

Get list of package selections, and write it to stdout. Without a pattern, non-installed packages (i.e. those which have been previously purged) will not be shown.

--set-selections

Set package selections using file read from stdin. This file should be in the format "*package state*", where state is one of **install**, **hold**, **deinstall** or **purge**. Blank lines and comment lines beginning with '#' are also permitted.

The *available* file needs to be up-to-date for this command to be useful, otherwise unknown packages will be ignored with a warning. See the **--update-avail** and **--merge-avail** commands for more information.

--clear-selections

Set the requested state of every non-essential package to deinstall (since **dpkg** 1.13.18). This is intended to be used immediately before **--set-selections**, to deinstall any packages not in list given to **--set-selections**.

--yet-to-unpack

Searches for packages selected for installation, but which for some reason still haven't been installed.

Note: This command makes use of both the available file and the package selections.

--predep-package

Print a single package which is the target of one or more relevant pre-dependencies and has itself no unsatisfied pre-dependencies.

If such a package is present, output it as a Packages file entry, which can be massaged as appropriate.

Note: This command makes use of both the available file and the package selections.

Returns 0 when a package is printed, 1 when no suitable package is available and 2 on error.

--add-architecture *architecture*

Add *architecture* to the list of architectures for which packages can be installed without using **--force-architecture** (since **dpkg** 1.16.2). The architecture **dpkg** is built for (i.e. the output of **--print-architecture**) is always part of that list.

--remove-architecture *architecture*

Remove *architecture* from the list of architectures for which packages can be installed without using **--force-architecture** (since **dpkg** 1.16.2). If the architecture is currently in use in the database then the operation will be refused, except if **--force-architecture** is specified. The architecture **dpkg** is built for (i.e. the output of **--print-architecture**) can never be removed from that list.

--print-architecture

Print architecture of packages **dpkg** installs (for example, "i386").

--print-foreign-architectures

Print a newline-separated list of the extra architectures **dpkg** is configured to allow packages to be installed for (since dpkg 1.16.2).

--assert-help

Give help about the **--assert-*feature*** options (since dpkg 1.21.0).

--assert-*feature*

Asserts that **dpkg** supports the requested feature. Returns 0 if the feature is fully supported, 1 if the feature is known but **dpkg** cannot provide support for it yet, and 2 if the feature is unknown. The current list of assertable features is:

support-predepends

Supports the **Pre-Depends** field (since dpkg 1.1.0).

working-epoch

Supports epochs in version strings (since dpkg 1.4.0.7).

long-filenames

Supports long filenames in **deb(5)** archives (since dpkg 1.4.1.17).

multi-conrep

Supports multiple **Conflicts** and **Replaces** (since dpkg 1.4.1.19).

multi-arch

Supports multi-arch fields and semantics (since dpkg 1.16.2).

versioned-provides

Supports versioned **Provides** (since dpkg 1.17.11).

protected-field

Supports the **Protected** field (since dpkg 1.20.1).

--validate-*thing string*

Validate that the *thing string* has a correct syntax (since dpkg 1.18.16). Returns 0 if the *string* is valid, 1 if the *string* is invalid but might be accepted in lax contexts, and 2 if the *string* is invalid. The current list of validatable *things* is:

pkgname

Validates the given package name (since dpkg 1.18.16).

trigname

Validates the given trigger name (since dpkg 1.18.16).

archname

Validates the given architecture name (since dpkg 1.18.16).

version

Validates the given version (since dpkg 1.18.16).

--compare-versions *ver1 op ver2*

Compare version numbers, where *op* is a binary operator. **dpkg** returns true (**0**) if the specified condition is satisfied, and false (**1**) otherwise. There are two groups of operators, which differ in how they treat an empty *ver1* or *ver2*. These treat an empty version as earlier than any version: **lt** **le** **eq** **ne** **ge** **gt**. These treat an empty version as later than any version: **lt-nl** **le-nl** **ge-nl** **gt-nl**. These are provided only for compatibility with control file syntax: <<< <= = >= >>>. The < and > operators are obsolete and should **not** be used, due to confusing semantics. To illustrate: **0.1 < 0.1** evaluates to true.

-?, --help

Display a brief help message.

--force-help

Give help about the **--force-*thing*** options.

-Dh, --debug=help

Give help about debugging options.

--version

Display **dpkg** version information.

When used with **--robot**, the output will be the program version number in a dotted numerical format, with no newline.

dpkg-deb actions

See **dpkg-deb(1)** for more information about the following actions, and other actions and options not exposed by the **dpkg** front-end.

-b, --build directory [archive|directory]

Build a deb package.

-c, --contents archive

List contents of a deb package.

-e, --control archive [directory]

Extract control-information from a package.

-x, --extract archive directory

Extract the files contained by package.

-X, --vextract archive directory

Extract and display the filenames contained by a package.

-f, --field archive [control-field...]

Display control field(s) of a package.

--ctrl-tarfile archive

Output the control tar-file contained in a Debian package.

--fsys-tarfile archive

Output the filesystem tar-file contained by a Debian package.

-I, --info archive [control-file...]

Show information about a package.

dpkg-query actions

See **dpkg-query(1)** for more information about the following actions, and other actions and options not exposed by the **dpkg** front-end.

-l, --list package-name-pattern...

List packages matching given pattern.

-s, --status package-name...

Report status of specified package.

-L, --listfiles package-name...

List files installed to your system from *package-name*.

-S, --search filename-search-pattern...

Search for a filename from installed packages.

-p, --print-avail package-name...

Display details about *package-name*, as found in */var/lib/dpkg/available*. Users of APT-based frontends should use **apt show package-name** instead.

OPTIONS

All options can be specified both on the command line and in the **dpkg** configuration file */etc/dpkg/dpkg.cfg* or fragment files (with names matching this shell pattern '[0-9a-zA-Z_-]*') on the configuration directory */etc/dpkg/dpkg.cfg.d/*. Each line in the configuration file is either an option (exactly the same as the command line option but without leading hyphens) or a comment (if it starts with a '#').

--abort-after=number

Change after how many errors **dpkg** will abort. The default is 50.

-B, --auto-deconfigure

When a package is removed, there is a possibility that another installed package depended on the removed package. Specifying this option will cause automatic deconfiguration of the package which depended on the removed package.

-D{octal}, --debug{octal}

Switch debugging on. *octal* is formed by bitwise-ORing desired values together from the list below (note that these values may change in future releases). **-Dh** or **--debug=help** display these debugging values.

Number	Description
1	Generally helpful progress information
2	Invocation and status of maintainer scripts
10	Output for each file processed
100	Lots of output for each file processed
20	Output for each configuration file
200	Lots of output for each configuration file
40	Dependencies and conflicts
400	Lots of dependencies/conflicts output
10000	Trigger activation and processing
20000	Lots of output regarding triggers
40000	Silly amounts of output regarding triggers
1000	Lots of drivel about e.g. the dpkg/info dir
2000	Insane amounts of drivel

--force-things**--no-force-things, --refuse-things**

Force or refuse (**no-force** and **refuse** mean the same thing) to do some things. *things* is a comma separated list of things specified below. **--force-help** displays a message describing them. Things marked with (*) are forced by default.

Warning: These options are mostly intended to be used by experts only. Using them without fully understanding their effects may break your whole system.

all: Turns on (or off) all force options.

downgrade(*): Install a package, even if newer version of it is already installed.

Warning: At present **dpkg** does not do any dependency checking on downgrades and therefore will not warn you if the downgrade breaks the dependency of some other package. This can have serious side effects, downgrading essential system components can even make your whole system unusable. Use with care.

configure-any: Configure also any unpacked but unconfigured packages on which the current package depends.

hold: Allow automatic installs, upgrades or removals of packages even when marked to be on “hold”.
Note: This does not prevent these actions when requested explicitly.

remove-reinstreq: Remove a package, even if it’s broken and marked to require reinstallation. This may, for example, cause parts of the package to remain on the system, which will then be forgotten by **dpkg**.

remove-protected: Remove, even if the package is considered protected (since dpkg 1.20.1). Protected packages contain mostly important system boot infrastructure. Removing them might cause the whole system to be unable to boot, so use with caution.

remove-essential: Remove, even if the package is considered essential. Essential packages contain

mostly very basic Unix commands. Removing them might cause the whole system to stop working, so use with caution.

depends: Turn all dependency problems into warnings. This affects the **Pre-Depends** and **Depends** fields.

depends-version: Don't care about versions when checking dependencies. This affects the **Pre-Depends** and **Depends** fields.

breaks: Install, even if this would break another package (since dpkg 1.14.6). This affects the **Breaks** field.

conflicts: Install, even if it conflicts with another package. This is dangerous, for it will usually cause overwriting of some files. This affects the **Conflicts** field.

confmiss: Always install the missing conffile without prompting. This is dangerous, since it means not preserving a change (removing) made to the file.

confnew: If a conffile has been modified and the version in the package did change, always install the new version without prompting, unless the **--force-confdef** is also specified, in which case the default action is preferred.

confold: If a conffile has been modified and the version in the package did change, always keep the old version without prompting, unless the **--force-confdef** is also specified, in which case the default action is preferred.

confdef: If a conffile has been modified and the version in the package did change, always choose the default action without prompting. If there is no default action it will stop to ask the user unless **--force-confnew** or **--force-confold** is also given, in which case it will use that to decide the final action.

confask: If a conffile has been modified always offer to replace it with the version in the package, even if the version in the package did not change (since dpkg 1.15.8). If any of **--force-confnew**, **--force-confold**, or **--force-confdef** is also given, it will be used to decide the final action.

overwrite: Overwrite one package's file with another's file.

overwrite-dir: Overwrite one package's directory with another's file.

overwrite-diverted: Overwrite a diverted file with an undiverted version.

statoverride-add: Overwrite an existing stat override when adding it (since dpkg 1.19.5).

statoverride-remove: Ignore a missing stat override when removing it (since dpkg 1.19.5).

security-mac^(*): Use platform-specific Mandatory Access Controls (MAC) based security when installing files into the filesystem (since dpkg 1.19.5). On Linux systems the implementation uses SELinux.

unsafe-io: Do not perform safe I/O operations when unpacking (since dpkg 1.15.8.6). Currently this implies not performing file system syncs before file renames, which is known to cause substantial performance degradation on some file systems, unfortunately the ones that require the safe I/O on the first place due to their unreliable behaviour causing zero-length files on abrupt system crashes.

Note: For ext4, the main offender, consider using instead the mount option **nodelalloc**, which will fix both the performance degradation and the data safety issues, the latter by making the file system not produce zero-length files on abrupt system crashes with any software not doing syncs before atomic renames.

Warning: Using this option might improve performance at the cost of losing data, use with care.

script-chrootless: Run maintainer scripts without **chroot**(2)ing into **instdir** even if the package does not support this mode of operation (since dpkg 1.18.5).

Warning: This can destroy your host system, use with extreme care.

architecture: Process even packages with wrong or no architecture.

bad-version: Process even packages with wrong versions (since dpkg 1.16.1).

bad-path: PATH is missing important programs, so problems are likely.

not-root: Try to (de)install things even when not root.

bad-verify: Install a package even if it fails authenticity check.

--ignore-depends=package,...

Ignore dependency-checking for specified packages (actually, checking is performed, but only warnings about conflicts are given, nothing else). This affects the **Pre-Depends**, **Depends** and **Breaks** fields.

--no-act, --dry-run, --simulate

Do everything which is supposed to be done, but don't write any changes. This is used to see what would happen with the specified action, without actually modifying anything.

Be sure to give **--no-act** before the action-parameter, or you might end up with undesirable results. (e.g. **dpkg --purge foo --no-act** will first purge package "foo" and then try to purge package "--no-act", even though you probably expected it to actually do nothing).

-R, --recursive

Recursively handle all regular files matching pattern ***.deb** found at specified directories and all of its subdirectories. This can be used with **-i**, **-A**, **--install**, **--unpack** and **--record-avail** actions.

-G Don't install a package if a newer version of the same package is already installed. This is an alias of **--refuse-downgrade**.

--admindir=dir

Set the administrative directory to *directory*. This directory contains many files that give information about status of installed or uninstalled packages, etc. Defaults to **<</var/lib/dpkg>>**.

--instdir=dir

Set the installation directory, which refers to the directory where packages are to be installed. **instdir** is also the directory passed to **chroot(2)** before running package's installation scripts, which means that the scripts see **instdir** as a root directory. Defaults to **<</>>**.

--root=dir

Set the root directory to **directory**, which sets the installation directory to **<<dir>>** and the administrative directory to **<<dir/var/lib/dpkg>>**.

-O, --selected-only

Only process the packages that are selected for installation. The actual marking is done with **dselect** or by **dpkg**, when it handles packages. For example, when a package is removed, it will be marked selected for deinstallation.

-E, --skip-same-version

Don't install the package if the same version of the package is already installed.

--pre-invoke=command

--post-invoke=command

Set an invoke hook *command* to be run via "sh -c" before or after the **dpkg** run for the *unpack*, *configure*, *install*, *triggers-only*, *remove*, *purge*, *add-architecture* and *remove-architecture* **dpkg** actions (since dpkg 1.15.4; *add-architecture* and *remove-architecture* actions since dpkg 1.17.19). This option can be specified multiple times. The order the options are specified is preserved, with the ones from the configuration files taking precedence. The environment variable **DPKG_HOOK_ACTION** is set for the hooks to the current **dpkg** action.

Note: Front-ends might call **dpkg** several times per invocation, which might run the hooks more times than expected.

--path-exclude=glob-pattern
--path-include=glob-pattern

Set *glob-pattern* as a path filter, either by excluding or re-including previously excluded paths matching the specified patterns during install (since dpkg 1.15.8).

Warning: Take into account that depending on the excluded paths you might completely break your system, use with caution.

The glob patterns use the same wildcards used in the shell, were '*' matches any sequence of characters, including the empty string and also '/'. For example, «*/usr/*/README*» matches «*/usr/share/doc/package/README*». As usual, '?' matches any single character (again, including '/'). And '[' starts a character class, which can contain a list of characters, ranges and complementations. See **glob(7)** for detailed information about globbing. **Note:** The current implementation might re-include more directories and symlinks than needed, in particular when there is a more specific re-inclusion, to be on the safe side and avoid possible unpack failures; future work might fix this.

This can be used to remove all paths except some particular ones; a typical case is:

```
--path-exclude=/usr/share/doc/*
--path-include=/usr/share/doc/*/copyright
```

to remove all documentation files except the copyright files.

These two options can be specified multiple times, and interleaved with each other. Both are processed in the given order, with the last rule that matches a file name making the decision.

The filters are applied when unpacking the binary packages, and as such only have knowledge of the type of object currently being filtered (e.g. a normal file or a directory) and have not visibility of what objects will come next. Because these filters have side effects (in contrast to **find(1)** filters), excluding an exact pathname that happens to be a directory object like */usr/share/doc* will not have the desired result, and only that pathname will be excluded (which could be automatically reincluded if the code sees the need). Any subsequent files contained within that directory will fail to unpack.

Hint: make sure the globs are not expanded by your shell.

--verify-format format-name

Sets the output format for the **--verify** command (since dpkg 1.17.2).

The only currently supported output format is **rpm**, which consists of a line for every path that failed any check. These lines have the following format:

```
missing [c] pathname [(error-message)]
??5????? [c] pathname
```

The first 9 characters are used to report the checks result, either a literal **missing** when the file is not present or its metadata cannot be fetched, or one of the following special characters that report the result for each check:

'?' Implies the check could not be done (lack of support, file permissions, etc).

'.' Implies the check passed.

'A-Za-z0-9'

Implies a specific check failed. The following positions and alphanumeric characters are currently supported:

1 '?'

These checks are currently not supported, will always be '?'.

2 'M'

The file mode check failed (since dpkg 1.21.0). Because pathname metadata is currently not tracked, this check can only be partially emulated via a very simple heuristic for pathnames that have a known digest, which implies they should be regular files, where the check will

fail if the pathname is not a regular file on the filesystem. This check will currently never succeed as it does not have enough information available.

3 ‘5’

The digest check failed, which means the file contents have changed.

4–9 ‘?’

These checks are currently not supported, will always be ‘?’.

The line is followed by a space and an attribute character. The following attribute character is supported:

‘c’ The pathname is a conffile.

Finally followed by another space and the pathname.

In case the entry was of the **missing** type, and the file was not actually present on the filesystem, then the line is followed by a space and the error message enclosed within parenthesis.

--status-fd *n*

Send machine-readable package status and progress information to file descriptor *n*. This option can be specified multiple times. The information is generally one record per line, in one of the following forms:

status: *package*: *status*

Package status changed; *status* is as in the status file.

status: *package* : **error** : *extended-error-message*

An error occurred. Any possible newlines in *extended-error-message* will be converted to spaces before output.

status: *file* : **conffile-prompt** : ‘*real-old*’ ‘*real-new*’ *useredited distedited*

User is being asked a conffile question.

processing: *stage*: *package*

Sent just before a processing stage starts. *stage* is one of **upgrade**, **install** (both sent before unpacking), **configure**, **trigproc**, **disappear**, **remove**, **purge**.

--status-logger=*command*

Send machine-readable package status and progress information to the shell *command*’s standard input, to be run via “sh –c” (since dpkg 1.16.0). This option can be specified multiple times. The output format used is the same as in --status-fd.

--log=*filename*

Log status change updates and actions to *filename*, instead of the default */var/log/dpkg.log*. If this option is given multiple times, the last filename is used. Log messages are of the form:

YYYY-MM-DD HH:MM:SS **startup** *type command*

For each dpkg invocation where *type* is **archives** (with a *command* of **unpack** or **install**) or **packages** (with a *command* of **configure**, **triggers-only**, **remove** or **purge**).

YYYY-MM-DD HH:MM:SS **status** *state pkg installed-version*

For status change updates.

YYYY-MM-DD HH:MM:SS *action pkg installed-version available-version*

For actions where *action* is one of **install**, **upgrade**, **configure**, **trigproc**, **disappear**, **remove** or **purge**.

YYYY-MM-DD HH:MM:SS **conffile** *filename decision*

For conffile changes where *decision* is either **install** or **keep**.

--robot

Use a machine-readable output format. This provides an interface for programs that need to parse the output of some of the commands that do not otherwise emit a machine-readable output format. No localization will be used, and the output will be modified to make it easier to parse.

The only currently supported command is **--version**.

--no-pager

Disables the use of any pager when showing information (since dpkg 1.19.2).

--no-debsig

Do not try to verify package signatures.

--no-triggers

Do not run any triggers in this run (since dpkg 1.14.17), but activations will still be recorded. If used with **--configure package** or **--triggers-only package** then the named package postinst will still be run even if only a triggers run is needed. Use of this option may leave packages in the improper **triggers-awaited** and **triggers-pending** states. This can be fixed later by running: **dpkg --configure --pending**.

--triggers

Cancels a previous **--no-triggers** (since dpkg 1.14.17).

EXIT STATUS

- 0** The requested action was successfully performed. Or a check or assertion command returned true.
- 1** A check or assertion command returned false.
- 2** Fatal or unrecoverable error due to invalid command-line usage, or interactions with the system, such as accesses to the database, memory allocations, etc.

ENVIRONMENT**External environment****PATH**

This variable is expected to be defined in the environment and point to the system paths where several required programs are to be found. If it's not set or the programs are not found, **dpkg** will abort.

HOME

If set, **dpkg** will use it as the directory from which to read the user specific configuration file.

TMPDIR

If set, **dpkg** will use it as the directory in which to create temporary files and directories.

SHELL

The program **dpkg** will execute when starting a new interactive shell, or when spawning a command via a shell.

PAGER**DPKG_PAGER**

The program **dpkg** will execute when running a pager, which will be executed with «**\$SHELL -c**», for example when displaying the conffile differences. If **SHELL** is not set, «**sh**» will be used instead. The **DPKG_PAGER** overrides the **PAGER** environment variable (since dpkg 1.19.2).

DPKG_COLORS

Sets the color mode (since dpkg 1.18.5). The currently accepted values are: **auto** (default), **always** and **never**.

DPKG_FORCE

Sets the force flags (since dpkg 1.19.5). When this variable is present, no built-in force defaults will be applied. If the variable is present but empty, all force flags will be disabled.

DPKG_ADMINDIR

If set and the **--admindir** or **--root** options have not been specified, it will be used as the **dpkg** administrative directory (since dpkg 1.20.0).

DPKG_FRONTEND_LOCKED

Set by a package manager frontend to notify dpkg that it should not acquire the frontend lock (since dpkg 1.19.1).

Internal environment**LESS**

Defined by **dpkg** to “**-FRSXMQ**”, if not already set, when spawning a pager (since dpkg 1.19.2). To change the default behavior, this variable can be preset to some other value including an empty string, or the **PAGER** or **DPKG_PAGER** variables can be set to disable specific options with «**-+**», for example **DPKG_PAGER=“less -+F”**.

DPKG_ROOT

Defined by **dpkg** on the maintainer script environment to indicate which installation to act on (since dpkg 1.18.5). The value is intended to be prepended to any path maintainer scripts operate on. During normal operation, this variable is empty. When installing packages into a different **instdir**, **dpkg** normally invokes maintainer scripts using **chroot(2)** and leaves this variable empty, but if **--force-script-chrootless** is specified then the **chroot(2)** call is skipped and **instdir** is non-empty.

DPKG_ADMINDIR

Defined by **dpkg** on the maintainer script environment to indicate the **dpkg** administrative directory to use (since dpkg 1.16.0). This variable is always set to the current **--admindir** value.

DPKG_FORCE

Defined by **dpkg** on the subprocesses environment to all the currently enabled force option names separated by commas (since dpkg 1.19.5).

DPKG_SHELL_REASON

Defined by **dpkg** on the shell spawned on the conffile prompt to examine the situation (since dpkg 1.15.6). Current valid value: **conffile-prompt**.

DPKG_CONFFILE_OLD

Defined by **dpkg** on the shell spawned on the conffile prompt to examine the situation (since dpkg 1.15.6). Contains the path to the old conffile.

DPKG_CONFFILE_NEW

Defined by **dpkg** on the shell spawned on the conffile prompt to examine the situation (since dpkg 1.15.6). Contains the path to the new conffile.

DPKG_HOOK_ACTION

Defined by **dpkg** on the shell spawned when executing a hook action (since dpkg 1.15.4). Contains the current **dpkg** action.

DPKG_RUNNING_VERSION

Defined by **dpkg** on the maintainer script environment to the version of the currently running **dpkg** instance (since dpkg 1.14.17).

DPKG_MAINTSCRIPT_PACKAGE

Defined by **dpkg** on the maintainer script environment to the (non-arch-qualified) package name being handled (since dpkg 1.14.17).

DPKG_MAINTSCRIPT_PACKAGE_REFCOUNT

Defined by **dpkg** on the maintainer script environment to the package reference count, i.e. the number of package instances with a state greater than **not-installed** (since dpkg 1.17.2).

DPKG_MAINTSCRIPT_ARCH

Defined by **dpkg** on the maintainer script environment to the architecture the package got built for (since dpkg 1.15.4).

DPKG_MAINTSCRIPT_NAME

Defined by **dpkg** on the maintainer script environment to the name of the script running, one of **preinst**, **postinst**, **prerm** or **postrm** (since dpkg 1.15.7).

DPKG_MAINTSCRIPT_DEBUG

Defined by **dpkg** on the maintainer script environment to a value (**'0'** or **'1'**) noting whether debugging has been requested (with the **--debug** option) for the maintainer scripts (since dpkg 1.18.4).

FILES*/etc/dpkg/dpkg.cfg.d/[0-9a-zA-Z_-]**

Configuration fragment files (since dpkg 1.15.4).

/etc/dpkg/dpkg.cfg

Configuration file with default options.

*/var/log/dpkg.log*Default log file (see */etc/dpkg/dpkg.cfg* and option **--log**).The other files listed below are in their default directories, see option **--admindir** to see how to change locations of these files.*/var/lib/dpkg/available*

List of available packages.

*/var/lib/dpkg/status*Statuses of available packages. This file contains information about whether a package is marked for removing or not, whether it is installed or not, etc. See section **INFORMATION ABOUT PACKAGES** for more info.The status file is backed up daily in */var/backups*. It can be useful if it's lost or corrupted due to filesystems troubles.The format and contents of a binary package are described in **deb(5)**.**BUGS****--no-act** usually gives less information than might be helpful.**EXAMPLES**To list installed packages related to the editor **vi**(1) (note that **dpkg-query** does not load the *available* file anymore by default, and the **dpkg-query --load-avail** option should be used instead for that):

```
dpkg -l '*vi*'
```

To see the entries in */var/lib/dpkg/available* of two packages:

```
dpkg --print-avail elvis vim | less
```

To search the listing of packages yourself:

```
less /var/lib/dpkg/available
```

To remove an installed elvis package:

```
dpkg -r elvis
```

To install a package, you first need to find it in an archive or CDROM. The *available* file shows that the vim package is in section **editors**:

```
cd /media/cdrom/pool/main/v/vim
dpkg -i vim_4.5-3.deb
```

To make a local copy of the package selection states:

```
dpkg --get-selections> myselections
```

You might transfer this file to another computer, and after having updated the *available* file there with your package manager frontend of choice (see <<https://wiki.debian.org/Teams/Dpkg/FAQ>> for more details), for example:

```
apt-cache dumpavail | dpkg --merge-avail
```

or with dpkg 1.17.6 and earlier:

```
avail=$(mktemp)
apt-cache dumpavail> "$avail"
dpkg --merge-avail "$avail"
rm "$avail"
```

you can install it with:

```
dpkg --clear-selections
dpkg --set-selections <myselections
```

Note that this will not actually install or remove anything, but just set the selection state on the requested packages. You will need some other application to actually download and install the requested packages. For example, run **apt-get dselect-upgrade**.

Ordinarily, you will find that **dselect(1)** provides a more convenient way to modify the package selection states.

ADDITIONAL FUNCTIONALITY

Additional functionality can be gained by installing any of the following packages: **apt**, **aptitude** and **debsums**.

NAME

dpkg.cfg – dpkg configuration file

DESCRIPTION

This file contains default options for dpkg. Each line contains a single option which is exactly the same as a normal command line option for dpkg except for the leading hyphens which are not used here. Quotes surrounding option values are stripped. Comments are allowed by starting a line with a hash sign ('#').

FILES

*/etc/dpkg/dpkg.cfg.d/[0-9a-zA-Z_-]**
/etc/dpkg/dpkg.cfg
~.dpkg.cfg

SEE ALSO

dpkg(1).

NAME

du – estimate file space usage

SYNOPSIS

du [*OPTION*]... [*FILE*]...
du [*OPTION*]... --files0-from=*F*

DESCRIPTION

Summarize disk usage of the set of FILES, recursively for directories.

Mandatory arguments to long options are mandatory for short options too.

-0, --null

end each output line with NUL, not newline

-a, --all

write counts for all files, not just directories

--apparent-size

print apparent sizes, rather than disk usage; although the apparent size is usually smaller, it may be larger due to holes in ('sparse') files, internal fragmentation, indirect blocks, and the like

-B, --block-size=SIZE

scale sizes by SIZE before printing them; e.g., '-BM' prints sizes in units of 1,048,576 bytes; see SIZE format below

-b, --bytes

equivalent to '--apparent-size --block-size=1'

-c, --total

produce a grand total

-D, --dereference-args

dereference only symlinks that are listed on the command line

-d, --max-depth=N

print the total for a directory (or file, with --all) only if it is N or fewer levels below the command line argument; --max-depth=0 is the same as --summarize

--files0-from=F

summarize disk usage of the NUL-terminated file names specified in file F; if F is -, then read names from standard input

-H

equivalent to --dereference-args (-D)

-h, --human-readable

print sizes in human readable format (e.g., 1K 234M 2G)

--inodes

list inode usage information instead of block usage

-k

like --block-size=1K

-L, --dereference

dereference all symbolic links

-l, --count-links

count sizes many times if hard linked

-m

like --block-size=1M

-P, --no-dereference

don't follow any symbolic links (this is the default)

-S, --separate-dirs

for directories do not include size of subdirectories

--si like **-h**, but use powers of 1000 not 1024

-s, --summarize display only a total for each argument

-t, --threshold=SIZE exclude entries smaller than SIZE if positive, or entries greater than SIZE if negative

--time show time of the last modification of any file in the directory, or any of its subdirectories

--time=WORD show time as WORD instead of modification time: atime, access, use, ctime or status

--time-style=STYLE show times using STYLE, which can be: full-iso, long-iso, iso, or +FORMAT; FORMAT is interpreted like in 'date'

-X, --exclude-from=FILE exclude files that match any pattern in FILE

--exclude=PATTERN exclude files that match PATTERN

-x, --one-file-system skip directories on different file systems

--help display this help and exit

--version output version information and exit

Display values are in units of the first available SIZE from **--block-size**, and the DU_BLOCK_SIZE, BLOCK_SIZE and BLOCKSIZE environment variables. Otherwise, units default to 1024 bytes (or 512 if POSIXLY_CORRECT is set).

The SIZE argument is an integer and optional unit (example: 10K is 10*1024). Units are K,M,G,T,P,E,Z,Y (powers of 1024) or KB,MB,... (powers of 1000). Binary prefixes can be used, too: KiB=K, MiB=M, and so on.

PATTERNS

PATTERN is a shell pattern (not a regular expression). The pattern? matches any one character, whereas * matches any string (composed of zero, one or multiple characters). For example, *.o will match any files whose names end in .o. Therefore, the command

```
du --exclude='*.o'
```

will skip all files and subdirectories ending in .o (including the file .o itself).

NAME

e2fsck – check a Linux ext2/ext3/ext4 file system

SYNOPSIS

```
e2fsck [ -pacnyrdfkvtDFV ] [ -b superblock ] [ -B blocksize ] [ -I|-L bad_blocks_file ] [ -C fd ] [ -j external-journal ] [ -E extended_options ] [ -z undo_file ] device
```

DESCRIPTION

e2fsck is used to check the ext2/ext3/ext4 family of file systems. For ext3 and ext4 file systems that use a journal, if the system has been shut down uncleanly without any errors, normally, after replaying the committed transactions in the journal, the file system should be marked as clean. Hence, for file systems that use journaling, **e2fsck** will normally replay the journal and exit, unless its superblock indicates that further checking is required.

device is a block device (e.g., */dev/sdc1*) or file containing the file system.

Note that in general it is not safe to run **e2fsck** on mounted file systems. The only exception is if the **-n** option is specified, and **-c**, **-I**, or **-L** options are *not* specified. However, even if it is safe to do so, the results printed by **e2fsck** are not valid if the file system is mounted. If **e2fsck** asks whether or not you should check a file system which is mounted, the only correct answer is “no”. Only experts who really know what they are doing should consider answering this question in any other way.

If **e2fsck** is run in interactive mode (meaning that none of **-y**, **-n**, or **-p** are specified), the program will ask the user to fix each problem found in the file system. A response of ‘y’ will fix the error; ‘n’ will leave the error unfixed; and ‘a’ will fix the problem and all subsequent problems; pressing Enter will proceed with the default response, which is printed before the question mark. Pressing Control-C terminates **e2fsck** immediately.

OPTIONS

- a** This option does the same thing as the **-p** option. It is provided for backwards compatibility only; it is suggested that people use **-p** option whenever possible.
- b** *superblock*
Instead of using the normal superblock, use an alternative superblock specified by *superblock*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system’s blocksize, the number of blocks per group, and features such as **sparse_super**.
Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system’s layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).
If an alternative superblock is specified and the file system is not opened read-only, **e2fsck** will make sure that the primary superblock is updated appropriately upon completion of the file system check.
- B** *blocksize*
Normally, **e2fsck** will search for the superblock at various different block sizes in an attempt to find the appropriate block size. This search can be fooled in some cases. This option forces **e2fsck** to only try locating the superblock at a particular blocksize. If the superblock is not found, **e2fsck** will terminate with a fatal error.
- c** This option causes **e2fsck** to use **badblocks(8)** program to do a read-only scan of the device in order to find any bad blocks. If any bad blocks are found, they are added to the bad block inode to prevent them from being allocated to a file or directory. If this option is specified twice, then the bad block scan will be done using a non-destructive read-write test.
- C** *fd* This option causes **e2fsck** to write completion information to the specified file descriptor so that the progress of the file system check can be monitored. This option is typically used by programs which are running **e2fsck**. If the file descriptor number is negative, then absolute value of the file descriptor will be used, and the progress information will be suppressed initially. It can later be enabled by sending the **e2fsck** process a SIGUSR1 signal. If the file descriptor specified is 0,

e2fsck will print a completion bar as it goes about its business. This requires that e2fsck is running on a video console or terminal.

- d** Print debugging output (useless unless you are debugging **e2fsck**).
- D** Optimize directories in file system. This option causes e2fsck to try to optimize all directories, either by re-indexing them if the file system supports directory indexing, or by sorting and compressing directories for smaller directories, or for file systems using traditional linear directories.

Even without the **-D** option, **e2fsck** may sometimes optimize a few directories --- for example, if directory indexing is enabled and a directory is not indexed and would benefit from being indexed, or if the index structures are corrupted and need to be rebuilt. The **-D** option forces all directories in the file system to be optimized. This can sometimes make them a little smaller and slightly faster to search, but in practice, you should rarely need to use this option.

The **-D** option will detect directory entries with duplicate names in a single directory, which e2fsck normally does not enforce for performance reasons.

-E *extended_options*

Set e2fsck extended options. Extended options are comma separated, and may take an argument using the equals ('=') sign. The following options are supported:

ea_ver=extended_attribute_version

Set the version of the extended attribute blocks which **e2fsck** will require while checking the file system. The version number may be 1 or 2. The default extended attribute version format is 2.

journal_only

Only replay the journal if required, but do not perform any further checks or repairs.

fragcheck

During pass 1, print a detailed report of any discontiguous blocks for files in the file system.

discard

Attempt to discard free blocks and unused inode blocks after the full file system check (discarding blocks is useful on solid state devices and sparse / thin-provisioned storage). Note that discard is done in pass 5 AFTER the file system has been fully checked and only if it does not contain recognizable errors. However there might be cases where **e2fsck** does not fully recognize a problem and hence in this case this option may prevent you from further manual data recovery.

nodiscard

Do not attempt to discard free blocks and unused inode blocks. This option is exactly the opposite of discard option. This is set as default.

no_optimize_extents

Do not offer to optimize the extent tree by eliminating unnecessary width or depth. This can also be enabled in the options section of **/etc/e2fsck.conf**.

optimize_extents

Offer to optimize the extent tree by eliminating unnecessary width or depth. This is the default unless otherwise specified in **/etc/e2fsck.conf**.

inode_count_fullmap

Trade off using memory for speed when checking a file system with a large number of hard-linked files. The amount of memory required is proportional to the number of inodes in the file system. For large file systems, this can be gigabytes of memory. (For example, a 40TB file system with 2.8 billion inodes will consume an additional 5.7 GB memory if this optimization is

enabled.) This optimization can also be enabled in the options section of */etc/e2fsck.conf*.

no_inode_count_fullmap

Disable the **inode_count_fullmap** optimization. This is the default unless otherwise specified in */etc/e2fsck.conf*.

readahead_kb

Use this many KiB of memory to pre-fetch metadata in the hopes of reducing e2fsck runtime. By default, this is set to the size of two block groups' inode tables (typically 4MiB on a regular ext4 file system); if this amount is more than 1/50th of total physical memory, readahead is disabled. Set this to zero to disable readahead entirely.

bmap2extent

Convert block-mapped files to extent-mapped files.

fixes_only

Only fix damaged metadata; do not optimize htree directories or compress extent trees. This option is incompatible with the -D and -E bmap2extent options.

check_encoding

Force verification of encoded filenames in case-insensitive directories. This is the default mode if the file system has the strict flag enabled.

unshare_blocks

If the file system has shared blocks, with the shared blocks read-only feature enabled, then this will unshare all shared blocks and unset the read-only feature bit. If there is not enough free space then the operation will fail. If the file system does not have the read-only feature bit, but has shared blocks anyway, then this option will have no effect. Note when using this option, if there is no free space to clone blocks, there is no prompt to delete files and instead the operation will fail.

Note that **unshare_blocks** implies the "-f" option to ensure that all passes are run. Additionally, if "-n" is also specified, e2fsck will simulate trying to allocate enough space to deduplicate. If this fails, the exit code will be non-zero.

-f Force checking even if the file system seems clean.

-F Flush the file system device's buffer caches before beginning. Only really useful for doing **e2fsck** time trials.

-j *external-journal*

Set the pathname where the external-journal for this file system can be found.

-k When combined with the **-c** option, any existing bad blocks in the bad blocks list are preserved, and any new bad blocks found by running **badblocks(8)** will be added to the existing bad blocks list.

-l *filename*

Add the block numbers listed in the file specified by *filename* to the list of bad blocks. The format of this file is the same as the one generated by the **badblocks(8)** program. Note that the block numbers are based on the blocksize of the file system. Hence, **badblocks(8)** must be given the blocksize of the file system in order to obtain correct results. As a result, it is much simpler and safer to use the **-c** option to **e2fsck**, since it will assure that the correct parameters are passed to the **badblocks** program.

-L *filename*

Set the bad blocks list to be the list of blocks specified by *filename*. (This option is the same as the **-l** option, except the bad blocks list is cleared before the blocks listed in the file are added to

the bad blocks list.)

- n** Open the file system read-only, and assume an answer of ‘no’ to all questions. Allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-p** or **-y** options.
- p** Automatically repair (“preen”) the file system. This option will cause **e2fsck** to automatically fix any file system problems that can be safely fixed without human intervention. If **e2fsck** discovers a problem which may require the system administrator to take additional corrective action, **e2fsck** will print a description of the problem and then exit with the value 4 logically or’ed into the exit code. (See the **EXIT CODE** section.) This option is normally used by the system’s boot scripts. It may not be specified at the same time as the **-n** or **-y** options.
- r** This option does nothing at all; it is provided only for backwards compatibility.
- t** Print timing statistics for **e2fsck**. If this option is used twice, additional timing statistics are printed on a pass by pass basis.
- v** Verbose mode.
- V** Print version information and exit.
- y** Assume an answer of ‘yes’ to all questions; allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-n** or **-p** options.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the **undo_file** argument, the undo file will be written to a file named **e2fsck-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable.

WARNING: The undo file cannot be used to recover from a power or system crash.

EXIT CODE

The exit code returned by **e2fsck** is the sum of the following conditions:

0	– No errors
1	– File system errors corrected
2	– File system errors corrected, system should be rebooted
4	– File system errors left uncorrected
8	– Operational error
16	– Usage or syntax error
32	– E2fsck canceled by user request
128	– Shared library error

SIGNALS

The following signals have the following effect when sent to **e2fsck**.

SIGUSR1

This signal causes **e2fsck** to start displaying a completion bar or emitting progress information. (See discussion of the **-C** option.)

SIGUSR2

This signal causes **e2fsck** to stop displaying a completion bar or emitting progress information.

REPORTING BUGS

Almost any piece of software will have bugs. If you manage to find a file system which causes **e2fsck** to crash, or which **e2fsck** is unable to repair, please report it to the author.

Please include as much information as possible in your bug report. Ideally, include a complete transcript of the **e2fsck** run, so I can see exactly what error messages are displayed. (Make sure the messages printed by **e2fsck** are in English; if your system has been configured so that **e2fsck**’s messages have been translated

into another language, please set the the **LC_ALL** environment variable to **C** so that the transcript of e2fsck's output will be useful to me.) If you have a writable file system where the transcript can be stored, the **script(1)** program is a handy way to save the output of **e2fsck** to a file.

It is also useful to send the output of **dumpe2fs(8)**. If a specific inode or inodes seems to be giving **e2fsck** trouble, try running the **debugfs(8)** command and send the output of the **stat(1u)** command run on the relevant inode(s). If the inode is a directory, the **debugfs** *dump* command will allow you to extract the contents of the directory inode, which can sent to me after being first run through **uuencode(1)**. The most useful data you can send to help reproduce the bug is a compressed raw image dump of the file system, generated using **e2image(8)**. See the **e2image(8)** man page for more details.

Always include the full version string which **e2fsck** displays when it is run, so I know which version you are running.

ENVIRONMENT

E2FSCK_CONFIG

Determines the location of the configuration file (see **e2fsck.conf(5)**).

AUTHOR

This version of **e2fsck** was written by Theodore Ts'o <tytso@mit.edu>.

NAME

e2fsck.conf – Configuration file for e2fsck

DESCRIPTION

e2fsck.conf is the configuration file for **e2fsck(8)**. It controls the default behavior of **e2fsck(8)** while it is checking ext2, ext3, or ext4 file systems.

The *e2fsck.conf* file uses an INI-style format. Stanzas, or top-level sections, are delimited by square braces: []. Within each section, each line defines a relation, which assigns tags to values, or to a subsection, which contains further relations or subsections. An example of the INI-style format used by this configuration file follows below:

```
[section1]
tag1 = value_a
tag1 = value_b
tag2 = value_c

[section 2]
tag3 =
    subtag1 = subtag_value_a
    subtag1 = subtag_value_b
    subtag2 = subtag_value_c
}
tag1 = value_d
tag2 = value_e
}
```

Comments are delimited by a semicolon (';') or a hash ('#') character at the beginning of the comment, and are terminated by the end of line character.

Tags and values must be quoted using double quotes if they contain spaces. Within a quoted string, the standard backslash interpretations apply: "\n" (for the newline character), "\t" (for the tab character), "\b" (for the backspace character), and "\\\" (for the backslash character).

The following stanzas are used in the *e2fsck.conf* file. They will be described in more detail in future sections of this document.

[options]

This stanza contains general configuration parameters for **e2fsck**'s behavior.

[defaults]

Contains relations which define the default parameters used by **e2fsck(8)**. In general, these defaults may be overridden by command-line options provided by the user.

[problems]

This stanza allows the administrator to reconfigure how e2fsck handles various file system inconsistencies.

[scratch_files]

This stanza controls when e2fsck will attempt to use scratch files to reduce the need for memory.

THE [options] STANZA

The following relations are defined in the *[options]* stanza.

allow_cancellation

If this relation is set to a boolean value of true, then if the user interrupts e2fsck using ^C, and the file system is not explicitly flagged as containing errors, e2fsck will exit with an exit status of 0 instead of 32. This setting defaults to false.

accept_time_fudge

Unfortunately, due to Windows' unfortunate design decision to configure the hardware clock to tick localtime, instead of the more proper and less error-prone UTC time, many users end up in the situation where the system clock is incorrectly set at the time when e2fsck is run.

Historically this was usually due to some distributions having buggy init scripts and/or installers that didn't correctly detect this case and take appropriate countermeasures. Unfortunately, this is occasionally true even today, usually due to a buggy or misconfigured virtualization manager or the installer not having access to a network time server during the installation process. So by default, we allow the superblock times to be fudged by up to 24 hours. This can be disabled by setting *accept_time_fudge* to the boolean value of false. This setting defaults to true.

broken_system_clock

The **e2fsck**(8) program has some heuristics that assume that the system clock is correct. In addition, many system programs make similar assumptions. For example, the UUID library depends on time not going backwards in order for it to be able to make its guarantees about issuing universally unique ID's. Systems with broken system clocks, are well, broken. However, broken system clocks, particularly in embedded systems, do exist. E2fsck will attempt to use heuristics to determine if the time can not be trusted; and to skip time-based checks if this is true. If this boolean is set to true, then e2fsck will always assume that the system clock can not be trusted.

buggy_init_scripts

This boolean relation is an alias for *accept_time_fudge* for backwards compatibility; it used to be that the behavior defined by *accept_time_fudge* above defaulted to false, and *buggy_init_scripts* would enable superblock time field to be wrong by up to 24 hours. When we changed the default, we also renamed this boolean relation to *accept_time_fudge*.

clear_test_fs_flag

This boolean relation controls whether or not **e2fsck**(8) will offer to clear the test_fs flag if the ext4 file system is available on the system. It defaults to true.

defer_check_on_battery

This boolean relation controls whether or not the interval between file system checks (either based on time or number of mounts) should be doubled if the system is running on battery. This setting defaults to true.

indexed_dir_slack_percentage

When **e2fsck**(8) repacks a indexed directory, reserve the specified percentage of empty space in each leaf nodes so that a few new entries can be added to the directory without splitting leaf nodes, so that the average fill ratio of directories can be maintained at a higher, more efficient level. This relation defaults to 20 percent.

inode_count_fullmap

If this boolean relation is true, trade off using memory for speed when checking a file system with a large number of hard-linked files. The amount of memory required is proportional to the number of inodes in the file system. For large file systems, this can be gigabytes of memory. (For example a 40TB file system with 2.8 billion inodes will consume an additional 5.7 GB memory if this optimization is enabled.) This setting defaults to false.

log_dir If the *log_filename* or *problem_log_filename* relations contains a relative pathname, then the log file will be placed in the directory named by the *log_dir* relation.

log_dir_fallback

This relation contains an alternate directory that will be used if the directory specified by *log_dir* is not available or is not writable.

log_dir_wait

If this boolean relation is true, them if the directories specified by *log_dir* or *log_dir_fallback* are not available or are not yet writable, e2fsck will save the output in a memory buffer, and a child process will periodically test to see if the log directory has become available after the boot sequence has mounted the requested file system for reading/writing. This implements the functionality provided by **logsave**(8) for e2fsck log files.

log_filename

This relation specifies the file name where a copy of e2fsck's output will be written. If certain problem reports are suppressed using the *max_count_problems* relation, (or on a per-problem basis using the *max_count* relation), the full set of problem reports will be written to the log file. The filename may contain various percent-expressions (%D, %T, %N, etc.) which will be expanded so that the file name for the log file can include things like date, time, device name, and other runtime parameters. See the **LOGGING** section for more details.

max_count_problems

This relation specifies the maximum number of problem reports of a particular type will be printed to stdout before further problem reports of that type are squelched. This can be useful if the console is slow (i.e., connected to a serial port) and so a large amount of output could end up delaying the boot process for a long time (potentially hours).

no_optimize_extents

If this boolean relation is true, do not offer to optimize the extent tree by reducing the tree's width or depth. This setting defaults to false.

problem_log_filename

This relation specifies the file name where a log of problem codes found by e2fsck be written. The filename may contain various percent-expressions (%D, %T, %N, etc.) which will be expanded so that the file name for the log file can include things like date, time, device name, and other runtime parameters. See the **LOGGING** section for more details.

readahead_mem_pct

Use this percentage of memory to try to read in metadata blocks ahead of the main e2fsck thread. This should reduce run times, depending on the speed of the underlying storage and the amount of free memory. There is no default, but see **readahead_kb** for more details.

readahead_kb

Use this amount of memory to read in metadata blocks ahead of the main checking thread. Setting this value to zero disables readahead entirely. By default, this is set the size of two block groups' inode tables (typically 4MiB on a regular ext4 file system); if this amount is more than 1/50th of total physical memory, readahead is disabled.

report_features

If this boolean relation is true, e2fsck will print the file system features as part of its verbose reporting (i.e., if the **-v** option is specified)

report_time

If this boolean relation is true, e2fsck will run as if the options **-tt** are always specified. This will cause e2fsck to print timing statistics on a pass by pass basis for full file system checks.

report_verbose

If this boolean relation is true, e2fsck will run as if the option **-v** is always specified. This will cause e2fsck to print some additional information at the end of each full file system check.

THE [defaults] STANZA

The following relations are defined in the *[defaults]* stanza.

undo_dir

This relation specifies the directory where the undo file should be stored. It can be overridden via the **E2FSPROGS_UNDO_DIR** environment variable. If the directory location is set to the value *none*, **e2fsck** will not create an undo file.

THE [problems] STANZA

Each tag in the *[problems]* stanza names a problem code specified with a leading "0x" followed by six hex digits. The value of the tag is a subsection where the relations in that subsection override the default treatment of that particular problem code.

Note that inappropriate settings in this stanza may cause **e2fsck** to behave incorrectly, or even crash. Most system administrators should not be making changes to this section without referring to source code.

Within each problem code's subsection, the following tags may be used:

description

This relation allows the message which is printed when this file system inconsistency is detected to be overridden.

preen_ok

This boolean relation overrides the default behavior controlling whether this file system problem should be automatically fixed when **e2fsck** is running in preen mode.

max_count

This integer relation overrides the *max_count_problems* parameter (set in the options section) for this particular problem.

no_ok This boolean relation overrides the default behavior determining whether or not the file system will be marked as inconsistent if the user declines to fix the reported problem.

no_default

This boolean relation overrides whether the default answer for this problem (or question) should be "no".

preen_nomessage

This boolean relation overrides the default behavior controlling whether or not the description for this file system problem should be suppressed when **e2fsck** is running in preen mode.

no_nomsg

This boolean relation overrides the default behavior controlling whether or not the description for this file system problem should be suppressed when a problem forced not to be fixed, either because **e2fsck** is run with the **-n** option or because the *force_no* flag has been set for the problem.

force_no

This boolean option, if set to true, forces a problem to never be fixed. That is, it will be as if the user problem responds 'no' to the question of 'should this problem be fixed?'. The *force_no* option even overrides the **-y** option given on the command-line (just for the specific problem, of course).

not_a_fix

This boolean option, if set to true, marks the problem as one where if the user gives permission to make the requested change, it does not mean that the file system had a problem which has since been fixed. This is used for requests to optimize the file system's data structure, such as pruning an extent tree.

THE [scratch_files] STANZA

The following relations are defined in the *[scratch_files]* stanza.

directory

If the directory named by this relation exists and is writeable, then e2fsck will attempt to use this directory to store scratch files instead of using in-memory data structures.

numdirs_threshold

If this relation is set, then in-memory data structures will be used if the number of directories in the file system are fewer than amount specified.

dirinfo This relation controls whether or not the scratch file directory is used instead of an in-memory data structure for directory information. It defaults to true.

icount This relation controls whether or not the scratch file directory is used instead of an in-memory data structure when tracking inode counts. It defaults to true.

LOGGING

E2fsck has the facility to save the information from an e2fsck run in a directory so that a system administrator can review its output at their leisure. This allows information captured during the automatic e2fsck preen run, as well as a manually started e2fsck run, to be saved for posterity. This facility is controlled by

the *log_filename*, *log_dir*, *log_dir_fallback*, and *log_dir_wait* relations in the *[options]* stanza.

The filename in *log_filename* may contain the following percent-expressions that will be expanded as follows.

%d	The current day of the month
%D	The current date; this is equivalent of %Y%m%d
%h	The hostname of the system.
%H	The current hour in 24-hour format (00..23)
%m	The current month as a two-digit number (01..12)
%M	The current minute (00..59)
%N	The name of the block device containing the file system, with any directory pathname stripped off.
%p	The pid of the e2fsck process
%s	The current time expressed as the number of seconds since 1970-01-01 00:00:00 UTC
%S	The current second (00..59)
%T	The current time; this is equivalent of %H%M%S
%u	The name of the user running e2fsck.
%U	This percent expression does not expand to anything, but it signals that any following date or time expressions should be expressed in UTC time instead of the local timezone.
%y	The last two digits of the current year (00..99)
%Y	The current year (i.e., 2012).

EXAMPLES

The following recipe will prevent e2fsck from aborting during the boot process when a file system contains orphaned files. (Of course, this is not always a good idea, since critical files that are needed for the security of the system could potentially end up in lost+found, and starting the system without first having a system administrator check things out may be dangerous.)

```
[problems]
0x040002 = {
    preen_ok = true
    description = "@u @i %i. "
}
```

The following recipe will cause an e2fsck logfile to be written to the directory /var/log/e2fsck, with a filename that contains the device name, the hostname of the system, the date, and time: e.g., "e2fsck-sda3.server.INFO.20120314-112142". If the directory containing /var/log is located on the root file system which is initially mounted read-only, then the output will be saved in memory and written out once the root file system has been remounted read/write. To avoid too much detail from being written to the serial console (which could potentially slow down the boot sequence), only print no more than 16 instances of each type of file system corruption.

```
[options]
max_count_problems = 16
log_dir = /var/log/e2fsck
log_filename = e2fsck-%N.%h.INFO.%D-%T
log_dir_wait = true
```

FILES

/etc/e2fsck.conf

The configuration file for **e2fsck(8)**.

SEE ALSO**e2fsck(8)**

emacs(1) - Linux man page

Name

emacs - GNU project Emacs

Synopsis

emacs [*command-line switches*] [*files ...*]

Description

GNU Emacs is a version of *Emacs*, written by the author of the original (PDP-10) *Emacs*, Richard Stallman.

The primary documentation of *GNU Emacs* is in the *GNU Emacs Manual*, which you can read using Info, either from *Emacs* or as a standalone program. Please look there for complete and up-to-date documentation. This man page is updated only when someone volunteers to do so; the *Emacs* maintainers' priority goal is to minimize the amount of time this man page takes away from other more useful projects.

The user functionality of *GNU Emacs* encompasses everything other *Emacs* editors do, and it is easily extensible since its editing commands are written in Lisp.

Emacs has an extensive interactive help facility, but the facility assumes that you know how to manipulate *Emacs* windows and buffers. CTRL-h or F1 enters the Help facility. Help Tutorial (CTRL-h t) starts an interactive tutorial which can teach beginners the fundamentals of *Emacs* in a few minutes. Help Apropos (CTRL-h a) helps you find a command given its functionality, Help Character (CTRL-h c) describes a given character's effect, and Help Function (CTRL-h f) describes a given Lisp function specified by name.

Emacs's Undo can undo several steps of modification to your buffers, so it is easy to recover from editing mistakes.

GNU Emacs's many special packages handle mail reading (RMail) and sending (Mail), outline editing (Outline), compiling (Compile), running subshells within *Emacs* windows (Shell), running a Lisp read-eval-print loop (Lisp-Interaction-Mode), automated psychotherapy (Doctor), and much more.

There is an extensive reference manual, but users of other *Emacs*es should have little trouble adapting even without a copy. Users new to *Emacs* will be able to use basic features fairly rapidly by studying the tutorial and using the self-documentation features.

Emacs Options

The following options are of general interest:

file

Edit *file*.

--file*file*, **--find-file** *file*, **--visit** *file*

The same as specifying *file* directly as an argument.

+*number*

Go to the line specified by *number* (do not insert a space between the "+" sign and the number). This applies only to the next file specified.

+*line:column*

Go to the specified *line* and *column*.

-q, **--no-init-file**

Do not load an init file.

--no-site-file

Do not load the site-wide startup file.

--no-desktop

Do not load a saved desktop.

-nI, **--no-shared-memory**

Do not use shared memory.

-Q, **--quick**

Equivalent to "-q --no-site-file --no-splash".

--no-splash

Do not display a splash screen during start-up.

--debug-init

Enable *Emacs* Lisp debugger during the processing of the user init file *~/.emacs*. This is useful for debugging problems in the init file.

-u *user*, **--user** *user*

Load *user*'s init file.

-t *file*, **--terminal** *file*

Use specified *file* as the terminal instead of using stdin/stdout. This must be the first argument specified in the command line.

--multibyte, **--no-unibyte**

Enable multibyte mode (enabled by default).

--unibyte, **--no-multibyte**

Enable unibyte mode.

--version

Display *Emacs* version information and exit.

--help

Display this help and exit.

The following options are lisp-oriented (these options are processed in the order encountered):

-f *function*, **--funcall***function*

Execute the lisp function *function*.

-l *file*, **--load** *file*

Load the lisp code in the file *file*.

--eval expr, --execute expr

Evaluate the Lisp expression *expr*.

The following options are useful when running *Emacs* as a batch editor:

--batch

Edit in batch mode. The editor will send messages to stderr. This option must be the first in the argument list. You must use -l and -f options to specify files to execute and functions to call.

--script file

Run *file* as an Emacs Lisp script.

--insert file

Insert contents of *file* into the current buffer.

--kill

Exit *Emacs* while in batch mode.

-L dir, --directory dir

Add *dir* to the list of directories *Emacs* searches for Lisp files.

Using Emacs with X

Emacs has been tailored to work well with the X window system. If you run *Emacs* from under X windows, it will create its own X window to display in. You will probably want to start the editor as a background process so that you can continue using your original window.

Emacs can be started with the following X switches:

--name name

Specify the name which should be assigned to the initial *Emacs* window.

This controls looking up X resources as well as the window title.

-T name, --title name

Specify the title for the initial X window.

-r, -rv, --reverse-video

Display the *Emacs* window in reverse video.

-fn font, --font font

Set the *Emacs* window's font to that specified by *font*. You will find the various X fonts in the */usr/lib/X11/fonts* directory. Note that *Emacs* will only accept fixed width fonts. Under the X11 Release 4 font-naming conventions, any font with the value "m" or "c" in the eleventh field of the font name is a fixed width font. Furthermore, fonts whose names are of the form *widthxheight* are generally fixed width, as is the font *fixed*. See [xlsfonts\(1\)](#) for more information.

When you specify a font, be sure to put a space between the switch and the font name.

--xrm *resources*

Set additional X resources.

--color, --color=mode

Override color mode for character terminals; *mode* defaults to 'auto', and can also be 'never', 'auto', 'always', or a mode name like 'ansi8'.

-bw *pixels*, **--border-width** *pixels*

Set the *Emacs* window's border width to the number of pixels specified by *pixels*. Defaults to one pixel on each side of the window.

-ib *pixels*, **--internal-border** *pixels*

Set the window's internal border width to the number of pixels specified by *pixels*. Defaults to one pixel of padding on each side of the window.

-g *geometry*, **--geometry** *geometry*

Set the *Emacs* window's width, height, and position as specified. The geometry specification is in the standard X format; see [X\(7\)](#) for more information. The width and height are specified in characters; the default is 80 by 24. See the *Emacs* manual, section "Options for Window Size and Position", for information on how window sizes interact with selecting or deselecting the tool bar and menu bar.

-lsp *pixels*, **--line-spacing** *pixels*

Additional space to put between lines.

-vb, --vertical-scroll-bars

Enable vertical scrollbars.

-fh, --fullheight

Make the first frame as high as the screen.

-fs, --fullscreen

Make the first frame fullscreen.

-fw, --fullwidth

Make the first frame as wide as the screen.

-fg *color*, **--foreground-color** *color*

On color displays, set the color of the text.

Use the command *M-x list-colors-display* for a list of valid color names.

-bg *color*, **--background-color** *color*

On color displays, set the color of the window's background.

-bd *color*, **--border-color** *color*

On color displays, set the color of the window's border.

-cr *color*, **--cursor-color** *color*

On color displays, set the color of the window's text cursor.

-ms *color*, **--mouse-color** *color*

On color displays, set the color of the window's mouse cursor.

-d *displayname*, **--display** *displayname*

Create the *Emacs* window on the display specified by *displayname*. Must be the first option specified in the command line.

-nbi, --no-bitmap-icon

Do not use picture of gnu for Emacs icon.

--iconic

Start *Emacs* in iconified state.

-nbc, --no-blinking-cursor

Disable blinking cursor.

-nw, --no-window-system

Tell *Emacs* not to use its special interface to X. If you use this switch when invoking *Emacs* from an [*xterm*\(1\)](#) window, display is done in that window.

-D, --basic-display

This option disables many display features; use it for debugging *Emacs*.

You can set X default values for your *Emacs* windows in your *.Xresources* file (see [*xrdb*\(1\)](#)). Use the following format:

emacs.keyword:value

where *value* specifies the default value of *keyword*. *Emacs* lets you set default values for the following keywords:

background (class Background)

For color displays, sets the window's background color.

bitmapIcon (class BitmapIcon)

If **bitmapIcon**'s value is set to *on*, the window will iconify into the "kitchen sink."

borderColor (class BorderColor)

For color displays, sets the color of the window's border.

borderWidth (class BorderWidth)

Sets the window's border width in pixels.

cursorColor (class Foreground)

For color displays, sets the color of the window's text cursor.

cursorBlink (class CursorBlink)

Specifies whether to make the cursor blink. The default is *on*. Use *off* or *false* to turn cursor blinking off.

font (class Font)

Sets the window's text font.

foreground (class Foreground)

For color displays, sets the window's text color.

fullscreen (class Fullscreen)

The desired fullscreen size. The value can be one of *fullboth*, *fullwidth*, or *fullheight*, which correspond to the command-line options '*-fs*', '*-fw*', and '*-fh*', respectively. Note that this applies to the initial frame only.

geometry (class Geometry)

Sets the geometry of the *Emacs* window (as described above).

iconName (class **Title**)

Sets the icon name for the *Emacs* window icon.

internalBorder (class **BorderWidth**)

Sets the window's internal border width in pixels.

lineSpacing (class **LineSpacing**)

Additional space ("leading") between lines, in pixels.

menuBar (class **MenuBar**)

Gives frames menu bars if *on*; don't have menu bars if *off*. See the Emacs manual, sections "Lucid Resources" and "LessTif Resources", for how to control the appearance of the menu bar if you have one.

minibuffer (class **Minibuffer**)

If *none*, don't make a minibuffer in this frame. It will use a separate minibuffer frame instead.

paneFont (class **Font**)

Font name for menu pane titles, in non-toolkit versions of *Emacs*.

pointerColor (class **Foreground**)

For color displays, sets the color of the window's mouse cursor.

privateColormap (class **PrivateColormap**)

If *on*, use a private color map, in the case where the "default visual" of class **PseudoColor** and **Emacs** is using it.

reverseVideo (class **ReverseVideo**)

If **reverseVideo**'s value is set to *on*, the window will be displayed in reverse video.

screenGamma (class **ScreenGamma**)

Gamma correction for colors, equivalent to the frame parameter 'screen-gamma'.

scrollBarWidth (class **ScrollBarWidth**)

The scroll bar width in pixels, equivalent to the frame parameter 'scroll-bar-width'.

selectionFont (class **SelectionFont**)

Font name for pop-up menu items, in non-toolkit versions of *Emacs*. (For toolkit versions, see the Emacs manual, sections "Lucid Resources" and "LessTif Resources".)

selectionTimeout (class **SelectionTimeout**)

Number of milliseconds to wait for a selection reply. A value of 0 means wait as long as necessary.

synchronous (class **Synchronous**)

Run Emacs in synchronous mode if *on*. Synchronous mode is useful for debugging X problems.

title (class **Title**)

Sets the title of the *Emacs* window.

toolBar (class **ToolBar**)

Number of lines to reserve for the tool bar.

useXIM (class **UseXIM**)

Turns off use of X input methods (XIM) if *false* or *off*.

verticalScrollBars (class **ScrollBars**)

Gives frames scroll bars if *on*; suppresses scroll bars if *off*.

visualClass (class **VisualClass**)

Specify the "visual" that X should use. This tells X how to handle colors. The value should start with one of *TrueColor*, *PseudoColor*, *DirectColor*, *StaticColor*, *GrayScale*, and *StaticGray*, followed by *-depth*, where *depth* is the number of color planes.

If you try to set color values while using a black and white display, the window's characteristics will default as follows: the foreground color will be set to black, the background color will be set to white, the border color will be set to grey, and the text and mouse cursors will be set to black.

Using the Mouse

The following lists some of the mouse button bindings for the *Emacs* window under X11.

MOUSE BUTTON	FUNCTION
left	Set point.
middle	Paste text.
right	Cut text into X cut buffer.
SHIFT- middle	Cut text into X cut buffer.
SHIFT-right	Paste text.
CTRL-middle	Cut text into X cut buffer and kill it.
CTRL-right	Select this window, then split it into two windows. Same as typing CTRL-x 2.
CTRL- SHIFT-left	X buffer menu -- hold the buttons and keys down, wait for menu to appear, select buffer, and release. Move mouse out of menu and release to cancel.
CTRL- SHIFT- middle	X help menu -- pop up index card menu for Emacs help.
CTRL- SHIFT-right	Select window with mouse, and delete all other windows. Same as typing CTRL-x 1.

Manuals

You can order printed copies of the GNU Emacs Manual from the Free Software Foundation, which develops GNU software. See the file ORDERS for ordering information.

Your local Emacs maintainer might also have copies available. As with all software and publications from FSF, everyone is permitted to make and distribute copies of the Emacs manual. The TeX source to the manual is also included in the Emacs source distribution.

Files

/usr/local/share/info -- files for the Info documentation browser. The complete text of the Emacs reference manual is included in a convenient tree structured form. Also includes the Emacs Lisp Reference Manual, useful to anyone wishing to write programs in the Emacs Lisp extension language.

/usr/local/share/emacs/\$VERSION/lisp -- Lisp source files and compiled files that define most editing commands. Some are preloaded; others are autoloaded from this directory when used.

/usr/local/libexec/emacs/\$VERSION/\$ARCH -- various programs that are used with GNU Emacs.

/usr/local/share/emacs/\$VERSION/etc -- various files of information.

/usr/local/share/emacs/\$VERSION/etc/DOC.* -- contains the documentation strings for the Lisp primitives and preloaded Lisp functions of GNU Emacs. They are stored here to reduce the size of Emacs proper.

/usr/local/share/emacs/\$VERSION/etc/SERVICE lists people offering various services to assist users of GNU Emacs, including education, troubleshooting, porting and customization.

Bugs

There is a mailing list, bug-gnu-emacs@gnu.org, for reporting Emacs bugs and fixes. But before reporting something as a bug, please try to be sure that it really is a bug, not a misunderstanding or a deliberate feature. We ask you to read the section "Reporting Emacs Bugs" near the end of the reference manual (or Info system) for hints on how and when to report bugs. Also, include the version number of the Emacs you are running in every bug report that you send in. Bugs tend actually to be fixed if they can be isolated, so it is in your interest to report them in such a way that they can be easily reproduced.

Do not expect a personal answer to a bug report. The purpose of reporting bugs is to get them fixed for everyone in the next release, if possible. For personal assistance, look in the SERVICE file (see above) for a list of people who offer it.

Please do not send anything but bug reports to this mailing list. For more information about Emacs mailing lists, see the file

/usr/local/share/emacs/\$VERSION/etc/MAILINGLISTS.

Unrestrictions

Emacs is free; anyone may redistribute copies of *Emacs* to anyone under the terms stated in the *Emacs* General Public License, a copy of which accompanies each copy of *Emacs* and which also appears in the reference manual.

Copies of *Emacs* may sometimes be received packaged with distributions of Unix systems, but it is never included in the scope of any license covering those systems. Such inclusion violates the terms on which distribution is permitted. In fact, the primary purpose of the General Public License is to prohibit anyone from attaching any other restrictions to redistribution of *Emacs*.

Richard Stallman encourages you to improve and extend *Emacs*, and urges that you contribute your extensions to the GNU library. Eventually GNU (Gnu's Not Unix) will be a complete replacement for Unix. Everyone will be free to use, copy, study and change the GNU system.

NAME

env – run a program in a modified environment

SYNOPSIS

env [*OPTION*]... [-] [*NAME=VALUE*]... [*COMMAND* [*ARG*]...]

DESCRIPTION

Set each NAME to VALUE in the environment and run COMMAND.

Mandatory arguments to long options are mandatory for short options too.

-i, --ignore-environment

start with an empty environment

-0, --null

end each output line with NUL, not newline

-u, --unset=NAME

remove variable from the environment

-C, --chdir=DIR

change working directory to DIR

-S, --split-string=S

process and split S into separate arguments; used to pass multiple arguments on shebang lines

--block-signal[=SIG]

block delivery of SIG signal(s) to COMMAND

--default-signal[=SIG]

reset handling of SIG signal(s) to the default

--ignore-signal[=SIG]

set handling of SIG signals(s) to do nothing

--list-signal-handling

list non default signal handling to stderr

-v, --debug

print verbose information for each processing step

--help

display this help and exit

--version

output version information and exit

A mere – implies **-i**. If no COMMAND, print the resulting environment.

SIG may be a signal name like 'PIPE', or a signal number like '13'. Without SIG, all known signals are included. Multiple signals can be comma-separated.

OPTIONS**-S/--split-string usage in scripts**

The **-S** option allows specifying multiple parameters in a script. Running a script named **1.pl** containing the following first line:

```
#!/usr/bin/env -S perl -w -T
```

```
...
```

Will execute **perl -w -T 1.pl**.

Without the '**-S**' parameter the script will likely fail with:

```
/usr/bin/env: 'perl -w -T': No such file or directory
```

See the full documentation for more details.

--default-signal[=SIG] usage

This option allows setting a signal handler to its default action, which is not possible using the traditional shell trap command. The following example ensures that seq will be terminated by SIGPIPE no matter how this signal is being handled in the process invoking the command.

```
sh -c 'env --default-signal=PIPE seq inf | head -n1'
```

NOTES

POSIX's exec(2) pages says:

"many existing applications wrongly assume that they start with certain signals set to the default action and/or unblocked.... Therefore, it is best not to block or ignore signals across execs without explicit reason to do so, and especially not to block signals across execs of arbitrary (not closely cooperating) programs."

NAME

environ – user environment

SYNOPSIS

```
extern char **environ;
```

DESCRIPTION

The variable *environ* points to an array of pointers to strings called the "environment". The last pointer in this array has the value NULL. This array of strings is made available to the process by the **execve(2)** call when a new program is started. When a child process is created via **fork(2)**, it inherits a *copy* of its parent's environment.

By convention, the strings in *environ* have the form "*name=value*". The name is case-sensitive and may not contain the character "="". The value can be anything that can be represented as a string. The name and the value may not contain an embedded null byte ('\0'), since this is assumed to terminate the string.

Environment variables may be placed in the shell's environment by the *export* command in **sh(1)**, or by the *setenv* command if you use **csh(1)**.

The initial environment of the shell is populated in various ways, such as definitions from */etc/environment* that are processed by **pam_env(8)** for all users at login time (on systems that employ **pam(8)**). In addition, various shell initialization scripts, such as the system-wide */etc/profile* script and per-user initializations script may include commands that add variables to the shell's environment; see the manual page of your preferred shell for details.

Bourne-style shells support the syntax

```
NAME=value command
```

to create an environment variable definition only in the scope of the process that executes *command*. Multiple variable definitions, separated by white space, may precede *command*.

Arguments may also be placed in the environment at the point of an **exec(3)**. A C program can manipulate its environment using the functions **getenv(3)**, **putenv(3)**, **setenv(3)**, and **unsetenv(3)**.

What follows is a list of environment variables typically seen on a system. This list is incomplete and includes only common variables seen by average users in their day-to-day routine. Environment variables specific to a particular program or library function are documented in the ENVIRONMENT section of the appropriate manual page.

USER The name of the logged-in user (used by some BSD-derived programs). Set at login time, see section NOTES below.

LOGNAME

The name of the logged-in user (used by some System-V derived programs). Set at login time, see section NOTES below.

HOME

A user's login directory. Set at login time, see section NOTES below.

LANG The name of a locale to use for locale categories when not overridden by **LC_ALL** or more specific environment variables such as **LC_COLLATE**, **LC_CTYPE**, **LC_MESSAGES**, **LC_MONETARY**, **LC_NUMERIC**, and **LC_TIME** (see **locale(7)** for further details of the **LC_*** environment variables).

PATH The sequence of directory prefixes that **sh(1)** and many other programs employ when searching for an executable file that is specified as a simple filename (i.a., a pathname that contains no slashes). The prefixes are separated by colons (:). The list of prefixes is searched from beginning to end, by checking the pathname formed by concatenating a prefix, a slash, and the filename, until a file with execute permission is found.

As a legacy feature, a zero-length prefix (specified as two adjacent colons, or an initial or terminating colon) is interpreted to mean the current working directory. However, use of this feature is deprecated, and POSIX notes that a conforming application shall use an explicit pathname (e.g., .)

to specify the current working directory.

Analogously to **PATH**, one has **CDPATH** used by some shells to find the target of a change directory command, **MANPATH** used by **man(1)** to find manual pages, and so on.

PWD Absolute path to the current working directory; required to be partially canonical (no . or .. components).

SHELL

The absolute pathname of the user's login shell. Set at login time, see section NOTES below.

TERM The terminal type for which output is to be prepared.

PAGER

The user's preferred utility to display text files. Any string acceptable as a command_string operand to the *sh -c* command shall be valid. If **PAGER** is null or is not set, then applications that launch a pager will default to a program such as **less(1)** or **more(1)**.

EDITOR/VISUAL

The user's preferred utility to edit text files. Any string acceptable as a command_string operand to the *sh -c* command shall be valid.

Note that the behavior of many programs and library routines is influenced by the presence or value of certain environment variables. Examples include the following:

- The variables **LANG**, **LANGUAGE**, **NLSPATH**, **LOCPATH**, **LC_ALL**, **LC_MESSAGES**, and so on influence locale handling; see **catopen(3)**, **gettext(3)**, and **locale(7)**.
- **TMPDIR** influences the path prefix of names created by **tempnam(3)** and other routines, and the temporary directory used by **sort(1)** and other programs.
- **LD_LIBRARY_PATH**, **LD_PRELOAD**, and other **LD_*** variables influence the behavior of the dynamic loader/linker. See **alsold.so(8)**.
- **POSIXLY_CORRECT** makes certain programs and library routines follow the prescriptions of POSIX.
- The behavior of **malloc(3)** is influenced by **MALLOC_*** variables.
- The variable **HOSTALIASES** gives the name of a file containing aliases to be used with **gethostbyname(3)**.
- **TZ** and **TZDIR** give timezone information used by **tzset(3)** and through that by functions like **ctime(3)**, **localtime(3)**, **mktime(3)**, **strftime(3)**. See also **tzselect(8)**.
- **TERMCAP** gives information on how to address a given terminal (or gives the name of a file containing such information).
- **COLUMNS** and **LINES** tell applications about the window size, possibly overriding the actual size.
- **PRINTER** or **LPDEST** may specify the desired printer to use. See **lpr(1)**.

NOTES

Historically and by standard, *environ* must be declared in the user program. However, as a (nonstandard) programmer convenience, *environ* is declared in the header file <*unistd.h*> if the **_GNU_SOURCE** feature test macro is defined (see **feature_test_macros(7)**).

The **prctl(2)** **PR_SET_MM_ENV_START** and **PR_SET_MM_ENV_END** operations can be used to control the location of the process's environment.

The **HOME**, **LOGNAME**, **SHELL**, and **USER** variables are set when the user is changed via a session management interface, typically by a program such as **login(1)** from a user database (such as **passwd(5)**). (Switching to the root user using **su(1)** may result in a mixed environment where **LOGNAME** and **USER** are retained from old user; see the **su(1)** manual page.)

BUGS

Clearly there is a security risk here. Many a system command has been tricked into mischief by a user who specified unusual values for **IFS** or **LD_LIBRARY_PATH**.

There is also the risk of name space pollution. Programs like *make* and *autoconf* allow overriding of default utility names from the environment with similarly named variables in all caps. Thus one uses **CC** to select the desired C compiler (and similarly **MAKE**, **AR**, **AS**, **FC**, **LD**, **LEX**, **RM**, **YACC**, etc.). However, in some traditional uses such an environment variable gives options for the program instead of a pathname. Thus, one has **MORE** and **LESS**. Such usage is considered mistaken, and to be avoided in new programs.

NAME

environment.d – Definition of user service environment

SYNOPSIS

```
~/.config/environment.d/*.conf
/etc/environment.d/*.conf
/run/environment.d/*.conf
/usr/lib/environment.d/*.conf
/etc/environment
```

DESCRIPTION

Configuration files in the environment.d/ directories contain lists of environment variable assignments for services started by the systemd user instance. **systemd-environment-d-generator(8)** parses them and updates the environment exported by the systemd user instance. See below for an discussion of which processes inherit those variables.

It is recommended to use numerical prefixes for file names to simplify ordering.

For backwards compatibility, a symlink to /etc/environment is installed, so this file is also parsed.

CONFIGURATION DIRECTORIES AND PRECEDENCE

Configuration files are read from directories in /etc/, /run/, /usr/local/lib/, and /lib/, in order of precedence, as listed in the SYNOPSIS section above. Files must have the ".conf" extension. Files in /etc/ override files with the same name in /run/, /usr/local/lib/, and /lib/. Files in /run/ override files with the same name under /usr/.

All configuration files are sorted by their filename in lexicographic order, regardless of which of the directories they reside in. If multiple files specify the same option, the entry in the file with the lexicographically latest name will take precedence. Thus, the configuration in a certain file may either be replaced completely (by placing a file with the same name in a directory with higher priority), or individual settings might be changed (by specifying additional settings in a file with a different name that is ordered later).

Packages should install their configuration files in /usr/lib/ (distribution packages) or /usr/local/lib/ (local installs). Files in /etc/ are reserved for the local administrator, who may use this logic to override the configuration files installed by vendor packages. It is recommended to prefix all filenames with a two-digit number and a dash, to simplify the ordering of the files.

If the administrator wants to disable a configuration file supplied by the vendor, the recommended way is to place a symlink to /dev/null in the configuration directory in /etc/, with the same filename as the vendor configuration file. If the vendor configuration file is included in the initrd image, the image has to be regenerated.

CONFIGURATION FORMAT

The configuration files contain a list of "KEY=VALUE" environment variable assignments, separated by newlines. The right hand side of these assignments may reference previously defined environment variables, using the "\${OTHER_KEY}" and "\$OTHER_KEY" format. It is also possible to use "\${FOO:-DEFAULT_VALUE}" to expand in the same way as "\${FOO}" unless the expansion would be empty, in which case it expands to DEFAULT_VALUE, and use "\${FOO:+ALTERNATE_VALUE}" to expand to ALTERNATE_VALUE as long as "\${FOO}" would have expanded to a non-empty value. No other elements of shell syntax are supported.

Each KEY must be a valid variable name. Empty lines and lines beginning with the comment character "#" are ignored.

Example**Example 1. Setup environment to allow access to a program installed in /opt/foo**

/etc/environment.d/60-foo.conf:

```
FOO_DEBUG=force-software-gl,log-verbose
PATH=/opt/foo/bin:$PATH
LD_LIBRARY_PATH=/opt/foo/lib${LD_LIBRARY_PATH:+:$LD_LIBRARY_PATH}
XDG_DATA_DIRS=/opt/foo/share:${XDG_DATA_DIRS:-/usr/local/share:/usr/share/}
```

APPLICABILITY

Environment variables exported by the user manager (**systemd --user** instance started in the `user@uid.service` system service) apply to any services started by that manager. In particular, this may include services which run user shells. For example in the GNOME environment, the graphical terminal emulator runs as the `gnome-terminal-server.service` user unit, which in turn runs the user shell, so that shell will inherit environment variables exported by the user manager. For other instances of the shell, not launched by the user manager, the environment they inherit is defined by the program that starts them. Hint: in general, **systemd.service(5)** units contain programs launched by systemd, and **systemd.scope(5)** units contain programs launched by something else.

Specifically, for ssh logins, the **sshd(8)** service builds an environment that is a combination of variables forwarded from the remote system and defined by **sshd**, see the discussion in **ssh(1)**. A graphical display session will have an analogous mechanism to define the environment. Note that some managers query the systemd user instance for the exported environment and inject this configuration into programs they start, using **systemctl show-environment** or the underlying D-Bus call.

```

DESCRIPTION

ethtool is used to query and control network device driver and hardware settings, particularly for wired Ethernet devices.

devname is the name of the network device on which ethtool should operate.

OPTIONS

ethtool with a single argument specifying the device name prints current settings of the specified device.

-h --help

Shows a short help message.

--version

Shows the ethtool version number.

--debug *N*

Turns on debugging messages. Argument is interpreted as a mask:

0x01 Parser information

--json Output results in JavaScript Object Notation (JSON). Only a subset of options support this. Those which do not will continue to output plain text in the presence of this option.

-I --include-statistics

Include command-related statistics in the output. This option allows displaying relevant device statistics for selected get commands.

-a --show-pause

Queries the specified Ethernet device for pause parameter information.

-A --pause

Changes the pause parameters of the specified Ethernet device.

autoneg on|off

Specifies whether pause autonegotiation should be enabled.

rx on|off

Specifies whether RX pause should be enabled.

tx on|off

Specifies whether TX pause should be enabled.

-c --show-coalesce

Queries the specified network device for coalescing information.

-C --coalesce

Changes the coalescing settings of the specified network device.

-g --show-ring

Queries the specified network device for rx/tx ring parameter information.

-G --set-ring

Changes the rx/tx ring parameters of the specified network device.

rx *N* Changes the number of ring entries for the Rx ring.

rx-mini *N*

Changes the number of ring entries for the Rx Mini ring.

rx-jumbo *N*

Changes the number of ring entries for the Rx Jumbo ring.

tx *N* Changes the number of ring entries for the Tx ring.

-i --driver

Queries the specified network device for associated driver information.

-d --register-dump

Retrieves and prints a register dump for the specified network device. The register format for some devices is known and decoded others are printed in hex. When *aw* is enabled, then ethtool dumps the raw register data to stdout. If *file* is specified, then use contents of previous raw register dump, rather than reading from the device.

-e --eeprom-dump

Retrieves and prints an EEPROM dump for the specified network device. When raw is enabled, then it dumps the raw EEPROM data to stdout. The length and offset parameters allow dumping certain portions of the EEPROM. Default is to dump the entire EEPROM.

raw on/off**offset N****length N****-E --change-eeprom**

If value is specified, changes EEPROM byte for the specified network device. offset and value specify which byte and its new value. If value is not specified, stdin is read and written to the EEPROM. The length and offset parameters allow writing to certain portions of the EEPROM. Because of the persistent nature of writing to the EEPROM, a device-specific magic key must be specified to prevent the accidental writing to the EEPROM.

-k --show-features --show-offload

Queries the specified network device for the state of protocol offload and other features.

-K --features --offload

Changes the offload parameters and other features of the specified network device. The following feature names are built-in and others may be defined by the kernel.

rx on|off

Specifies whether RX checksumming should be enabled.

tx on|off

Specifies whether TX checksumming should be enabled.

sg on|off

Specifies whether scatter-gather should be enabled.

tso on|off

Specifies whether TCP segmentation offload should be enabled.

ufo on|off

Specifies whether UDP fragmentation offload should be enabled

gso on|off

Specifies whether generic segmentation offload should be enabled

gro on|off

Specifies whether generic receive offload should be enabled

lro on|off

Specifies whether large receive offload should be enabled

rxvlan on|off

Specifies whether RX VLAN acceleration should be enabled

txvlan on|off

Specifies whether TX VLAN acceleration should be enabled

ntuple on|off

Specifies whether Rx ntuple filters and actions should be enabled

rxhash on|off

Specifies whether receive hashing offload should be enabled

-p --identify

Initiates adapter-specific action intended to enable an operator to easily identify the adapter by sight. Typically this involves blinking one or more LEDs on the specific network port.

[*N*] Length of time to perform phys-id, in seconds.

-P --show-permaddr

Queries the specified network device for permanent hardware address.

-r --negotiate

Restarts auto-negotiation on the specified Ethernet device, if auto-negotiation is enabled.

-S --statistics

Queries the specified network device for standard (IEEE, IETF, etc.), or NIC- and driver-specific statistics. NIC- and driver-specific statistics are requested when no group of statistics is specified.

NIC- and driver-specific statistics and standard statistics are independent, devices may implement either, both or none. There is little commonality between naming of NIC- and driver-specific statistics across vendors.

--all-groups

--groups [eth-phy] [eth-mac] [eth-ctrl] [rmon]

Request groups of standard device statistics.

--phy-statistics

Queries the specified network device for PHY specific statistics.

-t --test

Executes adapter selftest on the specified network device. Possible test modes are:

offline Perform full set of tests, possibly interrupting normal operation during the tests,

online Perform limited set of tests, not interrupting normal operation,

external_lb

Perform full set of tests, as for **offline**, and additionally an external-loopback test.

-s --change

Allows changing some or all settings of the specified network device. All following options only apply if **-s** was specified.

speed *N*

Set speed in Mb/s. **ethtool** with just the device name as an argument will show you the supported device speeds.

lanes *N* Set number of lanes.

duplex half|full

Sets full or half duplex mode.

port tp|auj|bnc|mii

Selects device port.

master-slave preferred-master|preferred-slave|forced-master|forced-slave

Configure MASTER/SLAVE role of the PHY. When the PHY is configured as MASTER, the PMA Transmit function shall source TX_TCLK from a local clock source. When configured as SLAVE, the PMA Transmit function shall source TX_TCLK from the clock recovered from data stream provided by MASTER. Not all devices support this.

preferred-master Prefer MASTER role on autonegotiation

preferred-slave Prefer SLAVE role on autonegotiation

forced-master Force the PHY in MASTER role. Can be used without autonegotiation

forced-slave Force the PHY in SLAVE role. Can be used without autonegotiation

mdix auto|on|off

Selects MDI-X mode for port. May be used to override the automatic detection feature of most adapters. An argument of **auto** means automatic detection of MDI status, **on** forces MDI-X (crossover) mode, while **off** means MDI (straight through) mode. The driver should

guarantee that this command takes effect immediately, and if necessary may reset the link to cause the change to take effect.

autoneg on|off

Specifies whether autonegotiation should be enabled. Autonegotiation is enabled by default, but in some network devices may have trouble with it, so you can disable it if really necessary.

advertise *N*

Sets the speed and duplex advertised by autonegotiation. The argument is a hexadecimal value using one or a combination of the following values:

0x001	10baseT Half	
0x002	10baseT Full	
0x004	100baseT Half

phyad *N*

PHY address.

xcvr internal|external

Selects transceiver type. Currently only internal and external can be specified, in the future further types might be added.

wol p|u|m|b|a|g|s|f|d...

Sets Wake-on-LAN options. Not all devices support this. The argument to this option is a string of characters specifying which options to enable.

- p** Wake on PHY activity
- u** Wake on unicast messages
- m** Wake on multicast messages
- b** Wake on broadcast messages
- a** Wake on ARP
- g** Wake on MagicPacket™
- s** Enable SecureOn™ password for MagicPacket™
- f** Wake on filter(s)
- d** Disable (wake on nothing). This option clears all previous options.

sopass xx:yy:zz:aa:bb:cc

Sets the SecureOn™ password. The argument to this option must be 6 bytes in Ethernet MAC hex format (xx:yy:zz:aa:bb:cc).

msglvl *N***msglvl *type on|off ...***

Sets the driver message type flags by name or number. *type* names the type of message to enable or disable; *N* specifies the new flags numerically. The defined type names and numbers are:

drv	0x0001	General driver status
probe	0x0002	Hardware probing
link	0x0004	Link state
timer	0x0008	Periodic status check
ifdown	0x0010	Interface being brought down
ifup	0x0020	Interface being brought up
rx_err	0x0040	Receive error
tx_err	0x0080	Transmit error
tx_queued	0x0100	Transmit queueing
intr	0x0200	Interrupt handling
tx_done	0x0400	Transmit completion
rx_status	0x0800	Receive completion
pktdata	0x1000	Packet contents
hw	0x2000	Hardware status
wol	0x4000	Wake-on-LAN status

The precise meanings of these type flags differ between drivers.

-n -u --show-nfc --show-ntuple

Retrieves receive network flow classification options or rules.

rx-flow-hash tcp4|udp4|ah4|esp4|sctp4|tcp6|udp6|ah6|esp6|sctp6

Retrieves the hash options for the specified flow type.

tcp4	TCP over IPv4
udp4	UDP over IPv4
ah4	IPSEC AH over IPv4
esp4	IPSEC ESP over IPv4
sctp4	SCTP over IPv4
tcp6	TCP over IPv6
udp6	UDP over IPv6
ah6	IPSEC AH over IPv6
esp6	IPSEC ESP over IPv6
sctp6	SCTP over IPv6

rule *N*

Retrieves the RX classification rule with the given ID.

-N -U --config-nfc --config-ntuple

Configures receive network flow classification options or rules.

rx-flow-hash tcp4|udp4|ah4|esp4|sctp4|tcp6|udp6|ah6|esp6|sctp6m|v|t|s|d|f|n|r...

Configures the hash options for the specified flow type.

- m** Hash on the Layer 2 destination address of the rx packet.
- v** Hash on the VLAN tag of the rx packet.
- t** Hash on the Layer 3 protocol field of the rx packet.
- s** Hash on the IP source address of the rx packet.
- d** Hash on the IP destination address of the rx packet.
- f** Hash on bytes 0 and 1 of the Layer 4 header of the rx packet.
- n** Hash on bytes 2 and 3 of the Layer 4 header of the rx packet.

r Discard all packets of this flow type. When this option is set, all other options are ignored.

flow-type ether|ip4|tcp4|udp4|sctp4|ah4|esp4|ip6|tcp6|udp6|ah6|esp6|sctp6

Inserts or updates a classification rule for the specified flow type.

ether	Ethernet
ip4	Raw IPv4
tcp4	TCP over IPv4
udp4	UDP over IPv4
sctp4	SCTP over IPv4
ah4	IPSEC AH over IPv4
esp4	IPSEC ESP over IPv4
ip6	Raw IPv6
tcp6	TCP over IPv6
udp6	UDP over IPv6
sctp6	SCTP over IPv6
ah6	IPSEC AH over IPv6
esp6	IPSEC ESP over IPv6

For all fields that allow both a value and a mask to be specified, the mask may be specified immediately after the value using the **m** keyword, or separately using the field name keyword with **-mask** appended, e.g. **src-mask**.

src xx:yy:zz:aa:bb:cc [m xx:yy:zz:aa:bb:cc]

Includes the source MAC address, specified as 6 bytes in hexadecimal separated by colons, along with an optional mask. Valid only for flow-type ether.

dst xx:yy:zz:aa:bb:cc [m xx:yy:zz:aa:bb:cc]

Includes the destination MAC address, specified as 6 bytes in hexadecimal separated by colons, along with an optional mask. Valid only for flow-type ether.

proto N [m N]

Includes the Ethernet protocol number (ethertype) and an optional mask. Valid only for flow-type ether.

src-ip ip-address [m ip-address]

Specify the source IP address of the incoming packet to match along with an optional mask. Valid for all IP based flow-types.

dst-ip ip-address [m ip-address]

Specify the destination IP address of the incoming packet to match along with an optional mask. Valid for all IP based flow-types.

tos N [m N]

Specify the value of the Type of Service field in the incoming packet to match along with an optional mask. Applies to all IPv4 based flow-types.

tclass N [m N]

Specify the value of the Traffic Class field in the incoming packet to match along with an optional mask. Applies to all IPv6 based flow-types.

l4proto N [m N]

Includes the layer 4 protocol number and optional mask. Valid only for flow-types ip4 and ip6.

src-port N [m N]

Specify the value of the source port field (applicable to TCP/UDP packets) in the incoming packet to match along with an optional mask. Valid for flow-types ip4, tcp4, udp4, and sctp4 and their IPv6 equivalents.

dst-port N [m N]

Specify the value of the destination port field (applicable to TCP/UDP packets) in the incoming packet to match along with an optional mask. Valid for flow-types ip4, tcp4, udp4, and sctp4 and their IPv6 equivalents.

spi N [m N]

Specify the value of the security parameter index field (applicable to AH/ESP packets) in the incoming packet to match along with an optional mask. Valid for flow-types ip4, ah4, and esp4 and their IPv6 equivalents.

l4data N [m N]

Specify the value of the first 4 Bytes of Layer 4 in the incoming packet to match along with an optional mask. Valid for ip4 and ip6 flow-types.

vlan-etype N [m N]

Includes the VLAN tag Ethertype and an optional mask.

vlan N [m N]

Includes the VLAN tag and an optional mask.

user-def N [m N]

Includes 64-bits of user-specific data and an optional mask.

dst-mac xx:yy:zz:aa:bb:cc [m xx:yy:zz:aa:bb:cc]

Includes the destination MAC address, specified as 6 bytes in hexadecimal separated by colons, along with an optional mask. Valid for all IP based flow-types.

action N

Specifies the Rx queue to send packets to, or some other action.

-1 Drop the matched flow

-2 Use the matched flow as a Wake-on-LAN filter

0 or higher Rx queue to route the flow

context N

Specifies the RSS context to spread packets over multiple queues; either **0** for the default RSS context, or a value returned by **ethtool -X ... context new**.

vf N

Specifies the Virtual Function the filter applies to. Not compatible with action.

queue N

Specifies the Rx queue to send packets to. Not compatible with action.

loc N

Specify the location/ID to insert the rule. This will overwrite any rule present in that location and will not go through any of the rule ordering process.

delete N

Deletes the RX classification rule with the given ID.

-w --get-dump

Retrieves and prints firmware dump for the specified network device. By default, it prints out the dump flag, version and length of the dump data. When *data* is indicated, then ethtool fetches the dump data and directs it to a *file*.

-W --set-dump

Sets the dump flag for the device.

-T --show-time-stamping

Show the device's time stamping capabilities and associated PTP hardware clock.

-x --show-rxfh-indir --show-rxfh

Retrieves the receive flow hash indirection table and/or RSS hash key.

-X --set-rxh-indir --rxh

Configures the receive flow hash indirection table and/or RSS hash key.

hkey Sets RSS hash key of the specified network device. RSS hash key should be of device supported length. Hash key format must be in xx:yy:zz:aa:bb:cc format meaning both the nibbles of a byte should be mentioned even if a nibble is zero.

hfunc Sets RSS hash function of the specified network device. List of RSS hash functions which kernel supports is shown as a part of the --show-rxh command output.

start *N* For the **equal** and **weight** options, sets the starting receive queue for spreading flows to *N*.

equal *N*

Sets the receive flow hash indirection table to spread flows evenly between the first *N* receive queues.

weight *W0 W1 ...*

Sets the receive flow hash indirection table to spread flows between receive queues according to the given weights. The sum of the weights must be non-zero and must not exceed the size of the indirection table.

default Sets the receive flow hash indirection table to its default value.

context *CTX* | **new**

Specifies an RSS context to act on; either **new** to allocate a new RSS context, or *CTX*, a value returned by a previous ... **context new**.

delete Delete the specified RSS context. May only be used in conjunction with**context** and a non-zero *CTX* value.

-f --flash

Write a firmware image to flash or other non-volatile memory on the device.

file Specifies the filename of the firmware image. The firmware must first be installed in one of the directories where the kernel firmware loader or firmware agent will look, such as /lib/firmware.

N If the device stores multiple firmware images in separate regions of non-volatile memory, this parameter may be used to specify which region is to be written. The default is 0, requesting that all regions are written. All other values are driver-dependent.

-l --show-channels

Queries the specified network device for the numbers of channels it has. A channel is an IRQ and the set of queues that can trigger that IRQ.

-L --set-channels

Changes the numbers of channels of the specified network device.

rx *N* Changes the number of channels with only receive queues.

tx *N* Changes the number of channels with only transmit queues.

other *N*

Changes the number of channels used only for other purposes e.g. link interrupts or SR-IOV co-ordination.

combined *N*

Changes the number of multi-purpose channels.

-m --dump-module-eeprom --module-info

Retrieves and if possible decodes the EEPROM from plugin modules, e.g SFP+, QSFP. If the driver and module support it, the optical diagnostic information is also read and decoded. When either one of *page*, *bank* or *i2c* parameters is specified, dumps only of a single page or its portion is allowed. In such a case *offset* and *length* parameters are treated relatively to EEPROM page boundaries.

--show-priv-flags

Queries the specified network device for its private flags. The names and meanings of private flags (if any) are defined by each network device driver.

--set-priv-flags

Sets the device's private flags as specified.

flag **on|off** Sets the state of the named private flag.

--show-eee

Queries the specified network device for its support of Energy-Efficient Ethernet (according to the IEEE 802.3az specifications)

--set-eee

Sets the device EEE behaviour.

eee on|off

Enables/disables the device support of EEE.

tx-lpi on|off

Determines whether the device should assert its Tx LPI.

advertise *N*

Sets the speeds for which the device should advertise EEE capabilities. Values are as for

--change advertise**tx-timer** *N*

Sets the amount of time the device should stay in idle mode prior to asserting its Tx LPI (in microseconds). This has meaning only when Tx LPI is enabled.

--set-phy-tunable

Sets the PHY tunable parameters.

downshift on|off

Specifies whether downshift should be enabled.

count *N*

Sets the PHY downshift re-tries count.

fast-link-down **on|off**

Specifies whether Fast Link Down should be enabled and time until link down (if supported).

msecs *N*

Sets the period after which the link is reported as down. Note that the PHY may choose the closest supported value. Only on reading back the tunable do you get the actual value.

energy-detect-power-down **on|off**

Specifies whether Energy Detect Power Down (EDPD) should be enabled (if supported). This will put the RX and TX circuit blocks into a low power mode, and the PHY will wake up periodically to send link pulses to avoid any lock-up situation with a peer PHY that may also have EDPD enabled. By default, this setting will also enable the periodic transmission of TX pulses.

msecs *N*

Some PHYs support configuration of the wake-up interval to send TX pulses.

This setting allows the control of this interval, and 0 disables TX pulses if the PHY supports this. Disabling TX pulses can create a lock-up situation where neither of the PHYs wakes the other one. If unspecified the default value (in milliseconds) will be used by the PHY.

--get-phy-tunable

Gets the PHY tunable parameters.

downshift

For operation in cabling environments that are incompatible with 1000BASE-T, PHY device provides an automatic link speed downshift operation. Link speed downshift after N failed 1000BASE-T auto-negotiation attempts. Downshift is useful where cable does not have the 4 pairs instance.

Gets the PHY downshift count/status.

fast-link-down

Depending on the mode it may take 0.5s - 1s until a broken link is reported as down. In certain use cases a link-down event needs to be reported as soon as possible. Some PHYs support a Fast Link Down Feature and may allow configuration of the delay before a broken link is reported as being down.

Gets the PHY Fast Link Down status / period.

energy-detect-power-down

Gets the current configured setting for Energy Detect Power Down (if supported).

--get-tunable

Get the tunable parameters.

rx-copybreak

Get the current rx copybreak value in bytes.

tx-copybreak

Get the current tx copybreak value in bytes.

pfc-prevention-tout

Get the current pfc prevention timeout value in msecs.

--set-tunable

Set driver's tunable parameters.

rx-copybreak *N*

Set the rx copybreak value in bytes.

tx-copybreak *N*

Set the tx copybreak value in bytes.

pfc-prevention-tout *N*

Set pfc prevention timeout in msecs. Value of 0 means disable and 65535 means auto.

--reset

Reset hardware components specified by flags and components listed below

flags *N* Resets the components based on direct flags mask

mgmt Management processor

irq Interrupt requester

dma DMA engine

filter Filtering/flow direction

offload Protocol offload

mac Media access controller

phy Transceiver/PHY

ram RAM shared between multiple components **ap** Application Processor

dedicated

All components dedicated to this interface

all

All components used by this interface, even if shared

--show-fec

Queries the specified network device for its support of Forward Error Correction.

--set-fec

Configures Forward Error Correction for the specified network device.

Forward Error Correction modes selected by a user are expected to be persisted after any hotplug events. If a module is swapped that does not support the current FEC mode, the driver or firmware must take the link down administratively and report the problem in the system logs for users to correct.

encoding auto|off|rs|baser|llrs [...]

Sets the FEC encoding for the device. Combinations of options are specified as e.g. **encoding auto rs**; the semantics of such combinations vary between drivers.

auto Use the driver's default encoding

off Turn off FEC

RS Force RS-FEC encoding

BaseR Force BaseR encoding

LLRS Force LLRS-FEC encoding

-Q|--per-queue

Applies provided sub command to specific queues.

queue_mask %x

Sets the specific queues which the sub command is applied to. If queue_mask is not set, the sub command will be applied to all queues.

sub_command

Sub command to apply. The supported sub commands include --show-coalesce and --coalesce.

q.B --cable-test

Perform a cable test and report the results. What results are returned depends on the capabilities of the network interface. Typically open pairs and shorted pairs can be reported, along with pairs being O.K. When a fault is detected the approximate distance to the fault may be reported.

--cable-test-tdr

Perform a cable test and report the raw Time Domain Reflectometer data. A pulse is sent down a cable pair and the amplitude of the reflection, for a given distance, is reported. A break in the cable returns a big reflection. Minor damage to the cable returns a small reflection. If the cable is shorted, the amplitude of the reflection can be negative. By default, data is returned for lengths between 0 and 150m at 1m steps, for all pairs. However parameters can be passed to restrict the collection of data. It should be noted, that the interface will round the distances to whatever granularity is actually implemented. This is often 0.8 of a meter. The results should include the actual rounded first and last distance and step size.

first N Distance along the cable, in meters, where the first measurement should be made.

last N Distance along the cable, in meters, where the last measurement should be made.

step N Distance, in meters, between each measurement.

pair N Which pair should be measured. Typically a cable has 4 pairs. 0 = Pair A, 1 = Pair B, ...

--monitor

Listens to netlink notification and displays them.

command

If argument matching a command is used, ethtool only shows notifications of this type. Without such argument or with --all, all notification types are shown.

devname

If a device name is used as argument, only notification for this device are shown. Default is to show notifications for all devices.

--show-tunnels

Show tunnel-related device capabilities and state. List UDP ports kernel has programmed the device to parse as VxLAN, or GENEVE tunnels.

BUGS

Not supported (in part or whole) on all network drivers.

AUTHOR

NAME

exfatlabel – Get or Set volume label or volume serial of an exFAT filesystem

SYNOPSIS

exfatlabel [**-i** *volume-label*] [**-v**] *device* [*label_string or serial_value*]
exfatlabel -V

DESCRIPTION

exfatlabel Print or set volume label of an existing exFAT filesystem.

If there is a *label_string* in argument of exfatlabel, It will be written to volume label field on given device. If not, exfatlabel will just print out after reading volume label field from given device. If -i or --volume-serial is given, It can be switched to volume serial mode.

OPTIONS

- i** Switch to volume serial mode.
- V** Prints the version number and exits.

exports(5) - Linux man page

Name

exports - NFS server export table

Description

The file */etc/exports* contains a table of local physical file systems on an NFS server that are accessible to NFS clients. The contents of the file are maintained by the server's system administrator.

Each file system in this table has a list of options and an access control list. The table is used by **exportfs(8)** to give information to **mountd(8)**.

The file format is similar to the SunOS *exports* file. Each line contains an export point and a whitespace-separated list of clients allowed to mount the file system at that point. Each listed client may be immediately followed by a parenthesized, comma-separated list of export options for that client. No whitespace is permitted between a client and its option list.

Also, each line may have one or more specifications for default options after the path name, in the form of a dash ("") followed by an option list. The option list is used for all subsequent exports on that line only.

Blank lines are ignored. A pound sign ("#") introduces a comment to the end of the line. Entries may be continued across newlines using a backslash. If an export name contains spaces it should be quoted using double quotes. You can also specify spaces or other unusual character in the export name using a backslash followed by the character code as three octal digits.

To apply changes to this file, run **exportfs**-ra or restart the NFS server.

Machine Name Formats

NFS clients may be specified in a number of ways:

single host

You may specify a host either by an abbreviated name recognized by the resolver, the fully qualified domain name, an IPv4 address, or an IPv6 address. IPv6 addresses must not be inside square brackets in */etc/exports* lest they be confused with character-class wildcard matches.

netgroups

NIS netgroups may be given as *@group*. Only the host part of each netgroup members is considered in checking for membership. Empty host parts or those containing a single dash (-) are ignored.

wildcards

+Machine names may contain the wildcard characters * and ?, or may contain character class lists within [square brackets]. This can be used to make the *exports* file more compact; for instance, *.cs.foo.edu matches all hosts in the domain cs.foo.edu. As these characters also match the dots in a domain name, the given pattern will also match all hosts within any subdomain of cs.foo.edu.

IP networks

You can also export directories to all hosts on an IP (sub-) network simultaneously. This is done by specifying an IP address and netmask pair as *address/netmask* where the netmask can be specified in dotted-decimal format, or as a contiguous mask length. For example, either '/255.255.252.0' or '/22' appended to the network base IPv4 address results in identical subnetworks with 10 bits of host. IPv6 addresses must use a contiguous mask length and must not be inside square brackets to avoid confusion with character-class wildcards. Wildcard characters generally do not work on IP addresses, though they may work by accident when reverse DNS lookups fail.

RPCSEC_GSS security

You may use the special strings "gss/krb5", "gss/krb5i", or "gss/krb5p" to restrict access to clients using rpcsec_gss security. However, this syntax is deprecated; on linux kernels since 2.6.23, you should instead use the "sec=" export option:

sec=

The *sec=* option, followed by a colon-delimited list of security flavors, restricts the export to clients using those flavors. Available security flavors include sys (the default--no cryptographic security), krb5 (authentication only), krb5i (integrity protection), and krb5p (privacy protection). For the purposes of security flavor negotiation, order counts: preferred flavors should be listed first. The order of the *sec=* option with respect to the other options does not matter, unless you want some options to be enforced differently depending on flavor. In that case you may include multiple *sec=* options, and following options will be enforced only for access using flavors listed in the immediately preceding *sec=* option. The only options that are permitted to vary in this way are *ro*, *rw*, *no_root_squash*, *root_squash*, and *all_squash*.

General Options

exports understands the following export options:

secure

This option requires that requests originate on an Internet port less than IPPORT_RESERVED (1024). This option is on by default. To turn it off, specify *insecure*.

rw

Allow both read and write requests on this NFS volume. The default is to disallow any request which changes the filesystem. This can also be made explicit by using the *ro*

option.

async

This option allows the NFS server to violate the NFS protocol and reply to requests before any changes made by that request have been committed to stable storage (e.g. disc drive).

Using this option usually improves performance, but at the cost that an unclean server restart (i.e. a crash) can cause data to be lost or corrupted.

sync

Reply to requests only after the changes have been committed to stable storage (see *async* above).

In releases of nfs-utils up to and including 1.0.0, the *async* option was the default. In all releases after 1.0.0, *sync* is the default, and *async* must be explicitly requested if needed. To help make system administrators aware of this change, **exportfs** will issue a warning if neither *sync* nor *async* is specified.

no_wdelay

This option has no effect if *async* is also set. The NFS server will normally delay committing a write request to disc slightly if it suspects that another related write request may be in progress or may arrive soon. This allows multiple write requests to be committed to disc with the one operation which can improve performance. If an NFS server received mainly small unrelated requests, this behaviour could actually reduce performance, so *no_wdelay* is available to turn it off. The default can be explicitly requested with the *wdelay* option.

nohide

This option is based on the option of the same name provided in IRIX NFS. Normally, if a server exports two filesystems one of which is mounted on the other, then the client will have to mount both filesystems explicitly to get access to them. If it just mounts the parent, it will see an empty directory at the place where the other filesystem is mounted. That filesystem is "hidden".

Setting the *nohide* option on a filesystem causes it not to be hidden, and an appropriately authorised client will be able to move from the parent to that filesystem without noticing the change.

However, some NFS clients do not cope well with this situation as, for instance, it is then possible for two files in the one apparent filesystem to have the same inode number.

The *nohide* option is currently only effective on *single host* exports. It does not work reliably with netgroup, subnet, or wildcard exports.

This option can be very useful in some situations, but it should be used with due care, and only after confirming that the client system copes with the situation effectively.

The option can be explicitly disabled with *hide*.

crossmnt

This option is similar to *nohide* but it makes it possible for clients to move from the filesystem marked with *crossmnt* to exported filesystems mounted on it. Thus when a child filesystem "B" is mounted on a parent "A", setting *crossmnt* on "A" has the same effect as setting "*nohide*" on B.

no_subtree_check

This option disables subtree checking, which has mild security implications, but can improve reliability in some circumstances.

If a subdirectory of a filesystem is exported, but the whole filesystem isn't then whenever a NFS request arrives, the server must check not only that the accessed file is in the appropriate filesystem (which is easy) but also that it is in the exported tree (which is harder). This check is called the *subtree_check*.

In order to perform this check, the server must include some information about the location of the file in the "filehandle" that is given to the client. This can cause problems with accessing files that are renamed while a client has them open (though in many simple cases it will still work).

Subtree checking is also used to make sure that files inside directories to which only root has access can only be accessed if the filesystem is exported with *no_root_squash* (see below), even if the file itself allows more general access.

As a general guide, a home directory filesystem, which is normally exported at the root and may see lots of file renames, should be exported with subtree checking disabled. A filesystem which is mostly readonly, and at least doesn't see many file renames (e.g. /usr or /var) and for which subdirectories may be exported, should probably be exported with subtree checks enabled.

The default of having subtree checks enabled, can be explicitly requested with *subtree_check*.

From release 1.1.0 of nfs-utils onwards, the default will be *no_subtree_check* as subtree_checking tends to cause more problems than it is worth. If you genuinely require subtree checking, you should explicitly put that option in the **exports** file. If you put neither option, **exportfs** will warn you that the change is pending.

insecure_locks

no_auth_nlm

This option (the two names are synonymous) tells the NFS server not to require authentication of locking requests (i.e. requests which use the NLM protocol).

Normally the NFS server will require a lock request to hold a credential for a user who has read access to the file. With this flag no access checks will be performed.

Early NFS client implementations did not send credentials with lock requests, and many current NFS clients still exist which are based on the old implementations. Use this flag if you find that you can only lock files which are world readable.

The default behaviour of requiring authentication for NLM requests can be explicitly requested with either of the synonymous *auth_nlm*, or *secure_locks*.

no_acl

On some specially patched kernels, and when exporting filesystems that support ACLs, this option tells **nfsd** not to reveal ACLs to clients, so they will see only a subset of actual permissions on the given file system. This option is safe for filesystems used by NFSv2 clients and old NFSv3 clients that perform access decisions locally. Current NFSv3 clients use the ACCESS RPC to perform all access decisions on the server. Note that the *no_acl* option only has effect on kernels specially patched to support it, and when exporting filesystems with ACL support. The default is to export with ACL support (i.e. by default, *no_acl* is off).

mountpoint=path *mp*

This option makes it possible to only export a directory if it has successfully been mounted. If no path is given (e.g. *mountpoint* or *mp*) then the export point must also be a mount point. If it isn't then the export point is not exported. This allows you to be sure that the directory underneath a mountpoint will never be exported by accident if, for example, the filesystem failed to mount due to a disc error.

If a path is given (e.g. *mountpoint=/path* or *mp=/path*) then the nominated path must be a mountpoint for the exportpoint to be exported.

fsid=num|root|uuid

NFS needs to be able to identify each filesystem that it exports. Normally it will use a UUID for the filesystem (if the filesystem has such a thing) or the device number of the device holding the filesystem (if the filesystem is stored on the device).

As not all filesystems are stored on devices, and not all filesystems have UUIDs, it is sometimes necessary to explicitly tell NFS how to identify a filesystem. This is done with the *fsid=* option.

For NFSv4, there is a distinguished filesystem which is the root of all exported filesystem. This is specified with *fsid=root* or *fsid=0* both of which mean exactly the same thing.

Other filesystems can be identified with a small integer, or a UUID which should contain 32 hex digits and arbitrary punctuation.

Linux kernels version 2.6.20 and earlier do not understand the UUID setting so a small integer must be used if an fsid option needs to be set for such kernels. Setting

both a small number and a UUID is supported so the same configuration can be made to work on old and new kernels alike.

refer=path@host[+host][:path@host[+host]]

A client referencing the export point will be directed to choose from the given list an alternative location for the filesystem. (Note that the server must have a mountpoint here, though a different filesystem is not required; so, for example, *mount --bind /path /path* is sufficient.)

replicas=path@host[+host][:path@host[+host]]

If the client asks for alternative locations for the export point, it will be given this list of alternatives. (Note that actual replication of the filesystem must be handled elsewhere.)

User ID Mapping

nfsd bases its access control to files on the server machine on the uid and gid provided in each NFS RPC request. The normal behavior a user would expect is that she can access her files on the server just as she would on a normal file system. This requires that the same uids and gids are used on the client and the server machine. This is not always true, nor is it always desirable.

Very often, it is not desirable that the root user on a client machine is also treated as root when accessing files on the NFS server. To this end, uid 0 is normally mapped to a different id: the so-called anonymous or *nobody* uid. This mode of operation (called 'root squashing') is the default, and can be turned off with *no_root_squash*.

By default, **exportfs** chooses a uid and gid of 65534 for squashed access. These values can also be overridden by the *anonuid* and *anongid* options. Finally, you can map all user requests to the anonymous uid by specifying the *all_squash* option.

Here's the complete list of mapping options:

root_squash

Map requests from uid/gid 0 to the anonymous uid/gid. Note that this does not apply to any other uids or gids that might be equally sensitive, such as user *bin* or group *staff*.

no_root_squash

Turn off root squashing. This option is mainly useful for diskless clients.

all_squash

Map all uids and gids to the anonymous user. Useful for NFS-exported public FTP directories, news spool directories, etc. The opposite option is *no_all_squash*, which is the default setting.

anonuid and **anongid**

These options explicitly set the uid and gid of the anonymous account. This option is primarily useful for PC/NFS clients, where you might want all requests appear to be from one user. As an example, consider the export entry for **/home/joe** in the

example section below, which maps all requests to uid 150 (which is supposedly that of user joe).

Example

```
# sample /etc/exports file
/
    master(rw) trusty(rw,no_root_squash)
/projects      proj*.local.domain(rw)
/usr          *.local.domain(ro) @trusted(rw)
/home/joe     pc001(rw,all_squash,anonuid=150,anongid=100)
/pub           *(ro,insecure,all_squash)
/srv/www      -sync,rw server @trusted @external(ro)
/foo           2001:db8:9:e54::/64(rw) 192.0.2.0/24(rw)
/build         buildhost[0-9].local.domain(rw)
```

The first line exports the entire filesystem to machines master and trusty. In addition to write access, all uid squashing is turned off for host trusty. The second and third entry show examples for wildcard hostnames and netgroups (this is the entry '@trusted'). The fourth line shows the entry for the PC/NFS client discussed above. Line 5 exports the public FTP directory to every host in the world, executing all requests under the nobody account. The *insecure* option in this entry also allows clients with NFS implementations that don't use a reserved port for NFS. The sixth line exports a directory read-write to the machine 'server' as well as the '@trusted' netgroup, and read-only to netgroup '@external', all three mounts with the 'sync' option enabled. The seventh line exports a directory to both an IPv6 and an IPv4 subnet. The eighth line demonstrates a character class wildcard match.

NAME

ext2 – the second extended file system
ext3 – the third extended file system
ext4 – the fourth extended file system

DESCRIPTION

The second, third, and fourth extended file systems, or ext2, ext3, and ext4 as they are commonly known, are Linux file systems that have historically been the default file system for many Linux distributions. They are general purpose file systems that have been designed for extensibility and backwards compatibility. In particular, file systems previously intended for use with the ext2 and ext3 file systems can be mounted using the ext4 file system driver, and indeed in many modern Linux distributions, the ext4 file system driver has been configured to handle mount requests for ext2 and ext3 file systems.

FILE SYSTEM FEATURES

A file system formatted for ext2, ext3, or ext4 can have some collection of the following file system feature flags enabled. Some of these features are not supported by all implementations of the ext2, ext3, and ext4 file system drivers, depending on Linux kernel version in use. On other operating systems, such as the GNU/HURD or FreeBSD, only a very restrictive set of file system features may be supported in their implementations of ext2.

64bit

Enables the file system to be larger than 2^{32} blocks. This feature is set automatically, as needed, but it can be useful to specify this feature explicitly if the file system might need to be resized larger than 2^{32} blocks, even if it was smaller than that threshold when it was originally created. Note that some older kernels and older versions of e2fsprogs will not support file systems with this ext4 feature enabled.

bigalloc

This ext4 feature enables clustered block allocation, so that the unit of allocation is a power of two number of blocks. That is, each bit in the what had traditionally been known as the block allocation bitmap now indicates whether a cluster is in use or not, where a cluster is by default composed of 16 blocks. This feature can decrease the time spent on doing block allocation and brings smaller fragmentation, especially for large files. The size can be specified using the **mke2fs -C** option.

Warning: The bigalloc feature is still under development, and may not be fully supported with your kernel or may have various bugs. Please see the web page <http://ext4.wiki.kernel.org/index.php/Bigalloc> for details. May clash with delayed allocation (see **nodelalloc** mount option).

This feature requires that the **extent** feature be enabled.

casifold

This ext4 feature provides file system level character encoding support for directories with the casifold (+F) flag enabled. This feature is name-preserving on the disk, but it allows applications to lookup for a file in the file system using an encoding equivalent version of the file name.

dir_index

Use hashed b-trees to speed up name lookups in large directories. This feature is supported by ext3 and ext4 file systems, and is ignored by ext2 file systems.

dir_nlink

Normally, ext4 allows an inode to have no more than 65,000 hard links. This applies to regular files as well as directories, which means that there can be no more than 64,998 subdirectories in a directory (because each of the '.' and '..' entries, as well as the directory entry for the directory in its parent directory counts as a hard link). This feature lifts this limit by causing ext4 to use a link count of 1 to indicate that the number of hard links to a directory is not known when the link count might exceed the maximum count limit.

ea_inode

Normally, a file's extended attributes and associated metadata must fit within the inode or the inode's associated extended attribute block. This feature allows the value of each extended attribute to be placed in the data blocks of a separate inode if necessary, increasing the limit on the size and number of extended attributes per file.

encrypt

Enables support for file-system level encryption of data blocks and file names. The inode metadata (timestamps, file size, user/group ownership, etc.) is *not* encrypted.

This feature is most useful on file systems with multiple users, or where not all files should be encrypted. In many use cases, especially on single-user systems, encryption at the block device layer using dm-crypt may provide much better security.

ext_attr

This feature enables the use of extended attributes. This feature is supported by ext2, ext3, and ext4.

extent

This ext4 feature allows the mapping of logical block numbers for a particular inode to physical blocks on the storage device to be stored using an extent tree, which is a more efficient data structure than the traditional indirect block scheme used by the ext2 and ext3 file systems. The use of the extent tree decreases metadata block overhead, improves file system performance, and decreases the need to run **e2fsck(8)** on the file system. (Note: both **extent** and **extents** are accepted as valid names for this feature for historical/backwards compatibility reasons.)

extra_isize

This ext4 feature reserves a specific amount of space in each inode for extended metadata such as nanosecond timestamps and file creation time, even if the current kernel does not currently need to reserve this much space. Without this feature, the kernel will reserve the amount of space for features it currently needs, and the rest may be consumed by extended attributes.

For this feature to be useful the inode size must be 256 bytes in size or larger.

filetype

This feature enables the storage of file type information in directory entries. This feature is supported by ext2, ext3, and ext4.

flex_bg

This ext4 feature allows the per-block group metadata (allocation bitmaps and inode tables) to be placed anywhere on the storage media. In addition, **mke2fs** will place the per-block group metadata together starting at the first block group of each "flex_bg group". The size of the **flex_bg** group can be specified using the **-G** option.

has_journal

Create a journal to ensure file system consistency even across unclean shutdowns. Setting the file system feature is equivalent to using the **-j** option with **mke2fs** or **tune2fs**. This feature is supported by ext3 and ext4, and ignored by the ext2 file system driver.

huge_file

This ext4 feature allows files to be larger than 2 terabytes in size.

inline_data

Allow data to be stored in the inode and extended attribute area.

journal_dev

This feature is enabled on the superblock found on an external journal device. The block size for the external journal must be the same as the file system which uses it.

The external journal device can be used by a file system by specifying the **-J device=<external-device>** option to **mke2fs(8)** or **tune2fs(8)**.

large_dir

This feature increases the limit on the number of files per directory by raising the maximum size of directories and, for hashed b-tree directories (see **dir_index**), the maximum height of the hashed b-tree used to store the directory entries.

large_file

This feature flag is set automatically by modern kernels when a file larger than 2 gigabytes is created. Very old kernels could not handle large files, so this feature flag was used to prohibit those kernels from mounting file systems that they could not understand.

metadata_csum

This ext4 feature enables metadata checksumming. This feature stores checksums for all of the file system metadata (superblock, group descriptor blocks, inode and block bitmaps, directories, and extent tree blocks). The checksum algorithm used for the metadata blocks is different than the one used for group descriptors with the **uninit_bg** feature. These two features are incompatible and **metadata_csum** will be used preferentially instead of **uninit_bg**.

metadata_csum_seed

This feature allows the file system to store the metadata checksum seed in the superblock, which allows the administrator to change the UUID of a file system using the **metadata_csum** feature while it is mounted.

meta_bg

This ext4 feature allows file systems to be resized on-line without explicitly needing to reserve space for growth in the size of the block group descriptors. This scheme is also used to resize file systems which are larger than 2^{32} blocks. It is not recommended that this feature be set when a file system is created, since this alternate method of storing the block group descriptors will slow down the time needed to mount the file system, and newer kernels can automatically set this feature as necessary when doing an online resize and no more reserved space is available in the resize inode.

mmp

This ext4 feature provides multiple mount protection (MMP). MMP helps to protect the file system from being multiply mounted and is useful in shared storage environments.

project

This ext4 feature provides project quota support. With this feature, the project ID of inode will be managed when the file system is mounted.

quota

Create quota inodes (inode #3 for userquota and inode #4 for group quota) and set them in the superblock. With this feature, the quotas will be enabled automatically when the file system is mounted.

Causes the quota files (i.e., user.quota and group.quota which existed in the older quota design) to be hidden inodes.

resize_inode

This file system feature indicates that space has been reserved so that the block group descriptor table can be extended while resizing a mounted file system. The online resize operation is carried out by the kernel, triggered by **resize2fs(8)**. By default **mke2fs** will attempt to reserve enough space so that the file system may grow to 1024 times its initial size. This can be changed using the **resize** extended option.

This feature requires that the **sparse_super** or **sparse_super2** feature be enabled.

sparse_super

This file system feature is set on all modern ext2, ext3, and ext4 file systems. It indicates that backup copies of the superblock and block group descriptors are present only in a few block groups, not all of them.

sparse_super2

This feature indicates that there will only be at most two backup superblocks and block group descriptors. The block groups used to store the backup superblock(s) and blockgroup descriptor(s) are stored in the superblock, but typically, one will be located at the beginning of block group #1, and one in the last block group in the file system. This feature is essentially a more extreme version of sparse_super and is designed to allow a much larger percentage of the disk to have contiguous blocks available for data files.

stable_inodes

Marks the file system's inode numbers and UUID as stable. **r esize2fs(8)** will not allow shrinking a file system with this feature, nor will **tune2fs(8)** allow changing its UUID. This feature allows the use of specialized encryption settings that make use of the inode numbers and UUID. Note that the **encrypt** feature still needs to be enabled separately. **stable_inodes** is a "compat" feature, so old kernels will allow it.

uninit_bg

This ext4 file system feature indicates that the block group descriptors will be protected using checksums, making it safe for **mke2fs(8)** to create a file system without initializing all of the block groups. The kernel will keep a high watermark of unused inodes, and initialize inode tables and blocks lazily. This feature speeds up the time to check the file system using **e2fsck(8)**, and it also speeds up the time required for **mke2fs(8)** to create the file system.

verity

Enables support for verity protected files. Verity files are readonly, and their data is transparently verified against a Merkle tree hidden past the end of the file. Using the Merkle tree's root hash, a verity file can be efficiently authenticated, independent of the file's size.

This feature is most useful for authenticating important read-only files on read-write file systems. If the file system itself is read-only, then using dm-verity to authenticate the entire block device may provide much better security.

MOUNT OPTIONS

This section describes mount options which are specific to ext2, ext3, and ext4. Other generic mount options may be used as well; see **mount(8)** for details.

Mount options for ext2

The 'ext2' file system is the standard Linux file system. Since Linux 2.5.46, for most mount options the default is determined by the file system superblock. Set them with **tune2fs(8)**.

acl|noacl

Support POSIX Access Control Lists (or not). See the **acl(5)** manual page.

bsddf|minixdf

Set the behavior for the *statfs* system call. The **minixdf** behavior is to return in the *f_blocks* field the total number of blocks of the file system, while the **bsddf** behavior (which is the default) is to subtract the overhead blocks used by the ext2 file system and not available for file storage. Thus

```
% mount /k -o minixdf; df /k; umount /k
```

File System	1024-blocks	Used	Available	Capacity	Mounted on
/dev/sda6	2630655	86954	2412169	3%	/k

```
% mount /k -o bsddf; df /k; umount /k
```

File System	1024-blocks	Used	Available	Capacity	Mounted on
/dev/sda6	2543714	13	2412169	0%	/k

(Note that this example shows that one can add command line options to the options given in */etc/fstab*.)

check=none or nocheck

No checking is done at mount time. This is the default. This is fast. It is wise to invoke **e2fsck(8)** every now and then, e.g. at boot time. The non-default behavior is unsupported (check=normal and check=strict options have been removed). Note that these mount options don't have to be supported if ext4 kernel driver is used for ext2 and ext3 file systems.

debug Print debugging info upon each (re)mount.

errors={continue|remount-ro|panic}

Define the behavior when an error is encountered. (Either ignore errors and just mark the file system erroneous and continue, or remount the file system read-only, or panic and halt the system.) The default is set in the file system superblock, and can be changed using **tune2fs(8)**.

grpid|bsdgroups and nogrpid|sysvgroups

These options define what group id a newly created file gets. When **grpid** is set, it takes the group id of the directory in which it is created; otherwise (the default) it takes the fsgid of the current process, unless the directory has the setgid bit set, in which case it takes the gid from the parent directory, and also gets the setgid bit set if it is a directory itself.

grpquota|noquota|quota|usrquota

The **usrquota** (same as **quota**) mount option enables user quota support on the file system. **grpquota** enables group quotas support. You need the quota utilities to actually enable and manage the quota system.

nouid32

Disables 32-bit UIDs and GIDs. This is for interoperability with older kernels which only store and expect 16-bit values.

oldalloc or orlov

Use old allocator or Orlov allocator for new inodes. Orlov is default.

resgid=n and resuid=n

The ext2 file system reserves a certain percentage of the available space (by default 5%, see **mke2fs(8)** and **tune2fs(8)**). These options determine who can use the reserved blocks. (Roughly: whoever has the specified uid, or belongs to the specified group.)

sb=n Instead of using the normal superblock, use an alternative superblock specified by *n*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system's blocksize, the number of blocks per group, and features such as **sparse_super**.

Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system's layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).

The block number here uses 1 k units. Thus, if you want to use logical block 32768 on a file system with 4 k blocks, use "sb=131072".

user_xattr|nouser_xattr

Support "user." extended attributes (or not).

Mount options for ext3

The ext3 file system is a version of the ext2 file system which has been enhanced with journaling. It supports the same options as ext2 as well as the following additions:

journal_dev=devnum/journal_path=path

When the external journal device's major/minor numbers have changed, these options allow the user to specify the new journal location. The journal device is identified either through its new major/minor numbers encoded in devnum, or via a path to the device.

norecovery/noload

Don't load the journal on mounting. Note that if the file system was not unmounted cleanly, skipping the journal replay will lead to the file system containing inconsistencies that can lead to any number of problems.

data={journal|ordered|writeback}

Specifies the journaling mode for file data. Metadata is always journaled. To use modes other than **ordered** on the root file system, pass the mode to the kernel as boot parameter, e.g. *root-flags=data=journal*.

journal

All data is committed into the journal prior to being written into the main file system.

ordered

This is the default mode. All data is forced directly out to the main file system prior to its metadata being committed to the journal.

writeback

Data ordering is not preserved – data may be written into the main file system after its metadata has been committed to the journal. This is rumoured to be the highest-throughput option. It guarantees internal file system integrity, however it can allow old data to appear in files after a crash and journal recovery.

data_err=ignore

Just print an error message if an error occurs in a file data buffer in ordered mode.

data_err=abort

Abort the journal if an error occurs in a file data buffer in ordered mode.

barrier=0 / barrier=1

This disables / enables the use of write barriers in the jbd code. barrier=0 disables, barrier=1 enables (default). This also requires an IO stack which can support barriers, and if jbd gets an error on a barrier write, it will disable barriers again with a warning. Write barriers enforce proper on-disk ordering of journal commits, making volatile disk write caches safe to use, at some performance penalty. If your disks are battery-backed in one way or another, disabling barriers may safely improve performance.

commit=nrsec

Start a journal commit every *nrsec* seconds. The default value is 5 seconds. Zero means default.

user_xattr

Enable Extended User Attributes. See the **attr(5)** manual page.

jqfmt={vfsold|vfsv0|vfsv1}

Apart from the old quota system (as in ext2, jqfmt=vfsold aka version 1 quota) ext3 also supports journaled quotas (version 2 quota). jqfmt=vfsv0 or jqfmt=vfsv1 enables journaled quotas. Journaled quotas have the advantage that even after a crash no quota check is required. When the **quota** file system feature is enabled, journaled quotas are used automatically, and this mount option is ignored.

usrjquota=aquota.user|grpjquota=aquota.group

For journaled quotas (jqfmt=vfsv0 or jqfmt=vfsv1), the mount options **usrjquota=aquota.user** and **grpjquota=aquota.group** are required to tell the quota system which quota database files to use. When the **quota** file system feature is enabled, journaled quotas are used automatically, and this mount option is ignored.

Mount options for ext4

The ext4 file system is an advanced level of the ext3 file system which incorporates scalability and reliability enhancements for supporting large file system.

The options **journal_dev**, **journal_path**, **norecovery**, **noload**, **data**, **commit**, **orlov**, **oldalloc**,

[no]user_xattr, [no]acl, bsddf, minixdf, debug, errors, data_err, grpid, bsdgroups, nogrpid, sysv-groups, resgid, resuid, sb, quota, noquota, nouid32, grpquota, usrquota, usrjquota, grpquota, and jqfmt are backwardly compatible with ext3 or ext2.

journal_checksum | nojournal_checksum

The journal_checksum option enables checksumming of the journal transactions. This will allow the recovery code in e2fsck and the kernel to detect corruption in the kernel. It is a compatible change and will be ignored by older kernels.

journal_async_commit

Commit block can be written to disk without waiting for descriptor blocks. If enabled older kernels cannot mount the device. This will enable 'journal_checksum' internally.

barrier=0 / barrier=1 / barrier / nobarrier

These mount options have the same effect as in ext3. The mount options "barrier" and "nobarrier" are added for consistency with other ext4 mount options.

The ext4 file system enables write barriers by default.

inode_readahead_blks=n

This tuning parameter controls the maximum number of inode table blocks that ext4's inode table readahead algorithm will pre-read into the buffer cache. The value must be a power of 2. The default value is 32 blocks.

stripe=n

Number of file system blocks that mballoc will try to use for allocation size and alignment. For RAID5/6 systems this should be the number of data disks * RAID chunk size in file system blocks.

delalloc

Deferring block allocation until write-out time.

nodealloc

Disable delayed allocation. Blocks are allocated when data is copied from user to page cache.

max_batch_time=usec

Maximum amount of time ext4 should wait for additional file system operations to be batch together with a synchronous write operation. Since a synchronous write operation is going to force a commit and then a wait for the I/O complete, it doesn't cost much, and can be a huge throughput win, we wait for a small amount of time to see if any other transactions can piggyback on the synchronous write. The algorithm used is designed to automatically tune for the speed of the disk, by measuring the amount of time (on average) that it takes to finish committing a transaction. Call this time the "commit time". If the time that the transaction has been running is less than the commit time, ext4 will try sleeping for the commit time to see if other operations will join the transaction. The commit time is capped by the max_batch_time, which defaults to 15000 µs (15 ms). This optimization can be turned off entirely by setting max_batch_time to 0.

min_batch_time=usec

This parameter sets the commit time (as described above) to be at least min_batch_time. It defaults to zero microseconds. Increasing this parameter may improve the throughput of multi-threaded, synchronous workloads on very fast disks, at the cost of increasing latency.

journal_ioprio=prio

The I/O priority (from 0 to 7, where 0 is the highest priority) which should be used for I/O operations submitted by kjournald2 during a commit operation. This defaults to 3, which is a slightly higher priority than the default I/O priority.

abort Simulate the effects of calling ext4_abort() for debugging purposes. This is normally used while remounting a file system which is already mounted.

auto_da_alloc|noauto_da_alloc

Many broken applications don't use fsync() when replacing existing files via patterns such as

```
fd = open("foo.new")/write(fd,...)/close(fd)/ rename("foo.new", "foo")
```

or worse yet

```
fd = open("foo", O_TRUNC)/write(fd,...)/close(fd).
```

If auto_da_alloc is enabled, ext4 will detect the replace-via-rename and replace-via-truncate patterns and force that any delayed allocation blocks are allocated such that at the next journal commit, in the default data=ordered mode, the data blocks of the new file are forced to disk before the rename() operation is committed. This provides roughly the same level of guarantees as ext3, and avoids the "zero-length" problem that can happen when a system crashes before the delayed allocation blocks are forced to disk.

noinit_itable

Do not initialize any uninitialized inode table blocks in the background. This feature may be used by installation CD's so that the install process can complete as quickly as possible; the inode table initialization process would then be deferred until the next time the file system is mounted.

init_itable=n

The lazy itable init code will wait n times the number of milliseconds it took to zero out the previous block group's inode table. This minimizes the impact on system performance while the file system's inode table is being initialized.

discard/nodiscard

Controls whether ext4 should issue discard/TRIM commands to the underlying block device when blocks are freed. This is useful for SSD devices and sparse/thinly-provisioned LUNs, but it is off by default until sufficient testing has been done.

block_validity/noblock_validity

This option enables/disables the in-kernel facility for tracking file system metadata blocks within internal data structures. This allows multi-block allocator and other routines to quickly locate extents which might overlap with file system metadata blocks. This option is intended for debugging purposes and since it negatively affects the performance, it is off by default.

dioread_lock/dioread_nolock

Controls whether or not ext4 should use the DIO read locking. If the dioread_nolock option is specified ext4 will allocate uninitialized extent before buffer write and convert the extent to initialized after IO completes. This approach allows ext4 code to avoid using inode mutex, which improves scalability on high speed storages. However this does not work with data journaling and dioread_nolock option will be ignored with kernel warning. Note that dioread_nolock code path is only used for extent-based files. Because of the restrictions this options comprises it is off by default (e.g. dioread_lock).

max_dir_size_kb=n

This limits the size of the directories so that any attempt to expand them beyond the specified limit in kilobytes will cause an ENOSPC error. This is useful in memory-constrained environments, where a very large directory can cause severe performance problems or even provoke the Out Of Memory killer. (For example, if there is only 512 MB memory available, a 176 MB directory may seriously cramp the system's style.)

i_version

Enable 64-bit inode version support. This option is off by default.

nombcache

This option disables use of mbcache for extended attribute deduplication. On systems where extended attributes are rarely or never shared between files, use of mbcache for deduplication adds

unnecessary computational overhead.

prjquota

The prjquota mount option enables project quota support on the file system. You need the quota utilities to actually enable and manage the quota system. This mount option requires the **project** file system feature.

FILE ATTRIBUTES

The ext2, ext3, and ext4 file systems support setting the following file attributes on Linux systems using the **chattr(1)** utility:

a - append only

A - no atime updates

d - no dump

D - synchronous directory updates

i - immutable

S - synchronous updates

u - undeletable

In addition, the ext3 and ext4 file systems support the following flag:

j - data journaling

Finally, the ext4 file system also supports the following flag:

e - extents format

For descriptions of these attribute flags, please refer to the **chattr(1)** man page.

KERNEL SUPPORT

This section lists the file system driver (e.g., ext2, ext3, ext4) and upstream kernel version where a particular file system feature was supported. Note that in some cases the feature was present in earlier kernel versions, but there were known, serious bugs. In other cases the feature may still be considered in an experimental state. Finally, note that some distributions may have backported features into older kernels; in particular the kernel versions in certain "enterprise distributions" can be extremely misleading.

filetype	ext2, 2.2.0
sparse_super	ext2, 2.2.0

NAME

ext2 – the second extended file system
ext3 – the third extended file system
ext4 – the fourth extended file system

DESCRIPTION

The second, third, and fourth extended file systems, or ext2, ext3, and ext4 as they are commonly known, are Linux file systems that have historically been the default file system for many Linux distributions. They are general purpose file systems that have been designed for extensibility and backwards compatibility. In particular, file systems previously intended for use with the ext2 and ext3 file systems can be mounted using the ext4 file system driver, and indeed in many modern Linux distributions, the ext4 file system driver has been configured to handle mount requests for ext2 and ext3 file systems.

FILE SYSTEM FEATURES

A file system formatted for ext2, ext3, or ext4 can have some collection of the following file system feature flags enabled. Some of these features are not supported by all implementations of the ext2, ext3, and ext4 file system drivers, depending on Linux kernel version in use. On other operating systems, such as the GNU/HURD or FreeBSD, only a very restrictive set of file system features may be supported in their implementations of ext2.

64bit

Enables the file system to be larger than 2^{32} blocks. This feature is set automatically, as needed, but it can be useful to specify this feature explicitly if the file system might need to be resized larger than 2^{32} blocks, even if it was smaller than that threshold when it was originally created. Note that some older kernels and older versions of e2fsprogs will not support file systems with this ext4 feature enabled.

bigalloc

This ext4 feature enables clustered block allocation, so that the unit of allocation is a power of two number of blocks. That is, each bit in the what had traditionally been known as the block allocation bitmap now indicates whether a cluster is in use or not, where a cluster is by default composed of 16 blocks. This feature can decrease the time spent on doing block allocation and brings smaller fragmentation, especially for large files. The size can be specified using the **mke2fs -C** option.

Warning: The bigalloc feature is still under development, and may not be fully supported with your kernel or may have various bugs. Please see the web page <http://ext4.wiki.kernel.org/index.php/Bigalloc> for details. May clash with delayed allocation (see **nodelalloc** mount option).

This feature requires that the **extent** feature be enabled.

casifold

This ext4 feature provides file system level character encoding support for directories with the casifold (+F) flag enabled. This feature is name-preserving on the disk, but it allows applications to lookup for a file in the file system using an encoding equivalent version of the file name.

dir_index

Use hashed b-trees to speed up name lookups in large directories. This feature is supported by ext3 and ext4 file systems, and is ignored by ext2 file systems.

dir_nlink

Normally, ext4 allows an inode to have no more than 65,000 hard links. This applies to regular files as well as directories, which means that there can be no more than 64,998 subdirectories in a directory (because each of the '.' and '..' entries, as well as the directory entry for the directory in its parent directory counts as a hard link). This feature lifts this limit by causing ext4 to use a link count of 1 to indicate that the number of hard links to a directory is not known when the link count might exceed the maximum count limit.

ea_inode

Normally, a file's extended attributes and associated metadata must fit within the inode or the inode's associated extended attribute block. This feature allows the value of each extended attribute to be placed in the data blocks of a separate inode if necessary, increasing the limit on the size and number of extended attributes per file.

encrypt

Enables support for file-system level encryption of data blocks and file names. The inode metadata (timestamps, file size, user/group ownership, etc.) is *not* encrypted.

This feature is most useful on file systems with multiple users, or where not all files should be encrypted. In many use cases, especially on single-user systems, encryption at the block device layer using dm-crypt may provide much better security.

ext_attr

This feature enables the use of extended attributes. This feature is supported by ext2, ext3, and ext4.

extent

This ext4 feature allows the mapping of logical block numbers for a particular inode to physical blocks on the storage device to be stored using an extent tree, which is a more efficient data structure than the traditional indirect block scheme used by the ext2 and ext3 file systems. The use of the extent tree decreases metadata block overhead, improves file system performance, and decreases the need to run **e2fsck(8)** on the file system. (Note: both **extent** and **extents** are accepted as valid names for this feature for historical/backwards compatibility reasons.)

extra_isize

This ext4 feature reserves a specific amount of space in each inode for extended metadata such as nanosecond timestamps and file creation time, even if the current kernel does not currently need to reserve this much space. Without this feature, the kernel will reserve the amount of space for features it currently needs, and the rest may be consumed by extended attributes.

For this feature to be useful the inode size must be 256 bytes in size or larger.

filetype

This feature enables the storage of file type information in directory entries. This feature is supported by ext2, ext3, and ext4.

flex_bg

This ext4 feature allows the per-block group metadata (allocation bitmaps and inode tables) to be placed anywhere on the storage media. In addition, **mke2fs** will place the per-block group metadata together starting at the first block group of each "flex_bg group". The size of the **flex_bg** group can be specified using the **-G** option.

has_journal

Create a journal to ensure file system consistency even across unclean shutdowns. Setting the file system feature is equivalent to using the **-j** option with **mke2fs** or **tune2fs**. This feature is supported by ext3 and ext4, and ignored by the ext2 file system driver.

huge_file

This ext4 feature allows files to be larger than 2 terabytes in size.

inline_data

Allow data to be stored in the inode and extended attribute area.

journal_dev

This feature is enabled on the superblock found on an external journal device. The block size for the external journal must be the same as the file system which uses it.

The external journal device can be used by a file system by specifying the **-J device=<external-device>** option to **mke2fs(8)** or **tune2fs(8)**.

large_dir

This feature increases the limit on the number of files per directory by raising the maximum size of directories and, for hashed b-tree directories (see **dir_index**), the maximum height of the hashed b-tree used to store the directory entries.

large_file

This feature flag is set automatically by modern kernels when a file larger than 2 gigabytes is created. Very old kernels could not handle large files, so this feature flag was used to prohibit those kernels from mounting file systems that they could not understand.

metadata_csum

This ext4 feature enables metadata checksumming. This feature stores checksums for all of the file system metadata (superblock, group descriptor blocks, inode and block bitmaps, directories, and extent tree blocks). The checksum algorithm used for the metadata blocks is different than the one used for group descriptors with the **uninit_bg** feature. These two features are incompatible and **metadata_csum** will be used preferentially instead of **uninit_bg**.

metadata_csum_seed

This feature allows the file system to store the metadata checksum seed in the superblock, which allows the administrator to change the UUID of a file system using the **metadata_csum** feature while it is mounted.

meta_bg

This ext4 feature allows file systems to be resized on-line without explicitly needing to reserve space for growth in the size of the block group descriptors. This scheme is also used to resize file systems which are larger than 2^{32} blocks. It is not recommended that this feature be set when a file system is created, since this alternate method of storing the block group descriptors will slow down the time needed to mount the file system, and newer kernels can automatically set this feature as necessary when doing an online resize and no more reserved space is available in the resize inode.

mmp

This ext4 feature provides multiple mount protection (MMP). MMP helps to protect the file system from being multiply mounted and is useful in shared storage environments.

project

This ext4 feature provides project quota support. With this feature, the project ID of inode will be managed when the file system is mounted.

quota

Create quota inodes (inode #3 for userquota and inode #4 for group quota) and set them in the superblock. With this feature, the quotas will be enabled automatically when the file system is mounted.

Causes the quota files (i.e., user.quota and group.quota which existed in the older quota design) to be hidden inodes.

resize_inode

This file system feature indicates that space has been reserved so that the block group descriptor table can be extended while resizing a mounted file system. The online resize operation is carried out by the kernel, triggered by **resize2fs(8)**. By default **mke2fs** will attempt to reserve enough space so that the file system may grow to 1024 times its initial size. This can be changed using the **resize** extended option.

This feature requires that the **sparse_super** or **sparse_super2** feature be enabled.

sparse_super

This file system feature is set on all modern ext2, ext3, and ext4 file systems. It indicates that backup copies of the superblock and block group descriptors are present only in a few block groups, not all of them.

sparse_super2

This feature indicates that there will only be at most two backup superblocks and block group descriptors. The block groups used to store the backup superblock(s) and blockgroup descriptor(s) are stored in the superblock, but typically, one will be located at the beginning of block group #1, and one in the last block group in the file system. This feature is essentially a more extreme version of sparse_super and is designed to allow a much larger percentage of the disk to have contiguous blocks available for data files.

stable_inodes

Marks the file system's inode numbers and UUID as stable. **r esize2fs(8)** will not allow shrinking a file system with this feature, nor will **tune2fs(8)** allow changing its UUID. This feature allows the use of specialized encryption settings that make use of the inode numbers and UUID. Note that the **encrypt** feature still needs to be enabled separately. **stable_inodes** is a "compat" feature, so old kernels will allow it.

uninit_bg

This ext4 file system feature indicates that the block group descriptors will be protected using checksums, making it safe for **mke2fs(8)** to create a file system without initializing all of the block groups. The kernel will keep a high watermark of unused inodes, and initialize inode tables and blocks lazily. This feature speeds up the time to check the file system using **e2fsck(8)**, and it also speeds up the time required for **mke2fs(8)** to create the file system.

verity

Enables support for verity protected files. Verity files are readonly, and their data is transparently verified against a Merkle tree hidden past the end of the file. Using the Merkle tree's root hash, a verity file can be efficiently authenticated, independent of the file's size.

This feature is most useful for authenticating important read-only files on read-write file systems. If the file system itself is read-only, then using dm-verity to authenticate the entire block device may provide much better security.

MOUNT OPTIONS

This section describes mount options which are specific to ext2, ext3, and ext4. Other generic mount options may be used as well; see **mount(8)** for details.

Mount options for ext2

The 'ext2' file system is the standard Linux file system. Since Linux 2.5.46, for most mount options the default is determined by the file system superblock. Set them with **tune2fs(8)**.

acl|noacl

Support POSIX Access Control Lists (or not). See the **acl(5)** manual page.

bsddf|minixdf

Set the behavior for the *statfs* system call. The **minixdf** behavior is to return in the *f_blocks* field the total number of blocks of the file system, while the **bsddf** behavior (which is the default) is to subtract the overhead blocks used by the ext2 file system and not available for file storage. Thus

```
% mount /k -o minixdf; df /k; umount /k
```

File System	1024-blocks	Used	Available	Capacity	Mounted on
/dev/sda6	2630655	86954	2412169	3%	/k

```
% mount /k -o bsddf; df /k; umount /k
```

File System	1024-blocks	Used	Available	Capacity	Mounted on
/dev/sda6	2543714	13	2412169	0%	/k

(Note that this example shows that one can add command line options to the options given in */etc/fstab*.)

check=none or nocheck

No checking is done at mount time. This is the default. This is fast. It is wise to invoke **e2fsck(8)** every now and then, e.g. at boot time. The non-default behavior is unsupported (check=normal and check=strict options have been removed). Note that these mount options don't have to be supported if ext4 kernel driver is used for ext2 and ext3 file systems.

debug Print debugging info upon each (re)mount.

errors={continue|remount-ro|panic}

Define the behavior when an error is encountered. (Either ignore errors and just mark the file system erroneous and continue, or remount the file system read-only, or panic and halt the system.) The default is set in the file system superblock, and can be changed using **tune2fs(8)**.

grpuid|bsdgroups and nogrpid|sysvgroups

These options define what group id a newly created file gets. When **grpuid** is set, it takes the group id of the directory in which it is created; otherwise (the default) it takes the fsgid of the current process, unless the directory has the setgid bit set, in which case it takes the gid from the parent directory, and also gets the setgid bit set if it is a directory itself.

grpquota|noquota|quota|usrquota

The **usrquota** (same as **quota**) mount option enables user quota support on the file system. **grpquota** enables group quotas support. You need the quota utilities to actually enable and manage the quota system.

nouid32

Disables 32-bit UIDs and GIDs. This is for interoperability with older kernels which only store and expect 16-bit values.

oldalloc or orlov

Use old allocator or Orlov allocator for new inodes. Orlov is default.

resgid=n and resuid=n

The ext2 file system reserves a certain percentage of the available space (by default 5%, see **mke2fs(8)** and **tune2fs(8)**). These options determine who can use the reserved blocks. (Roughly: whoever has the specified uid, or belongs to the specified group.)

sb=n Instead of using the normal superblock, use an alternative superblock specified by *n*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system's blocksize, the number of blocks per group, and features such as **sparse_super**.

Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system's layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).

The block number here uses 1 k units. Thus, if you want to use logical block 32768 on a file system with 4 k blocks, use "sb=131072".

user_xattr|nouser_xattr

Support "user." extended attributes (or not).

Mount options for ext3

The ext3 file system is a version of the ext2 file system which has been enhanced with journaling. It supports the same options as ext2 as well as the following additions:

journal_dev=devnum/journal_path=path

When the external journal device's major/minor numbers have changed, these options allow the user to specify the new journal location. The journal device is identified either through its new major/minor numbers encoded in devnum, or via a path to the device.

norecovery/noload

Don't load the journal on mounting. Note that if the file system was not unmounted cleanly, skipping the journal replay will lead to the file system containing inconsistencies that can lead to any number of problems.

data={journal|ordered|writeback}

Specifies the journaling mode for file data. Metadata is always journaled. To use modes other than **ordered** on the root file system, pass the mode to the kernel as boot parameter, e.g. *root-flags=data=journal*.

journal

All data is committed into the journal prior to being written into the main file system.

ordered

This is the default mode. All data is forced directly out to the main file system prior to its metadata being committed to the journal.

writeback

Data ordering is not preserved – data may be written into the main file system after its metadata has been committed to the journal. This is rumoured to be the highest-throughput option. It guarantees internal file system integrity, however it can allow old data to appear in files after a crash and journal recovery.

data_err=ignore

Just print an error message if an error occurs in a file data buffer in ordered mode.

data_err=abort

Abort the journal if an error occurs in a file data buffer in ordered mode.

barrier=0 / barrier=1

This disables / enables the use of write barriers in the jbd code. barrier=0 disables, barrier=1 enables (default). This also requires an IO stack which can support barriers, and if jbd gets an error on a barrier write, it will disable barriers again with a warning. Write barriers enforce proper on-disk ordering of journal commits, making volatile disk write caches safe to use, at some performance penalty. If your disks are battery-backed in one way or another, disabling barriers may safely improve performance.

commit=nrsec

Start a journal commit every *nrsec* seconds. The default value is 5 seconds. Zero means default.

user_xattr

Enable Extended User Attributes. See the **attr(5)** manual page.

jqfmt={vfsold|vfsv0|vfsv1}

Apart from the old quota system (as in ext2, jqfmt=vfsold aka version 1 quota) ext3 also supports journaled quotas (version 2 quota). jqfmt=vfsv0 or jqfmt=vfsv1 enables journaled quotas. Journaled quotas have the advantage that even after a crash no quota check is required. When the **quota** file system feature is enabled, journaled quotas are used automatically, and this mount option is ignored.

usrjquota=aquota.user|grpjquota=aquota.group

For journaled quotas (jqfmt=vfsv0 or jqfmt=vfsv1), the mount options **usrjquota=aquota.user** and **grpjquota=aquota.group** are required to tell the quota system which quota database files to use. When the **quota** file system feature is enabled, journaled quotas are used automatically, and this mount option is ignored.

Mount options for ext4

The ext4 file system is an advanced level of the ext3 file system which incorporates scalability and reliability enhancements for supporting large file system.

The options **journal_dev**, **journal_path**, **norecovery**, **noload**, **data**, **commit**, **orlov**, **oldalloc**,

[no]user_xattr, [no]acl, bsddf, minixdf, debug, errors, data_err, grpid, bsdgroups, nogrpid, sysv-groups, resgid, resuid, sb, quota, noquota, nouid32, grpquota, usrquota, usrjquota, grpquota, and jqfmt are backwardly compatible with ext3 or ext2.

journal_checksum | nojournal_checksum

The journal_checksum option enables checksumming of the journal transactions. This will allow the recovery code in e2fsck and the kernel to detect corruption in the kernel. It is a compatible change and will be ignored by older kernels.

journal_async_commit

Commit block can be written to disk without waiting for descriptor blocks. If enabled older kernels cannot mount the device. This will enable 'journal_checksum' internally.

barrier=0 / barrier=1 / barrier / nobarrier

These mount options have the same effect as in ext3. The mount options "barrier" and "nobarrier" are added for consistency with other ext4 mount options.

The ext4 file system enables write barriers by default.

inode_readahead_blks=n

This tuning parameter controls the maximum number of inode table blocks that ext4's inode table readahead algorithm will pre-read into the buffer cache. The value must be a power of 2. The default value is 32 blocks.

stripe=n

Number of file system blocks that mballoc will try to use for allocation size and alignment. For RAID5/6 systems this should be the number of data disks * RAID chunk size in file system blocks.

delalloc

Deferring block allocation until write-out time.

nodealloc

Disable delayed allocation. Blocks are allocated when data is copied from user to page cache.

max_batch_time=usec

Maximum amount of time ext4 should wait for additional file system operations to be batch together with a synchronous write operation. Since a synchronous write operation is going to force a commit and then a wait for the I/O complete, it doesn't cost much, and can be a huge throughput win, we wait for a small amount of time to see if any other transactions can piggyback on the synchronous write. The algorithm used is designed to automatically tune for the speed of the disk, by measuring the amount of time (on average) that it takes to finish committing a transaction. Call this time the "commit time". If the time that the transaction has been running is less than the commit time, ext4 will try sleeping for the commit time to see if other operations will join the transaction. The commit time is capped by the max_batch_time, which defaults to 15000 µs (15 ms). This optimization can be turned off entirely by setting max_batch_time to 0.

min_batch_time=usec

This parameter sets the commit time (as described above) to be at least min_batch_time. It defaults to zero microseconds. Increasing this parameter may improve the throughput of multi-threaded, synchronous workloads on very fast disks, at the cost of increasing latency.

journal_ioprio=prio

The I/O priority (from 0 to 7, where 0 is the highest priority) which should be used for I/O operations submitted by kjournald2 during a commit operation. This defaults to 3, which is a slightly higher priority than the default I/O priority.

abort Simulate the effects of calling ext4_abort() for debugging purposes. This is normally used while remounting a file system which is already mounted.

auto_da_alloc|noauto_da_alloc

Many broken applications don't use fsync() when replacing existing files via patterns such as

```
fd = open("foo.new")/write(fd,...)/close(fd)/ rename("foo.new", "foo")
```

or worse yet

```
fd = open("foo", O_TRUNC)/write(fd,...)/close(fd).
```

If auto_da_alloc is enabled, ext4 will detect the replace-via-rename and replace-via-truncate patterns and force that any delayed allocation blocks are allocated such that at the next journal commit, in the default data=ordered mode, the data blocks of the new file are forced to disk before the rename() operation is committed. This provides roughly the same level of guarantees as ext3, and avoids the "zero-length" problem that can happen when a system crashes before the delayed allocation blocks are forced to disk.

noinit_itable

Do not initialize any uninitialized inode table blocks in the background. This feature may be used by installation CD's so that the install process can complete as quickly as possible; the inode table initialization process would then be deferred until the next time the file system is mounted.

init_itable=n

The lazy itable init code will wait n times the number of milliseconds it took to zero out the previous block group's inode table. This minimizes the impact on system performance while the file system's inode table is being initialized.

discard/nodiscard

Controls whether ext4 should issue discard/TRIM commands to the underlying block device when blocks are freed. This is useful for SSD devices and sparse/thinly-provisioned LUNs, but it is off by default until sufficient testing has been done.

block_validity/noblock_validity

This option enables/disables the in-kernel facility for tracking file system metadata blocks within internal data structures. This allows multi-block allocator and other routines to quickly locate extents which might overlap with file system metadata blocks. This option is intended for debugging purposes and since it negatively affects the performance, it is off by default.

dioread_lock/dioread_nolock

Controls whether or not ext4 should use the DIO read locking. If the dioread_nolock option is specified ext4 will allocate uninitialized extent before buffer write and convert the extent to initialized after IO completes. This approach allows ext4 code to avoid using inode mutex, which improves scalability on high speed storages. However this does not work with data journaling and dioread_nolock option will be ignored with kernel warning. Note that dioread_nolock code path is only used for extent-based files. Because of the restrictions this options comprises it is off by default (e.g. dioread_lock).

max_dir_size_kb=n

This limits the size of the directories so that any attempt to expand them beyond the specified limit in kilobytes will cause an ENOSPC error. This is useful in memory-constrained environments, where a very large directory can cause severe performance problems or even provoke the Out Of Memory killer. (For example, if there is only 512 MB memory available, a 176 MB directory may seriously cramp the system's style.)

i_version

Enable 64-bit inode version support. This option is off by default.

nombcache

This option disables use of mbcache for extended attribute deduplication. On systems where extended attributes are rarely or never shared between files, use of mbcache for deduplication adds

unnecessary computational overhead.

prjquota

The prjquota mount option enables project quota support on the file system. You need the quota utilities to actually enable and manage the quota system. This mount option requires the **project** file system feature.

FILE ATTRIBUTES

The ext2, ext3, and ext4 file systems support setting the following file attributes on Linux systems using the **chattr(1)** utility:

a - append only

A - no atime updates

d - no dump

D - synchronous directory updates

i - immutable

S - synchronous updates

u - undeletable

In addition, the ext3 and ext4 file systems support the following flag:

j - data journaling

Finally, the ext4 file system also supports the following flag:

e - extents format

For descriptions of these attribute flags, please refer to the **chattr(1)** man page.

KERNEL SUPPORT

This section lists the file system driver (e.g., ext2, ext3, ext4) and upstream kernel version where a particular file system feature was supported. Note that in some cases the feature was present in earlier kernel versions, but there were known, serious bugs. In other cases the feature may still be considered in an experimental state. Finally, note that some distributions may have backported features into older kernels; in particular the kernel versions in certain "enterprise distributions" can be extremely misleading.

filetype	ext2, 2.2.0
sparse_super	ext2, 2.2.0

NAME

ext2 – the second extended file system
ext3 – the third extended file system
ext4 – the fourth extended file system

DESCRIPTION

The second, third, and fourth extended file systems, or ext2, ext3, and ext4 as they are commonly known, are Linux file systems that have historically been the default file system for many Linux distributions. They are general purpose file systems that have been designed for extensibility and backwards compatibility. In particular, file systems previously intended for use with the ext2 and ext3 file systems can be mounted using the ext4 file system driver, and indeed in many modern Linux distributions, the ext4 file system driver has been configured to handle mount requests for ext2 and ext3 file systems.

FILE SYSTEM FEATURES

A file system formatted for ext2, ext3, or ext4 can have some collection of the following file system feature flags enabled. Some of these features are not supported by all implementations of the ext2, ext3, and ext4 file system drivers, depending on Linux kernel version in use. On other operating systems, such as the GNU/HURD or FreeBSD, only a very restrictive set of file system features may be supported in their implementations of ext2.

64bit

Enables the file system to be larger than 2^{32} blocks. This feature is set automatically, as needed, but it can be useful to specify this feature explicitly if the file system might need to be resized larger than 2^{32} blocks, even if it was smaller than that threshold when it was originally created. Note that some older kernels and older versions of e2fsprogs will not support file systems with this ext4 feature enabled.

bigalloc

This ext4 feature enables clustered block allocation, so that the unit of allocation is a power of two number of blocks. That is, each bit in the what had traditionally been known as the block allocation bitmap now indicates whether a cluster is in use or not, where a cluster is by default composed of 16 blocks. This feature can decrease the time spent on doing block allocation and brings smaller fragmentation, especially for large files. The size can be specified using the **mke2fs -C** option.

Warning: The bigalloc feature is still under development, and may not be fully supported with your kernel or may have various bugs. Please see the web page <http://ext4.wiki.kernel.org/index.php/Bigalloc> for details. May clash with delayed allocation (see **nodelalloc** mount option).

This feature requires that the **extent** feature be enabled.

casifold

This ext4 feature provides file system level character encoding support for directories with the casifold (+F) flag enabled. This feature is name-preserving on the disk, but it allows applications to lookup for a file in the file system using an encoding equivalent version of the file name.

dir_index

Use hashed b-trees to speed up name lookups in large directories. This feature is supported by ext3 and ext4 file systems, and is ignored by ext2 file systems.

dir_nlink

Normally, ext4 allows an inode to have no more than 65,000 hard links. This applies to regular files as well as directories, which means that there can be no more than 64,998 subdirectories in a directory (because each of the '.' and '..' entries, as well as the directory entry for the directory in its parent directory counts as a hard link). This feature lifts this limit by causing ext4 to use a link count of 1 to indicate that the number of hard links to a directory is not known when the link count might exceed the maximum count limit.

ea_inode

Normally, a file's extended attributes and associated metadata must fit within the inode or the inode's associated extended attribute block. This feature allows the value of each extended attribute to be placed in the data blocks of a separate inode if necessary, increasing the limit on the size and number of extended attributes per file.

encrypt

Enables support for file-system level encryption of data blocks and file names. The inode metadata (timestamps, file size, user/group ownership, etc.) is *not* encrypted.

This feature is most useful on file systems with multiple users, or where not all files should be encrypted. In many use cases, especially on single-user systems, encryption at the block device layer using dm-crypt may provide much better security.

ext_attr

This feature enables the use of extended attributes. This feature is supported by ext2, ext3, and ext4.

extent

This ext4 feature allows the mapping of logical block numbers for a particular inode to physical blocks on the storage device to be stored using an extent tree, which is a more efficient data structure than the traditional indirect block scheme used by the ext2 and ext3 file systems. The use of the extent tree decreases metadata block overhead, improves file system performance, and decreases the need to run **e2fsck(8)** on the file system. (Note: both **extent** and **extents** are accepted as valid names for this feature for historical/backwards compatibility reasons.)

extra_isize

This ext4 feature reserves a specific amount of space in each inode for extended metadata such as nanosecond timestamps and file creation time, even if the current kernel does not currently need to reserve this much space. Without this feature, the kernel will reserve the amount of space for features it currently needs, and the rest may be consumed by extended attributes.

For this feature to be useful the inode size must be 256 bytes in size or larger.

filetype

This feature enables the storage of file type information in directory entries. This feature is supported by ext2, ext3, and ext4.

flex_bg

This ext4 feature allows the per-block group metadata (allocation bitmaps and inode tables) to be placed anywhere on the storage media. In addition, **mke2fs** will place the per-block group metadata together starting at the first block group of each "flex_bg group". The size of the **flex_bg** group can be specified using the **-G** option.

has_journal

Create a journal to ensure file system consistency even across unclean shutdowns. Setting the file system feature is equivalent to using the **-j** option with **mke2fs** or **tune2fs**. This feature is supported by ext3 and ext4, and ignored by the ext2 file system driver.

huge_file

This ext4 feature allows files to be larger than 2 terabytes in size.

inline_data

Allow data to be stored in the inode and extended attribute area.

journal_dev

This feature is enabled on the superblock found on an external journal device. The block size for the external journal must be the same as the file system which uses it.

The external journal device can be used by a file system by specifying the **-J device=<external-device>** option to **mke2fs(8)** or **tune2fs(8)**.

large_dir

This feature increases the limit on the number of files per directory by raising the maximum size of directories and, for hashed b-tree directories (see **dir_index**), the maximum height of the hashed b-tree used to store the directory entries.

large_file

This feature flag is set automatically by modern kernels when a file larger than 2 gigabytes is created. Very old kernels could not handle large files, so this feature flag was used to prohibit those kernels from mounting file systems that they could not understand.

metadata_csum

This ext4 feature enables metadata checksumming. This feature stores checksums for all of the file system metadata (superblock, group descriptor blocks, inode and block bitmaps, directories, and extent tree blocks). The checksum algorithm used for the metadata blocks is different than the one used for group descriptors with the **uninit_bg** feature. These two features are incompatible and **metadata_csum** will be used preferentially instead of **uninit_bg**.

metadata_csum_seed

This feature allows the file system to store the metadata checksum seed in the superblock, which allows the administrator to change the UUID of a file system using the **metadata_csum** feature while it is mounted.

meta_bg

This ext4 feature allows file systems to be resized on-line without explicitly needing to reserve space for growth in the size of the block group descriptors. This scheme is also used to resize file systems which are larger than 2^{32} blocks. It is not recommended that this feature be set when a file system is created, since this alternate method of storing the block group descriptors will slow down the time needed to mount the file system, and newer kernels can automatically set this feature as necessary when doing an online resize and no more reserved space is available in the resize inode.

mmp

This ext4 feature provides multiple mount protection (MMP). MMP helps to protect the file system from being multiply mounted and is useful in shared storage environments.

project

This ext4 feature provides project quota support. With this feature, the project ID of inode will be managed when the file system is mounted.

quota

Create quota inodes (inode #3 for userquota and inode #4 for group quota) and set them in the superblock. With this feature, the quotas will be enabled automatically when the file system is mounted.

Causes the quota files (i.e., user.quota and group.quota which existed in the older quota design) to be hidden inodes.

resize_inode

This file system feature indicates that space has been reserved so that the block group descriptor table can be extended while resizing a mounted file system. The online resize operation is carried out by the kernel, triggered by **resize2fs(8)**. By default **mke2fs** will attempt to reserve enough space so that the file system may grow to 1024 times its initial size. This can be changed using the **resize** extended option.

This feature requires that the **sparse_super** or **sparse_super2** feature be enabled.

sparse_super

This file system feature is set on all modern ext2, ext3, and ext4 file systems. It indicates that backup copies of the superblock and block group descriptors are present only in a few block groups, not all of them.

sparse_super2

This feature indicates that there will only be at most two backup superblocks and block group descriptors. The block groups used to store the backup superblock(s) and blockgroup descriptor(s) are stored in the superblock, but typically, one will be located at the beginning of block group #1, and one in the last block group in the file system. This feature is essentially a more extreme version of sparse_super and is designed to allow a much larger percentage of the disk to have contiguous blocks available for data files.

stable_inodes

Marks the file system's inode numbers and UUID as stable. **r esize2fs(8)** will not allow shrinking a file system with this feature, nor will **tune2fs(8)** allow changing its UUID. This feature allows the use of specialized encryption settings that make use of the inode numbers and UUID. Note that the **encrypt** feature still needs to be enabled separately. **stable_inodes** is a "compat" feature, so old kernels will allow it.

uninit_bg

This ext4 file system feature indicates that the block group descriptors will be protected using checksums, making it safe for **mke2fs(8)** to create a file system without initializing all of the block groups. The kernel will keep a high watermark of unused inodes, and initialize inode tables and blocks lazily. This feature speeds up the time to check the file system using **e2fsck(8)**, and it also speeds up the time required for **mke2fs(8)** to create the file system.

verity

Enables support for verity protected files. Verity files are readonly, and their data is transparently verified against a Merkle tree hidden past the end of the file. Using the Merkle tree's root hash, a verity file can be efficiently authenticated, independent of the file's size.

This feature is most useful for authenticating important read-only files on read-write file systems. If the file system itself is read-only, then using dm-verity to authenticate the entire block device may provide much better security.

MOUNT OPTIONS

This section describes mount options which are specific to ext2, ext3, and ext4. Other generic mount options may be used as well; see **mount(8)** for details.

Mount options for ext2

The 'ext2' file system is the standard Linux file system. Since Linux 2.5.46, for most mount options the default is determined by the file system superblock. Set them with **tune2fs(8)**.

acl|noacl

Support POSIX Access Control Lists (or not). See the **acl(5)** manual page.

bsddf|minixdf

Set the behavior for the *statfs* system call. The **minixdf** behavior is to return in the *f_blocks* field the total number of blocks of the file system, while the **bsddf** behavior (which is the default) is to subtract the overhead blocks used by the ext2 file system and not available for file storage. Thus

```
% mount /k -o minixdf; df /k; umount /k
```

File System	1024-blocks	Used	Available	Capacity	Mounted on
/dev/sda6	2630655	86954	2412169	3%	/k

```
% mount /k -o bsddf; df /k; umount /k
```

File System	1024-blocks	Used	Available	Capacity	Mounted on
/dev/sda6	2543714	13	2412169	0%	/k

(Note that this example shows that one can add command line options to the options given in */etc/fstab*.)

check=none or nocheck

No checking is done at mount time. This is the default. This is fast. It is wise to invoke **e2fsck(8)** every now and then, e.g. at boot time. The non-default behavior is unsupported (check=normal and check=strict options have been removed). Note that these mount options don't have to be supported if ext4 kernel driver is used for ext2 and ext3 file systems.

debug Print debugging info upon each (re)mount.

errors={continue|remount-ro|panic}

Define the behavior when an error is encountered. (Either ignore errors and just mark the file system erroneous and continue, or remount the file system read-only, or panic and halt the system.) The default is set in the file system superblock, and can be changed using **tune2fs(8)**.

grpid|bsdgroups and nogrpid|sysvgroups

These options define what group id a newly created file gets. When **grpid** is set, it takes the group id of the directory in which it is created; otherwise (the default) it takes the fsgid of the current process, unless the directory has the setgid bit set, in which case it takes the gid from the parent directory, and also gets the setgid bit set if it is a directory itself.

grpquota|noquota|quota|usrquota

The **usrquota** (same as **quota**) mount option enables user quota support on the file system. **grpquota** enables group quotas support. You need the quota utilities to actually enable and manage the quota system.

nouid32

Disables 32-bit UIDs and GIDs. This is for interoperability with older kernels which only store and expect 16-bit values.

oldalloc or orlov

Use old allocator or Orlov allocator for new inodes. Orlov is default.

resgid=n and resuid=n

The ext2 file system reserves a certain percentage of the available space (by default 5%, see **mke2fs(8)** and **tune2fs(8)**). These options determine who can use the reserved blocks. (Roughly: whoever has the specified uid, or belongs to the specified group.)

sb=n Instead of using the normal superblock, use an alternative superblock specified by *n*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system's blocksize, the number of blocks per group, and features such as **sparse_super**.

Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system's layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).

The block number here uses 1 k units. Thus, if you want to use logical block 32768 on a file system with 4 k blocks, use "sb=131072".

user_xattr|nouser_xattr

Support "user." extended attributes (or not).

Mount options for ext3

The ext3 file system is a version of the ext2 file system which has been enhanced with journaling. It supports the same options as ext2 as well as the following additions:

journal_dev=devnum/journal_path=path

When the external journal device's major/minor numbers have changed, these options allow the user to specify the new journal location. The journal device is identified either through its new major/minor numbers encoded in devnum, or via a path to the device.

norecovery/noload

Don't load the journal on mounting. Note that if the file system was not unmounted cleanly, skipping the journal replay will lead to the file system containing inconsistencies that can lead to any number of problems.

data={journal|ordered|writeback}

Specifies the journaling mode for file data. Metadata is always journaled. To use modes other than **ordered** on the root file system, pass the mode to the kernel as boot parameter, e.g. *root-flags=data=journal*.

journal

All data is committed into the journal prior to being written into the main file system.

ordered

This is the default mode. All data is forced directly out to the main file system prior to its metadata being committed to the journal.

writeback

Data ordering is not preserved – data may be written into the main file system after its metadata has been committed to the journal. This is rumoured to be the highest-throughput option. It guarantees internal file system integrity, however it can allow old data to appear in files after a crash and journal recovery.

data_err=ignore

Just print an error message if an error occurs in a file data buffer in ordered mode.

data_err=abort

Abort the journal if an error occurs in a file data buffer in ordered mode.

barrier=0 / barrier=1

This disables / enables the use of write barriers in the jbd code. barrier=0 disables, barrier=1 enables (default). This also requires an IO stack which can support barriers, and if jbd gets an error on a barrier write, it will disable barriers again with a warning. Write barriers enforce proper on-disk ordering of journal commits, making volatile disk write caches safe to use, at some performance penalty. If your disks are battery-backed in one way or another, disabling barriers may safely improve performance.

commit=nrsec

Start a journal commit every *nrsec* seconds. The default value is 5 seconds. Zero means default.

user_xattr

Enable Extended User Attributes. See the **attr(5)** manual page.

jqfmt={vfsold|vfsv0|vfsv1}

Apart from the old quota system (as in ext2, jqfmt=vfsold aka version 1 quota) ext3 also supports journaled quotas (version 2 quota). jqfmt=vfsv0 or jqfmt=vfsv1 enables journaled quotas. Journaled quotas have the advantage that even after a crash no quota check is required. When the **quota** file system feature is enabled, journaled quotas are used automatically, and this mount option is ignored.

usrjquota=aquota.user|grpjquota=aquota.group

For journaled quotas (jqfmt=vfsv0 or jqfmt=vfsv1), the mount options **usrjquota=aquota.user** and **grpjquota=aquota.group** are required to tell the quota system which quota database files to use. When the **quota** file system feature is enabled, journaled quotas are used automatically, and this mount option is ignored.

Mount options for ext4

The ext4 file system is an advanced level of the ext3 file system which incorporates scalability and reliability enhancements for supporting large file system.

The options **journal_dev**, **journal_path**, **norecovery**, **noload**, **data**, **commit**, **orlov**, **oldalloc**,

[no]user_xattr, [no]acl, bsddf, minixdf, debug, errors, data_err, grpid, bsdgroups, nogrpid, sysv-groups, resgid, resuid, sb, quota, noquota, nouid32, grpquota, usrquota, usrjquota, grpquota, and jqfmt are backwardly compatible with ext3 or ext2.

journal_checksum | nojournal_checksum

The journal_checksum option enables checksumming of the journal transactions. This will allow the recovery code in e2fsck and the kernel to detect corruption in the kernel. It is a compatible change and will be ignored by older kernels.

journal_async_commit

Commit block can be written to disk without waiting for descriptor blocks. If enabled older kernels cannot mount the device. This will enable 'journal_checksum' internally.

barrier=0 / barrier=1 / barrier / nobarrier

These mount options have the same effect as in ext3. The mount options "barrier" and "nobarrier" are added for consistency with other ext4 mount options.

The ext4 file system enables write barriers by default.

inode_readahead_blks=n

This tuning parameter controls the maximum number of inode table blocks that ext4's inode table readahead algorithm will pre-read into the buffer cache. The value must be a power of 2. The default value is 32 blocks.

stripe=n

Number of file system blocks that mballoc will try to use for allocation size and alignment. For RAID5/6 systems this should be the number of data disks * RAID chunk size in file system blocks.

delalloc

Deferring block allocation until write-out time.

nodealloc

Disable delayed allocation. Blocks are allocated when data is copied from user to page cache.

max_batch_time=usec

Maximum amount of time ext4 should wait for additional file system operations to be batch together with a synchronous write operation. Since a synchronous write operation is going to force a commit and then a wait for the I/O complete, it doesn't cost much, and can be a huge throughput win, we wait for a small amount of time to see if any other transactions can piggyback on the synchronous write. The algorithm used is designed to automatically tune for the speed of the disk, by measuring the amount of time (on average) that it takes to finish committing a transaction. Call this time the "commit time". If the time that the transaction has been running is less than the commit time, ext4 will try sleeping for the commit time to see if other operations will join the transaction. The commit time is capped by the max_batch_time, which defaults to 15000 µs (15 ms). This optimization can be turned off entirely by setting max_batch_time to 0.

min_batch_time=usec

This parameter sets the commit time (as described above) to be at least min_batch_time. It defaults to zero microseconds. Increasing this parameter may improve the throughput of multi-threaded, synchronous workloads on very fast disks, at the cost of increasing latency.

journal_ioprio=prio

The I/O priority (from 0 to 7, where 0 is the highest priority) which should be used for I/O operations submitted by kjournald2 during a commit operation. This defaults to 3, which is a slightly higher priority than the default I/O priority.

abort Simulate the effects of calling ext4_abort() for debugging purposes. This is normally used while remounting a file system which is already mounted.

auto_da_alloc|noauto_da_alloc

Many broken applications don't use fsync() when replacing existing files via patterns such as

```
fd = open("foo.new")/write(fd,...)/close(fd)/ rename("foo.new", "foo")
```

or worse yet

```
fd = open("foo", O_TRUNC)/write(fd,...)/close(fd).
```

If auto_da_alloc is enabled, ext4 will detect the replace-via-rename and replace-via-truncate patterns and force that any delayed allocation blocks are allocated such that at the next journal commit, in the default data=ordered mode, the data blocks of the new file are forced to disk before the rename() operation is committed. This provides roughly the same level of guarantees as ext3, and avoids the "zero-length" problem that can happen when a system crashes before the delayed allocation blocks are forced to disk.

noinit_itable

Do not initialize any uninitialized inode table blocks in the background. This feature may be used by installation CD's so that the install process can complete as quickly as possible; the inode table initialization process would then be deferred until the next time the file system is mounted.

init_itable=n

The lazy itable init code will wait n times the number of milliseconds it took to zero out the previous block group's inode table. This minimizes the impact on system performance while the file system's inode table is being initialized.

discard/nodiscard

Controls whether ext4 should issue discard/TRIM commands to the underlying block device when blocks are freed. This is useful for SSD devices and sparse/thinly-provisioned LUNs, but it is off by default until sufficient testing has been done.

block_validity/noblock_validity

This option enables/disables the in-kernel facility for tracking file system metadata blocks within internal data structures. This allows multi-block allocator and other routines to quickly locate extents which might overlap with file system metadata blocks. This option is intended for debugging purposes and since it negatively affects the performance, it is off by default.

dioread_lock/dioread_nolock

Controls whether or not ext4 should use the DIO read locking. If the dioread_nolock option is specified ext4 will allocate uninitialized extent before buffer write and convert the extent to initialized after IO completes. This approach allows ext4 code to avoid using inode mutex, which improves scalability on high speed storages. However this does not work with data journaling and dioread_nolock option will be ignored with kernel warning. Note that dioread_nolock code path is only used for extent-based files. Because of the restrictions this options comprises it is off by default (e.g. dioread_lock).

max_dir_size_kb=n

This limits the size of the directories so that any attempt to expand them beyond the specified limit in kilobytes will cause an ENOSPC error. This is useful in memory-constrained environments, where a very large directory can cause severe performance problems or even provoke the Out Of Memory killer. (For example, if there is only 512 MB memory available, a 176 MB directory may seriously cramp the system's style.)

i_version

Enable 64-bit inode version support. This option is off by default.

nombcache

This option disables use of mbcache for extended attribute deduplication. On systems where extended attributes are rarely or never shared between files, use of mbcache for deduplication adds

unnecessary computational overhead.

prjquota

The prjquota mount option enables project quota support on the file system. You need the quota utilities to actually enable and manage the quota system. This mount option requires the **project** file system feature.

FILE ATTRIBUTES

The ext2, ext3, and ext4 file systems support setting the following file attributes on Linux systems using the **chattr(1)** utility:

a - append only

A - no atime updates

d - no dump

D - synchronous directory updates

i - immutable

S - synchronous updates

u - undeletable

In addition, the ext3 and ext4 file systems support the following flag:

j - data journaling

Finally, the ext4 file system also supports the following flag:

e - extents format

For descriptions of these attribute flags, please refer to the **chattr(1)** man page.

KERNEL SUPPORT

This section lists the file system driver (e.g., ext2, ext3, ext4) and upstream kernel version where a particular file system feature was supported. Note that in some cases the feature was present in earlier kernel versions, but there were known, serious bugs. In other cases the feature may still be considered in an experimental state. Finally, note that some distributions may have backported features into older kernels; in particular the kernel versions in certain "enterprise distributions" can be extremely misleading.

filetype	ext2, 2.2.0

NAME

extlinux – install the SYSLINUX bootloader on an ext2/ext3/ext4/btrfs/xfs filesystem

SYNOPSIS

extlinux [*options*] *directory*

DESCRIPTION

EXTLINUX is a new syslinux derivative, which boots from a Linux ext2/ext3/ext4/btrfs or xfs filesystem. It works the same way as **SYSLINUX**, with a few slight modifications. It is intended to simplify first-time installation of Linux, and for creation of rescue and other special-purpose boot disks.

The installer is designed to be run on a mounted directory. For example, if you have an ext2, ext3, ext4, or btrfs usb key mounted on /mnt, you can run the following command:

```
extlinux --install /mnt
```

OPTIONS

-H, --heads=#

Force the number of heads.

-i, --install

Install over the current bootsector.

-O, --clear-once

Clear the boot-once command.

-o, --once=*command*

Execute a command once upon boot.

-M, --menu-save=*label*

Set the label to select as default on the next boot

-r, --raid

Fall back to the next device on boot failure.

--reset-adv

Reset auxiliary data.

-S, --sectors=#

Force the number of sectors per track.

-U, --update

Updates a previous **EXTLINUX** installation.

-z, --zip

Force zipdrive geometry (-H 64 -S 32).

--device=*devicename*

Override the automatic detection of device names. This option is intended for special environments only and should not be used by normal users. Misuse of this option can cause disk corruption and lost data.

FILES

The extlinux configuration file needs to be named syslinux.cfg or extlinux.conf and needs to be stored in the extlinux installation directory. For more information about the contents of extlinux.conf, see syslinux(1) manpage, section files.

LIMITATIONS

Booting from XFS only works when an MBR partition table is used (not on GPT partition tables).

BUGS

I would appreciate hearing of any problems you have with SYSLINUX. I would also like to hear from you if you have successfully used SYSLINUX, especially if you are using it for a distribution.

If you are reporting problems, please include all possible information about your system and your BIOS; the vast majority of all problems reported turn out to be BIOS or hardware bugs, and I need as much

information as possible in order to diagnose the problems.

There is a mailing list `<syslinux@zytor.com>` for discussion among SYSLINUX users and for announcements of new and test versions. You can subscribe to this mailing list `<http://www.zytor.com/mailman/listinfo/syslinux>`.

NAME

fatlabel – set or get MS-DOS filesystem label or volume ID

SYNOPSIS

fatlabel [*OPTIONS*] *DEVICE* [*NEW*]

DESCRIPTION

fatlabel will display or change the volume label or volume ID on the MS-DOS filesystem located on *DEVICE*. By default it works in label mode. It can be switched to volume ID mode with the option **-i** or **--volume-id**.

If *NEW* is omitted, then the existing label or volume ID is written to the standard output. A label can't be longer than 11 bytes and should be in all upper case for best compatibility. An empty string or a label consisting only of white space is not allowed. A volume ID must be given as a hexadecimal number (no leading "0x" or similar) and must fit into 32 bits.

OPTIONS

-i, --volume-id

Switch to volume ID mode.

-r, --reset

Remove label in label mode or generate new ID in volume ID mode.

-c PAGE, --codepage=PAGE

Use DOS codepage *PAGE* to encode/decode label. By default codepage 850 is used.

-h, --help

Display a help message and terminate.

-V, --version

Show version number and terminate.

COMPATIBILITY and BUGS

For historic reasons FAT label is stored in two different locations: in the boot sector and as a special volume label entry in the root directory. MS-DOS 5.00, MS-DOS 6.22, MS-DOS 7.10, Windows 98, Windows XP and also Windows 10 read FAT label only from the root directory. Absence of the volume label in the root directory is interpreted as empty or none label, even if boot sector contains some valid label.

When Windows XP or Windows 10 system changes a FAT label it stores it only in the root directory — letting boot sector unchanged. Which leads to problems when a label is removed on Windows. Old label is still stored in the boot sector but is removed from the root directory.

dosfslabel prior to the version 3.0.7 operated only with FAT labels stored in the boot sector, completely ignoring a volume label in the root directory.

dosfslabel in versions 3.0.7–3.0.15 reads FAT labels from the root directory and in case of absence, it fall-backs to a label stored in the boot sector. Change operation resulted in updating a label in the boot sector and *sometimes* also in the root directory due to the bug. That bug was fixed in **dosfslabel** version 3.0.16 and since this version **dosfslabel** updates label in both location.

Since version 4.2, **fatlabel** reads a FAT label only from the root directory (like MS-DOS and Windows systems), but changes a FAT label in both locations. In version 4.2 was fixed handling of empty labels and labels which starts with a byte 0xE5. Also in this version was added support for non-ASCII labels according to the specified DOS codepage and were added checks if a new label is valid.

It is strongly suggested to not use **dosfslabel** prior to version 3.0.16.

DOS CODEPAGES

MS-DOS and Windows systems use DOS (OEM) codepage for encoding and decoding FAT label. In Windows systems DOS codepage is global for all running applications and cannot be configured explicitly. It is

set implicitly by option *Language for non-Unicode programs* available in *Regional and Language Options* via *Control Panel*. Default DOS codepage for fatlabel is 850. See following mapping table between DOS codepage and Language for non-Unicode programs:

Codepage	Language
437	English (India), English (Malaysia), English (Republic of the Philippines), English (Singapore), English (South Africa), English (United States), English (Zimbabwe), Filipino, Hausa, Igbo, Inuktitut, Kinyarwanda, Kiswahili, Yoruba
720	Arabic, Dari, Persian, Urdu, Uyghur
737	Greek
775	Estonian, Latvian, Lithuanian
850	Afrikaans, Alsatian, Basque, Breton, Catalan, Corsican, Danish, Dutch, English (Australia), English (Belize), English (Canada), English (Caribbean), English (Ireland), English (Jamaica), English (New Zealand), English (Trinidad and Tobago), English (United Kingdom), Faroese, Finnish, French, Frisian, Galician, German, Greenlandic, Icelandic, Indonesian, Irish, isiXhosa, isiZulu, Italian, K'iche, Lower Sorbian, Luxembourgish, Malay, Mapudungun, Mohawk, Norwegian, Occitan, Portuguese, Quechua, Romansh, Sami, Scottish Gaelic, Sesotho sa Leboa, Setswana, Spanish, Swedish, Tamazight, Upper Sorbian, Welsh, Wolof
852	Albanian, Bosnian (Latin), Croatian, Czech, Hungarian, Polish, Romanian, Serbian (Latin), Slovak, Slovenian, Turkmen
855	Bosnian (Cyrillic), Serbian (Cyrillic)
857	Azeri (Latin), Turkish, Uzbek (Latin)
862	Hebrew
866	Azeri (Cyrillic), Bashkir, Belarusian, Bulgarian, Kyrgyz, Macedonian, Mongolian, Russian, Tajik, Tatar, Ukrainian, Uzbek (Cyrillic), Yakut
874	Thai
932	Japanese
936	Chinese (Simplified)
949	Korean
950	Chinese (Traditional)
1258	Vietnamese

NAME

fdisk – manipulate disk partition table

SYNOPSIS

fdisk [options] *device*

fdisk -l [*device...*]

DESCRIPTION

fdisk is a dialog–driven program for creation and manipulation of partition tables. It understands GPT, MBR, Sun, SGI and BSD partition tables.

Block devices can be divided into one or more logical disks called *partitions*. This division is recorded in the *partition table*, usually found in sector 0 of the disk. (In the BSD world one talks about ‘disk slices’ and a ‘disklabel’.)

All partitioning is driven by device I/O limits (the topology) by default. **fdisk** is able to optimize the disk layout for a 4K–sector size and use an alignment offset on modern devices for MBR and GPT. It is always a good idea to follow **fdisk**’s defaults as the default values (e.g., first and last partition sectors) and partition sizes specified by the +/−<size>{M,G,...} notation are always aligned according to the device properties.

CHS (Cylinder–Head–Sector) addressing is deprecated and not used by default. Please, do not follow old articles and recommendations with **fdisk -S <n> -H <n>** advices for SSD or 4K–sector devices.

Note that **partx(8)** provides a rich interface for scripts to print disk layouts, **fdisk** is mostly designed for humans. Backward compatibility in the output of **fdisk** is not guaranteed. The input (the commands) should always be backward compatible.

OPTIONS

-b, --sector-size *sectorsize*

Specify the sector size of the disk. Valid values are 512, 1024, 2048, and 4096. (Recent kernels know the sector size. Use this option only on old kernels or to override the kernel’s ideas.) Since util–linux–2.17, **fdisk** differentiates between logical and physical sector size. This option changes both sector sizes to *sectorsize*.

-B, --protect-boot

Don’t erase the beginning of the first disk sector when creating a new disk label. This feature is supported for GPT and MBR.

-c, --compatibility[=mode]

Specify the compatibility mode, ‘dos’ or ‘nondos’. The default is non–DOS mode. For backward compatibility, it is possible to use the option without the *mode* argument — then the default is used. Note that the optional *mode* argument cannot be separated from the **-c** option by a space, the correct form is for example **-c=dos**.

-h, --help

Display help text and exit.

-V, --version

Print version and exit.

-L, --color[=when]

Colorize the output. The optional argument *when* can be **auto**, **never** or **always**. If the *when* argument is omitted, it defaults to **auto**. The colors can be disabled; for the current built–in default see the **--help** output. See also the **COLORS** section.

-l, --list

List the partition tables for the specified devices and then exit.

If no devices are given, the devices mentioned in */proc/partitions* (if this file exists) are used. Devices are always listed in the order in which they are specified on the command-line, or by the kernel listed in */proc/partitions*.

-x, --list-details

Like **--list**, but provides more details.

--lock[=mode]

Use exclusive BSD lock for device or file it operates. The optional argument *mode* can be **yes**, **no** (or 1 and 0) or **nonblock**. If the *mode* argument is omitted, it defaults to **yes**. This option overwrites environment variable **\$LOCK_BLOCK_DEVICE**. The default is not to use any lock at all, but it's recommended to avoid collisions with **systemd-udevd(8)** or other tools.

-n, --noauto-pt

Don't automatically create a default partition table on empty device. The partition table has to be explicitly created by user (by command like 'o', 'g', etc.).

-o, --output list

Specify which output columns to print. Use **--help** to get a list of all supported columns.

The default list of columns may be extended if *list* is specified in the format *+list* (e.g., **-o +UUID**).

-s, --getsz

Print the size in 512-byte sectors of each given block device. This option is DEPRECATED in favour of **blockdev(8)**.

-t, --type type

Enable support only for disklabels of the specified *type*, and disable support for all other types.

-u, --units[=unit]

When listing partition tables, show sizes in 'sectors' or in 'cylinders'. The default is to show sizes in sectors. For backward compatibility, it is possible to use the option without the *unit* argument — then the default is used. Note that the optional *unit* argument cannot be separated from the **-u** option by a space, the correct form is for example '**-u=cylinders**'.

-C, --cylinders number

Specify the *number* of cylinders of the disk. I have no idea why anybody would want to do so.

-H, --heads number

Specify the number of heads of the disk. (Not the physical number, of course, but the number used for partition tables.) Reasonable values are 255 and 16.

-S, --sectors number

Specify the number of sectors per track of the disk. (Not the physical number, of course, but the number used for partition tables.) A reasonable value is 63.

-w, --wipe when

Wipe filesystem, RAID and partition-table signatures from the device, in order to avoid possible collisions. The argument *when* can be **auto**, **never** or **always**. When this option is not given, the default is **auto**, in which case signatures are wiped only when in interactive mode. In all cases detected signatures are reported by warning messages before a new partition table is created. See also **wipefs(8)**

command.

-W, --wipe-partitions *when*

Wipe filesystem, RAID and partition-table signatures from a newly created partitions, in order to avoid possible collisions. The argument *when* can be **auto**, **never** or **always**. When this option is not given, the default is **auto**, in which case signatures are wiped only when in interactive mode and after confirmation by user. In all cases detected signatures are reported by warning messages before a new partition is created. See also **wipefs(8)** command.

-V, --version

Display version information and exit.

DEVICES

The *device* is usually */dev/sda*, */dev/sdb* or so. A device name refers to the entire disk. Old systems without libata (a library used inside the Linux kernel to support ATA host controllers and devices) make a difference between IDE and SCSI disks. In such cases the device name will be */dev/hd** (IDE) or */dev/sd** (SCSI).

The *partition* is a device name followed by a partition number. For example, */dev/sda1* is the first partition on the first hard disk in the system. See also Linux kernel documentation (the *Documentation/admin-guide/devices.txt* file).

SIZES

The "last sector" dialog accepts partition size specified by number of sectors or by *+/-<size>{K,B,M,G,...}* notation.

If the size is prefixed by '+' then it is interpreted as relative to the partition first sector. If the size is prefixed by '-' then it is interpreted as relative to the high limit (last available sector for the partition).

In the case the size is specified in bytes than the number may be followed by the multiplicative suffixes KiB=1024, MiB=1024*1024, and so on for GiB, TiB, PiB, EiB, ZiB and YiB. The "iB" is optional, e.g., "K" has the same meaning as "KiB".

The relative sizes are always aligned according to device I/O limits. The *+/-<size>{K,B,M,G,...}* notation is recommended.

For backward compatibility **fdisk** also accepts the suffixes KB=1000, MB=1000*1000, and so on for GB, TB, PB, EB, ZB and YB. These 10^N suffixes are deprecated.

SCRIPT FILES

fdisk allows reading (by 'T' command) **sfdisk(8)** compatible script files. The script is applied to in-memory partition table, and then it is possible to modify the partition table before you write it to the device.

And vice-versa it is possible to write the current in-memory disk layout to the script file by command 'O'.

The script files are compatible between **cfdisk(8)**, **sfdisk(8)**, **fdisk** and other libfdisk applications. For more details see **sfdisk(8)**.

DISK LABELS

GPT (GUID Partition Table)

GPT is modern standard for the layout of the partition table. GPT uses 64-bit logical block addresses, checksums, UUIDs and names for partitions and an unlimited number of partitions (although the number of partitions is usually restricted to 128 in many partitioning tools).

Note that the first sector is still reserved for a **protective MBR** in the GPT specification. It prevents MBR-only partitioning tools from mis-recognizing and overwriting GPT disks.

GPT is always a better choice than MBR, especially on modern hardware with a UEFI boot loader.

DOS–type (MBR)

A DOS–type partition table can describe an unlimited number of partitions. In sector 0 there is room for the description of 4 partitions (called ‘primary’). One of these may be an extended partition; this is a box holding logical partitions, with descriptors found in a linked list of sectors, each preceding the corresponding logical partitions. The four primary partitions, present or not, get numbers 1–4. Logical partitions are numbered starting from 5.

In a DOS–type partition table the starting offset and the size of each partition is stored in two ways: as an absolute number of sectors (given in 32 bits), and as a **Cylinders/Heads/Sectors** triple (given in 10+8+6 bits). The former is OK — with 512–byte sectors this will work up to 2 TB. The latter has two problems. First, these C/H/S fields can be filled only when the number of heads and the number of sectors per track are known. And second, even if we know what these numbers should be, the 24 bits that are available do not suffice. DOS uses C/H/S only, Windows uses both, Linux never uses C/H/S. The **C/H/S addressing is deprecated** and may be unsupported in some later **fdisk** version.

Please, read the DOS–mode section if you want DOS–compatible partitions. **fdisk** does not care about cylinder boundaries by default.

BSD/Sun–type

A BSD/Sun disklabel can describe 8 partitions, the third of which should be a ‘whole disk’ partition. Do not start a partition that actually uses its first sector (like a swap partition) at cylinder 0, since that will destroy the disklabel. Note that a **BSD label** is usually nested within a DOS partition.

IRIX/SGI–type

An IRIX/SGI disklabel can describe 16 partitions, the eleventh of which should be an entire ‘volume’ partition, while the ninth should be labeled ‘volume header’. The volume header will also cover the partition table, i.e., it starts at block zero and extends by default over five cylinders. The remaining space in the volume header may be used by header directory entries. No partitions may overlap with the volume header. Also do not change its type or make some filesystem on it, since you will lose the partition table. Use this type of label only when working with Linux on IRIX/SGI machines or IRIX/SGI disks under Linux.

A **sync(2)** and an **ioctl(BLKRRPART)** (rereading the partition table from disk) are performed before exiting when the partition table has been updated.

DOS MODE AND DOS 6.X WARNING

Note that all this is deprecated. You don’t have to care about things like geometry and cylinders on modern operating systems. If you really want DOS–compatible partitioning then you have to enable DOS mode and cylinder units by using the ‘–c=dos –u=cylinders’ **fdisk command–line options.**

The DOS 6.x FORMAT command looks for some information in the first sector of the data area of the partition, and treats this information as more reliable than the information in the partition table. DOS FORMAT expects DOS FDISK to clear the first 512 bytes of the data area of a partition whenever a size change occurs. DOS FORMAT will look at this extra information even if the /U flag is given — we consider this a bug in DOS FORMAT and DOS FDISK.

The bottom line is that if you use **fdisk** or **cfdisk(8)** to change the size of a DOS partition table entry, then you must also use **dd(1)** to **zero the first 512 bytes** of that partition before using DOS FORMAT to format the partition. For example, if you were using **fdisk** to make a DOS partition table entry for **/dev/sda1**, then (after exiting **fdisk** and rebooting Linux so that the partition table information is valid) you would use the command **dd if=/dev/zero of=/dev/sda1 bs=512 count=1** to zero the first 512 bytes of the partition.

fdisk usually obtains the disk geometry automatically. This is not necessarily the physical disk geometry (indeed, modern disks do not really have anything like a physical geometry, certainly not something that can be described in the simplistic Cylinders/Heads/Sectors form), but it is the disk geometry that MS–DOS

uses for the partition table.

Usually all goes well by default, and there are no problems if Linux is the only system on the disk. However, if the disk has to be shared with other operating systems, it is often a good idea to let an **fdisk** from another operating system make at least one partition. When Linux boots it looks at the partition table, and tries to deduce what (fake) geometry is required for good cooperation with other systems.

Whenever a partition table is printed out in DOS mode, a consistency check is performed on the partition table entries. This check verifies that the physical and logical start and end points are identical, and that each partition starts and ends on a cylinder boundary (except for the first partition).

Some versions of MS-DOS create a first partition which does not begin on a cylinder boundary, but on sector 2 of the first cylinder. Partitions beginning in cylinder 1 cannot begin on a cylinder boundary, but this is unlikely to cause difficulty unless you have OS/2 on your machine.

For best results, you should always use an OS-specific partition table program. For example, you should make DOS partitions with the DOS FDISK program and Linux partitions with the Linux **fdisk** or Linux **cfdisk(8)** programs.

COLORS

The output colorization is implemented by **terminal-colors.d(5)** functionality. Implicit coloring can be disabled by an empty file

/etc/terminal-colors.d/fdisk.disable

for the **fdisk** command or for all tools by

/etc/terminal-colors.d/disable

The user-specific *\$XDG_CONFIG_HOME/terminal-colors.d* or *\$HOME/.config/terminal-colors.d* overrides the global setting.

Note that the output colorization may be enabled by default, and in this case *terminal-colors.d* directories do not have to exist yet.

The logical color names supported by **fdisk** are:

header

The header of the output tables.

help-title

The help section titles.

warn

The warning messages.

welcome

The welcome message.

ENVIRONMENT

FDISK_DEBUG=all

enables fdisk debug output.

LIBFDISK_DEBUG=all

enables libfdisk debug output.

LIBBLKID_DEBUG=all
enables libblkid debug output.

LIBSMARTCOLS_DEBUG=all
enables libsmartcols debug output.

LIBSMARTCOLS_DEBUG_PADDING=on
use visible padding characters.

LOCK_BLOCK_DEVICE=<mode>
use exclusive BSD lock. The mode is "1" or "0". See **--lock** for more details.

NAME

find – search for files in a directory hierarchy

SYNOPSIS

find [-H] [-L] [-P] [-D debugopts] [-Olevel] [starting-point...] [expression]

DESCRIPTION

This manual page documents the GNU version of **find**. GNU**find** searches the directory tree rooted at each given starting-point by evaluating the given expression from left to right, according to the rules of precedence (see section OPERATORS), until the outcome is known (the left hand side is false for *and* operations, true for *or*), at which point **find** moves on to the next file name. If no starting-point is specified, ‘.’ is assumed.

If you are using **find** in an environment where security is important (for example if you are using it to search directories that are writable by other users), you should read the ‘Security Considerations’ chapter of the findutils documentation, which is called **Finding Files** and comes with findutils. That document also includes a lot more detail and discussion than this manual page, so you may find it a more useful source of information.

OPTIONS

The **-H**, **-L** and **-P** options control the treatment of symbolic links. Command-line arguments following these are taken to be names of files or directories to be examined, up to the first argument that begins with ‘-’, or the argument ‘(’ or ‘!’. That argument and any following arguments are taken to be the expression describing what is to be searched for. If no paths are given, the current directory is used. If no expression is given, the expression **-print** is used (but you should probably consider using **-print0** instead, anyway).

This manual page talks about ‘options’ within the expression list. These options control the behaviour of **find** but are specified immediately after the last path name. The five ‘real’ options **-H**, **-L**, **-P**, **-D** and **-O** must appear before the first path name, if at all. A double dash -- could theoretically be used to signal that any remaining arguments are not options, but this does not really work due to the way **find** determines the end of the following path arguments: it does that by reading until an expression argument comes (which also starts with a ‘-’). Now, if a path argument would start with a ‘-’, then **find** would treat it as expression argument instead. Thus, to ensure that all start points are taken as such, and especially to prevent that wildcard patterns expanded by the calling shell are not mistakenly treated as expression arguments, it is generally safer to prefix wildcards or dubious path names with either ‘./’ or to use absolute path names starting with ‘/’.

- P** Never follow symbolic links. This is the default behaviour. When**find** examines or prints information about files, and the file is a symbolic link, the information used shall be taken from the properties of the symbolic link itself.
- L** Follow symbolic links. When **find** examines or prints information about files, the information used shall be taken from the properties of the file to which the link points, not from the link itself (unless it is a broken symbolic link or **find** is unable to examine the file to which the link points). Use of this option implies **-noleaf**. If you later use the **-P** option, **-noleaf** will still be in effect. If **-L** is in effect and **find** discovers a symbolic link to a subdirectory during its search, the subdirectory pointed to by the symbolic link will be searched.

When the **-L** option is in effect, the **-type** predicate will always match against the type of the file that a symbolic link points to rather than the link itself (unless the symbolic link is broken). Actions that can cause symbolic links to become broken while **find** is executing (for example **-delete**) can give rise to confusing behaviour. Using **-L** causes the **-lname** and **-ilname** predicates always to return false.
- H** Do not follow symbolic links, except while processing the command line arguments. When**find** examines or prints information about files, the information used shall be taken from the properties of the symbolic link itself. The only exception to this behaviour is when a file specified on the command line is a symbolic link, and the link can be resolved. For that situation, the information

used is taken from whatever the link points to (that is, the link is followed). The information about the link itself is used as a fallback if the file pointed to by the symbolic link cannot be examined. If **-H** is in effect and one of the paths specified on the command line is a symbolic link to a directory, the contents of that directory will be examined (though of course **-maxdepth 0** would prevent this).

If more than one of **-H**, **-L** and **-P** is specified, each overrides the others; the last one appearing on the command line takes effect. Since it is the default, the **-P** option should be considered to be in effect unless either **-H** or **-L** is specified.

GNU **find** frequently stats files during the processing of the command line itself, before any searching has begun. These options also affect how those arguments are processed. Specifically, there are a number of tests that compare files listed on the command line against a file we are currently considering. In each case, the file specified on the command line will have been examined and some of its properties will have been saved. If the named file is in fact a symbolic link, and the **-P** option is in effect (or if neither **-H** nor **-L** were specified), the information used for the comparison will be taken from the properties of the symbolic link. Otherwise, it will be taken from the properties of the file the link points to. If **find** cannot follow the link (for example because it has insufficient privileges or the link points to a nonexistent file) the properties of the link itself will be used.

When the **-H** or **-L** options are in effect, any symbolic links listed as the argument of **-newer** will be dereferenced, and the timestamp will be taken from the file to which the symbolic link points. The same consideration applies to **-newerXY**, **-anewer** and **-cnewer**.

The **-follow** option has a similar effect to **-L**, though it takes effect at the point where it appears (that is, if **-L** is not used but **-follow** is, any symbolic links appearing after **-follow** on the command line will be dereferenced, and those before it will not).

-D debugopts

Print diagnostic information; this can be helpful to diagnose problems with why **find** is not doing what you want. The list of debug options should be comma separated. Compatibility of the debug options is not guaranteed between releases of findutils. For a complete list of valid debug options, see the output of **find -D help**. Valid debug options include

- | | |
|--------|--|
| exec | Show diagnostic information relating to -exec , -execdir , -ok and -okdir |
| opt | Prints diagnostic information relating to the optimisation of the expression tree; see the -O option. |
| rates | Prints a summary indicating how often each predicate succeeded or failed. |
| search | Navigate the directory tree verbosely. |
| stat | Print messages as files are examined with the stat and Istat system calls. The find program tries to minimise such calls. |
| tree | Show the expression tree in its original and optimised form. |
| all | Enable all of the other debug options (but help). |
| help | Explain the debugging options. |

-Olevel

Enables query optimisation. The **find** program reorders tests to speed up execution while preserving the overall effect; that is, predicates with side effects are not reordered relative to each other. The optimisations performed at each optimisation level are as follows.

- | | |
|---|--|
| 0 | Equivalent to optimisation level 1. |
| 1 | This is the default optimisation level and corresponds to the traditional behaviour. Expressions are reordered so that tests based only on the names of files (for example -name and -regex) are performed first. |

- 2 Any **-type** or **-xtype** tests are performed after any tests based only on the names of files, but before any tests that require information from the inode. On many modern versions of Unix, file types are returned by **readdir()** and so these predicates are faster to evaluate than predicates which need to stat the file first. If you use the **-fstype** *FOO* predicate and specify a filesystem type *FOO* which is not known (that is, present in '/etc/mtab') at the time **find** starts, that predicate is equivalent to **-false**.
- 3 At this optimisation level, the full cost-based query optimiser is enabled. The order of tests is modified so that cheap (i.e. fast) tests are performed first and more expensive ones are performed later, if necessary. Within each cost band, predicates are evaluated earlier or later according to whether they are likely to succeed or not. For **-o**, predicates which are likely to succeed are evaluated earlier, and for **-a**, predicates which are likely to fail are evaluated earlier.

The cost-based optimiser has a fixed idea of how likely any given test is to succeed. In some cases the probability takes account of the specific nature of the test (for example, **-type f** is assumed to be more likely to succeed than **-type c**). The cost-based optimiser is currently being evaluated. If it does not actually improve the performance of **find**, it will be removed again. Conversely, optimisations that prove to be reliable, robust and effective may be enabled at lower optimisation levels over time. However, the default behaviour (i.e. optimisation level 1) will not be changed in the 4.3.x release series. The findutils test suite runs all the tests on **find** at each optimisation level and ensures that the result is the same.

EXPRESSION

The part of the command line after the list of starting points is the *expression*. This is a kind of query specification describing how we match files and what we do with the files that were matched. An expression is composed of a sequence of things:

Tests Tests return a true or false value, usually on the basis of some property of a file we are considering. The **-empty** test for example is true only when the current file is empty.

Actions

Actions have side effects (such as printing something on the standard output) and return either true or false, usually based on whether or not they are successful. The **-print** action for example prints the name of the current file on the standard output.

Global options

Global options affect the operation of tests and actions specified on any part of the command line. Global options always return true. The **-depth** option for example makes **find** traverse the file system in a depth-first order.

Positional options

Positional options affect only tests or actions which follow them. Positional options always return true. The **-r egextype** option for example is positional, specifying the regular expression dialect for regular expressions occurring later on the command line.

Operators

Operators join together the other items within the expression. They include for example **-o** (meaning logical OR) and **-a** (meaning logical AND). Where an operator is missing, **-a** is assumed.

The **-print** action is performed on all files for which the whole expression is true, unless it contains an action other than **-prune** or **-quit**. Actions which inhibit the default **-print** are **-delete**, **-exec**, **-execdir**, **-ok**, **-okdir**, **-fls**, **-fprintf**, **-fprintf**, **-ls**, **-print** and **-printf**.

The **-delete** action also acts like an option (since it implies **-depth**).

POSITIONAL OPTIONS

Positional options always return true. They affect only tests occurring later on the command line.

-daystart

Measure times (for **-amin**, **-atime**, **-cmin**, **-ctime**, **-mmin**, and **-mtime**) from the beginning of today rather than from 24 hours ago. This option only affects tests which appear later on the command line.

-follow

Deprecated; use the **-L** option instead. Dereference symbolic links. Implies **-oleaf**. The **-f follow** option affects only those tests which appear after it on the command line. Unless the **-H** or **-L** option has been specified, the position of the **-follow** option changes the behaviour of the **-newer** predicate; any files listed as the argument of **-newer** will be dereferenced if they are symbolic links. The same consideration applies to **-newerXY**, **-anewer** and **-cnewer**. Similarly, the **-type** predicate will always match against the type of the file that a symbolic link points to rather than the link itself. Using **-follow** causes the **-lname** and **-ilname** predicates always to return false.

-regextype type

Changes the regular expression syntax understood by **-regex** and **-iregex** tests which occur later on the command line. To see which regular expression types are known, use **-regextype help**. The Texinfo documentation (see **SEE ALSO**) explains the meaning of and differences between the various types of regular expression.

-warn, -nowarn

Turn warning messages on or off. These warnings apply only to the command line usage, not to any conditions that **find** might encounter when it searches directories. The default behaviour corresponds to **-warn** if standard input is a tty, and to **-nowarn** otherwise. If a warning message relating to command-line usage is produced, the exit status of **find** is not affected. If the **POSIXLY_CORRECT** environment variable is set, and **-warn** is also used, it is not specified which, if any, warnings will be active.

GLOBAL OPTIONS

Global options always return true. Global options take effect even for tests which occur earlier on the command line. To prevent confusion, global options should be specified on the command-line after the list of start points, just before the first test, positional option or action. If you specify a global option in some other place, **find** will issue a warning message explaining that this can be confusing.

The global options occur after the list of start points, and so are not the same kind of option as **-L**, for example.

-d A synonym for **-depth**, for compatibility with FreeBSD, NetBSD, MacOS X and OpenBSD.

-depth Process each directory's contents before the directory itself. The **-delete** action also implies **-depth**.

-help, --help

Print a summary of the command-line usage of **find** and exit.

-ignore_readdir_race

Normally, **find** will emit an error message when it fails to stat a file. If you give this option and a file is deleted between the time **find** reads the name of the file from the directory and the time it tries to stat the file, no error message will be issued. This also applies to files or directories whose names are given on the command line. This option takes effect at the time the command line is read, which means that you cannot search one part of the filesystem with this option on and part of it with this option off (if you need to do that, you will need to issue two **find** commands instead, one with the option and one without it).

Furthermore, **find** with the **-ignore_readdir_race** option will ignore errors of the **-delete** action in the case the file has disappeared since the parent directory was read: it will not output an error diagnostic, and the return code of the **-delete** action will be true.

-maxdepth levels

Descend at most *levels* (a non-negative integer) levels of directories below the starting-points. Using **-maxdepth 0** means only apply the tests and actions to the starting-points themselves.

-mindepth levels

Do not apply any tests or actions at levels less than *levels* (a non-negative integer). Using **-mindepth 1** means process all files except the starting-points.

-mount

Don't descend directories on other filesystems. An alternate name for **-xdev**, for compatibility with some other versions of **find**.

-noignore_readdir_race

Turns off the effect of **-ignore_readdir_race**.

-noleaf Do not optimize by assuming that directories contain 2 fewer subdirectories than their hard link count. This option is needed when searching filesystems that do not follow the Unix directory-link convention, such as CD-ROM or MS-DOS filesystems or AFS volume mount points. Each directory on a normal Unix filesystem has at least 2 hard links: its name and its '.' entry. Additionally, its subdirectories (if any) each have a '..' entry linked to that directory. When **find** is examining a directory, after it has statted 2 fewer subdirectories than the directory's link count, it knows that the rest of the entries in the directory are non-directories ('leaf' files in the directory tree). If only the files' names need to be examined, there is no need to stat them; this gives a significant increase in search speed.

-version, --version

Print the **find** version number and exit.

-xdev Don't descend directories on other filesystems.

TESTS

Some tests, for example **-newerXY** and **-samefile**, allow comparison between the file currently being examined and some reference file specified on the command line. When these tests are used, the interpretation of the reference file is determined by the options **-H**, **-L** and **-P** and any previous **-follow**, but the reference file is only examined once, at the time the command line is parsed. If the reference file cannot be examined (for example, the **stat(2)** system call fails for it), an error message is issued, and **find** exits with a nonzero status.

A numeric argument *n* can be specified to tests (like **-amin**, **-mtime**, **-gid**, **-inum**, **-links**, **-size**, **-uid** and

-used) as

- +n for greater than *n*,
- n for less than *n*,
- n* for exactly *n*.

Supported tests:

-amin *n*

File was last accessed less than, more than or exactly *n* minutes ago.

-anewer *reference*

Time of the last access of the current file is more recent than that of the last data modification of the *reference* file. If *reference* is a symbolic link and the **-H** option or the **-L** option is in effect, then the time of the last data modification of the file it points to is always used.

-atime *n*

File was last accessed less than, more than or exactly *n**24 hours ago. When find figures out how many 24-hour periods ago the file was last accessed, any fractional part is ignored, so to match **-atime +1**, a file has to have been accessed at least *two* days ago.

-cmin *n*

File's status was last changed less than, more than or exactly *n* minutes ago.

-cnewer *reference*

Time of the last status change of the current file is more recent than that of the last data modification of the *reference* file. If *reference* is a symbolic link and the **-H** option or the **-L** option is in effect, then the time of the last data modification of the file it points to is always used.

-ctime *n*

File's status was last changed less than, more than or exactly *n**24 hours ago. See the comments for **-atime** to understand how rounding affects the interpretation of file status change times.

-empty File is empty and is either a regular file or a directory.

-executable

Matches files which are executable and directories which are searchable (in a file name resolution sense) by the current user. This takes into account access control lists and other permissions artefacts which the **-perm** test ignores. This test makes use of the **access(2)** system call, and so can be fooled by NFS servers which do UID mapping (or root-squashing), since many systems implement **access(2)** in the client's kernel and so cannot make use of the UID mapping information held on the server. Because this test is based only on the result of the **access(2)** system call, there is no guarantee that a file for which this test succeeds can actually be executed.

-false Always false.

-fstype *type*

File is on a filesystem of type *type*. The valid filesystem types vary among different versions of Unix; an incomplete list of filesystem types that are accepted on some version of Unix or another is: ufs, 4.2, 4.3, nfs, tmp, mfs, S51K, S52K. You can use **-printf** with the %F directive to see the types of your filesystems.

-gid *n* File's numeric group ID is less than, more than or exactly *n*.

-group *gname*

File belongs to group *gname* (numeric group ID allowed).

-ilname *pattern*

Like **-lname**, but the match is case insensitive. If the **-L** option or the **-f follow** option is in effect, this test returns false unless the symbolic link is broken.

-iname *pattern*

Like **-name**, but the match is case insensitive. For example, the patterns ‘fo*’ and ‘F??’ match the file names ‘Foo’, ‘FOO’, ‘foo’, ‘fOo’, etc. The pattern ‘*foo*’ will also match a file called ‘.foobar’.

-inum *n*

File has inode number smaller than, greater than or exactly *n*. It is normally easier to use the **-samefile** test instead.

-ipath *pattern*

Like **-path**, but the match is case insensitive.

-iregex *pattern*

Like **-regex**, but the match is case insensitive.

-iwholename *pattern*

See **-ipath**. This alternative is less portable than **-ipath**.

-links *n*

File has less than, more than or exactly *n* hard links.

-lname *pattern*

File is a symbolic link whose contents match shell pattern *pattern*. The metacharacters do not treat ‘/’ or ‘.’ specially. If the **-L** option or the **-f follow** option is in effect, this test returns false unless the symbolic link is broken.

-mmin *n*

File's data was last modified less than, more than or exactly *n* minutes ago.

-mtime *n*

File's data was last modified less than, more than or exactly *n**24 hours ago. See the comments for **-atime** to understand how rounding affects the interpretation of file modification times.

-name *pattern*

Base of file name (the path with the leading directories removed) matches shell pattern *pattern*. Because the leading directories are removed, the file names considered for a match with **-name** will never include a slash, so ‘-name a/b’ will never match anything (you probably need to use **-path** instead). A warning is issued if you try to do this, unless the environment variable **POSIXLY_CORRECT** is set. The metacharacters (‘*’, ‘?’, and ‘[]’) match a ‘.’ at the start of the base name (this is a change in findutils-4.2.2; see section STANDARDS CONFORMANCE

below). To ignore a directory and the files under it, use **-prune** rather than checking every file in the tree; see an example in the description of that action. Braces are not recognised as being special, despite the fact that some shells including Bash imbue braces with a special meaning in shell patterns. The filename matching is performed with the use of the **fnmatch(3)** library function. Don't forget to enclose the pattern in quotes in order to protect it from expansion by the shell.

-newer *reference*

Time of the last data modification of the current file is more recent than that of the last data modification of the *reference* file. If *reference* is a symbolic link and the **-H** option or the **-L** option is in effect, then the time of the last data modification of the file it points to is always used.

-newerXY *reference*

Succeeds if timestamp *X* of the file being considered is newer than timestamp *Y* of the file *reference*. The letters *X* and *Y* can be any of the following letters:

- a The access time of the file *reference*
- B The birth time of the file *reference*
- c The inode status change time of *reference*
- m The modification time of the file *reference*
- t *reference* is interpreted directly as a time

Some combinations are invalid; for example, it is invalid for *X* to be *t*. Some combinations are not implemented on all systems; for example *B* is not supported on all systems. If an invalid or unsupported combination of *XY* is specified, a fatal error results. Time specifications are interpreted as for the argument to the **-d** option of GNU **date**. If you try to use the birth time of a reference file, and the birth time cannot be determined, a fatal error message results. If you specify a test which refers to the birth time of files being examined, this test will fail for any files where the birth time is unknown.

-nogroup

No group corresponds to file's numeric group ID.

-nouser

No user corresponds to file's numeric user ID.

-path *pattern*

File name matches shell pattern *pattern*. The metacharacters do not treat '/' or '.' specially; so, for example,

```
find . -path "./sr*sc"
```

will print an entry for a directory called *./src/misc* (if one exists). To ignore a whole directory tree, use **-prune** rather than checking every file in the tree. Note that the pattern match test applies to the whole file name, starting from one of the start points named on the command line. It would only make sense to use an absolute path name here if the relevant start point is also an absolute path. This means that this command will never match anything:

```
find bar -path /foo/bar/myfile -print
```

Find compares the **-path** argument with the concatenation of a directory name and the base name of the file it's examining. Since the concatenation will never end with a slash, **-path** arguments ending in a slash will match nothing (except perhaps a start point specified on the command line). The predicate **-path** is also supported by HP-UX **find** and is part of the POSIX 2008 standard.

-perm mode

File's permission bits are exactly *mode* (octal or symbolic). Since an exact match is required, if you want to use this form for symbolic modes, you may have to specify a rather complex mode string. For example ‘-perm g=w’ will only match files which have mode 0020 (that is, ones for which group write permission is the only permission set). It is more likely that you will want to use the ‘/’ or ‘-’ forms, for example ‘-perm -g=w’, which matches any file with group write permission. See the **EXAMPLES** section for some illustrative examples.

-perm -mode

All of the permission bits *mode* are set for the file. Symbolic modes are accepted in this form, and this is usually the way in which you would want to use them. You must specify ‘u’, ‘g’ or ‘o’ if you use a symbolic mode. See the **EXAMPLES** section for some illustrative examples.

-perm /mode

Any of the permission bits *mode* are set for the file. Symbolic modes are accepted in this form. You must specify ‘u’, ‘g’ or ‘o’ if you use a symbolic mode. See the **EXAMPLES** section for some illustrative examples. If no permission bits in *mode* are set, this test matches any file (the idea here is to be consistent with the behaviour of **-perm -000**).

-perm +mode

This is no longer supported (and has been deprecated since 2005). Use **-perm /mode** instead.

-readable

Matches files which are readable by the current user. This takes into account access control lists and other permissions artefacts which the **-perm** test ignores. This test makes use of the **access(2)** system call, and so can be fooled by NFS servers which do UID mapping (or root-squashing), since many systems implement **access(2)** in the client's kernel and so cannot make use of the UID mapping information held on the server.

-regex pattern

File name matches regular expression *pattern*. This is a match on the whole path, not a search. For example, to match a file named */fubar3*, you can use the regular expression ‘.*bar.’ or ‘.*b.*3’, but not ‘f.*r3’. The regular expressions understood by **find** are by default Emacs Regular Expressions (except that ‘.’ matches newline), but this can be changed with the **-regextype** option.

-samefile name

File refers to the same inode as *name*. When **-L** is in effect, this can include symbolic links.

-size n[cwbkMG]

File uses less than, more than or exactly *n* units of space, rounding up. The following suffixes can be used:

- ‘b’ for 512-byte blocks (this is the default if no suffix is used)
- ‘c’ for bytes
- ‘w’ for two-byte words
- ‘k’ for kibibytes (KiB, units of 1024 bytes)
- ‘M’ for mebibytes (MiB, units of 1024 * 1024 = 1 048 576 bytes)
- ‘G’ for gibibytes (GiB, units of 1024 * 1024 * 1024 = 1 073 741 824 bytes)

The size is simply the *st_size* member of the struct *stat* populated by the *Istat* (or *stat*) system call, rounded up as shown above. In other words, it's consistent with the result you get for **ls -l**. Bear

in mind that the ‘%k’ and ‘%b’ format specifiers of **-printf** handle sparse files differently. The ‘b’ suffix always denotes 512-byte blocks and never 1024-byte blocks, which is different to the behaviour of **-ls**.

The + and - prefixes signify greater than and less than, as usual; i.e., an exact size of *n* units does not match. Bear in mind that the size is rounded up to the next unit. Therefore **-size -1M** is not equivalent to **-size -1048576c**. The former only matches empty files, the latter matches files from 0 to 1,048,575 bytes.

-true Always true.

-type *c* File is of type *c*:

b	block (buffered) special
c	character (unbuffered) special
d	directory
p	named pipe (FIFO)
f	regular file
l	symbolic link; this is never true if the -L option or the -follow option is in effect, unless the symbolic link is broken. If you want to search for symbolic links when -L is in effect, use -xtype .
s	socket
D	door (Solaris)

To search for more than one type at once, you can supply the combined list of type letters separated by a comma ‘,’ (GNU extension).

-uid *n* File’s numeric user ID is less than, more than or exactly *n*.

-used *n*

File was last accessed less than, more than or exactly *n* days after its status was last changed.

-user *uname*

File is owned by user *uname* (numeric user ID allowed).

-wholename *pattern*

See **-path**. This alternative is less portable than **-path**.

-writable

Matches files which are writable by the current user. This takes into account access control lists and other permissions artefacts which the **-perm** test ignores. This test makes use of the **access(2)** system call, and so can be fooled by NFS servers which do UID mapping (or root-squashing), since many systems implement **access(2)** in the client’s kernel and so cannot make use of the UID mapping information held on the server.

-xtype *c*

The same as **-type** unless the file is a symbolic link. For symbolic links: if the **-H** or **-P** option was specified, true if the file is a link to a file of type *c*; if the **-L** option has been given, true if *c* is ‘l’. In other words, for symbolic links, **-xtype** checks the type of the file that **-type** does not check.

-context *pattern*

(SELinux only) Security context of the file matches glob *pattern*.

ACTIONS

- delete** Delete files; true if removal succeeded. If the removal failed, an error message is issued. If **-delete** fails, **find**'s exit status will be nonzero (when it eventually exits). Use of **-delete** automatically turns on the '**-depth**' option.

Warnings: Don't forget that the **find** command line is evaluated as an expression, so putting **-delete** first will make **find** try to delete everything below the starting points you specified. When testing a **find** command line that you later intend to use with **-delete**, you should explicitly specify **-depth** in order to avoid later surprises. Because **-delete** implies **-depth**, you cannot usefully use **-prune** and **-delete** together.

Together with the **-ignore_readdir_race** option, **find** will ignore errors of the **-delete** action in the case the file has disappeared since the parent directory was read: it will not output an error diagnostic, and the return code of the **-delete** action will be true.

-exec *command* ;

Execute *command*; true if 0 status is returned. All following arguments to **find** are taken to be arguments to the command until an argument consisting of ';' is encountered. The string '{ }' is replaced by the current file name being processed everywhere it occurs in the arguments to the command, not just in arguments where it is alone, as in some versions of **find**. Both of these constructions might need to be escaped (with a '\') or quoted to protect them from expansion by the shell. See the **EXAMPLES** section for examples of the use of the **-exec** option. The specified command is run once for each matched file. The command is executed in the starting directory. There are unavoidable security problems surrounding use of the **-exec** action; you should use the **-execdir** option instead.

-exec *command* { } +

This variant of the **-exec** action runs the specified command on the selected files, but the command line is built by appending each selected file name at the end; the total number of invocations of the command will be much less than the number of matched files. The command line is built in much the same way that **xargs** builds its command lines. Only one instance of '{ }' is allowed within the command, and it must appear at the end, immediately before the '+'; it needs to be escaped (with a '\') or quoted to protect it from interpretation by the shell. The command is executed in the starting directory. If any invocation with the '+' form returns a non-zero value as exit status, then **find** returns a non-zero exit status. If **find** encounters an error, this can sometimes cause an immediate exit, so some pending commands may not be run at all. For this reason **-exec my-command ... { } + -quit** may not result in *my-command* actually being run. This variant of **-exec** always returns true.

-execdir *command* ;**-execdir *command* { } +**

Like **-exec**, but the specified command is run from the subdirectory containing the matched file, which is not normally the directory in which you started **find**. As with **-exec**, the '{ }' should be quoted if **find** is being invoked from a shell. This a much more secure method for invoking commands, as it avoids race conditions during resolution of the paths to the matched files. As with the **-exec** action, the '+' form of **-execdir** will build a command line to process more than one matched file, but any given invocation of *command* will only list files that exist in the same subdirectory. If you use this option, you must ensure that your \$PATH environment variable does not reference ':'; otherwise, an attacker can run any commands they like by leaving an appropriately-

named file in a directory in which you will run **-execdir**. The same applies to having entries in **\$PATH** which are empty or which are not absolute directory names. If any invocation with the ‘+’ form returns a non-zero value as exit status, then **find** returns a non-zero exit status. If **find** encounters an error, this can sometimes cause an immediate exit, so some pending commands may not be run at all. The result of the action depends on whether the + or the ; variant is being used; **-execdir command {} +** always returns true, while **-execdir command {} ;** returns true only if *command* returns 0.

-fls *file* True; like **-ls** but write to *file* like **-fprintf**. The output file is always created, even if the predicate is never matched. See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

-fprintf *file*

True; print the full file name into file *file*. If *file* does not exist when **find** is run, it is created; if it does exist, it is truncated. The file names */dev/stdout* and */dev/stderr* are handled specially; they refer to the standard output and standard error output, respectively. The output file is always created, even if the predicate is never matched. See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

-fprintf0 *file*

True; like **-print0** but write to *file* like **-fprintf**. The output file is always created, even if the predicate is never matched. See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

-printf *file format*

True; like **-printf** but write to *file* like **-fprintf**. The output file is always created, even if the predicate is never matched. See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

-ls

True; list current file in **ls -dils** format on standard output. The block counts are of 1 KB blocks, unless the environment variable **POSIXLY_CORRECT** is set, in which case 512-byte blocks are used. See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

-ok *command* ;

Like **-exec** but ask the user first. If the user agrees, run the command. Otherwise just return false. If the command is run, its standard input is redirected from */dev/null*.

The response to the prompt is matched against a pair of regular expressions to determine if it is an affirmative or negative response. This regular expression is obtained from the system if the ‘**POSIXLY_CORRECT**’ environment variable is set, or otherwise from **find**’s message translations. If the system has no suitable definition, **find**’s own definition will be used. In either case, the interpretation of the regular expression itself will be affected by the environment variables ‘**LC_CTYPE**’ (character classes) and ‘**LC_COLLATE**’ (character ranges and equivalence classes).

-okdir *command* ;

Like **-execdir** but ask the user first in the same way as for **-ok**. If the user does not agree, just return false. If the command is run, its standard input is redirected from */dev/null*.

-print True; print the full file name on the standard output, followed by a newline. If you are piping the output of **find** into another program and there is the faintest possibility that the files which you are searching for might contain a newline, then you should seriously consider using the **-print0** option instead of **-print**. See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

-print0 True; print the full file name on the standard output, followed by a null character (instead of the newline character that **-print** uses). This allows file names that contain newlines or other types of white space to be correctly interpreted by programs that process the **find** output. This option corresponds to the **-0** option of **xargs**.

-printf *format*

True; print *format* on the standard output, interpreting ‘\’ escapes and ‘%’ directives. Field widths and precisions can be specified as with the **printf(3)** C function. Please note that many of the fields are printed as %s rather than %d, and this may mean that flags don’t work as you might expect. This also means that the ‘-’ flag does work (it forces fields to be left-aligned). Unlike **-print**, **-printf** does not add a newline at the end of the string. The escapes and directives are:

\a	Alarm bell.
\b	Backspace.
\c	Stop printing from this format immediately and flush the output.
\f	Form feed.
\n	Newline.
\r	Carriage return.
\t	Horizontal tab.
\v	Vertical tab.
\0	ASCII NUL.
\\\	A literal backslash (‘\’).

\NNN The character whose ASCII code is NNN (octal).

A ‘\’ character followed by any other character is treated as an ordinary character, so they both are printed.

%% A literal percent sign.

%a File’s last access time in the format returned by the C **ctime(3)** function.

%Ak File’s last access time in the format specified by *k*, which is either ‘@’ or a directive for the C **strftime(3)** function. The following shows an incomplete list of possible values for *k*. Please refer to the documentation of **strftime(3)** for the full list. Some of the conversion specification characters might not be available on all systems, due to differences in the implementation of the **strftime(3)** library function.

@ seconds since Jan. 1, 1970, 00:00 GMT, with fractional part.

Time fields:

H	hour (00..23)
I	hour (01..12)
k	hour (0..23)
l	hour (1..12)
M	minute (00..59)

p	locale's AM or PM
r	time, 12-hour (hh:mm:ss [AP]M)
S	Second (00.00 .. 61.00). There is a fractional part.
T	time, 24-hour (hh:mm:ss.xxxxxxxxxx)
+	Date and time, separated by '+', for example '2004-04-28+22:22:05.0'. This is a GNU extension. The time is given in the current timezone (which may be affected by setting the TZ environment variable). The seconds field includes a fractional part.
X	locale's time representation (H:M:S). The seconds field includes a fractional part.
Z	time zone (e.g., EDT), or nothing if no time zone is determinable
Date fields:	
a	locale's abbreviated weekday name (Sun..Sat)
A	locale's full weekday name, variable length (Sunday..Saturday)
b	locale's abbreviated month name (Jan..Dec)
B	locale's full month name, variable length (January..December)
c	locale's date and time (Sat Nov 04 12:02:33 EST 1989). The format is the same as for ctime(3) and so to preserve compatibility with that format, there is no fractional part in the seconds field.
d	day of month (01..31)
D	date (mm/dd/yy)
F	date (yyyy-mm-dd)
h	same as b
j	day of year (001..366)
m	month (01..12)
U	week number of year with Sunday as first day of week (00..53)
w	day of week (0..6)
W	week number of year with Monday as first day of week (00..53)
x	locale's date representation (mm/dd/yy)
y	last two digits of year (00..99)
Y	year (1970...)
%b	The amount of disk space used for this file in 512-byte blocks. Since disk space is allocated in multiples of the filesystem block size this is usually greater than %s/512, but it can also be smaller if the file is a sparse file.
%c	File's last status change time in the format returned by the C ctime(3) function.
%Ck	File's last status change time in the format specified by k, which is the same as for %A.
%d	File's depth in the directory tree; 0 means the file is a starting-point.
%D	The device number on which the file exists (the st_dev field of struct stat), in decimal.
%f	Print the basename; the file's name with any leading directories removed (only the last element). For /, the result is '/'. See the EXAMPLES section for an example.

%F	Type of the filesystem the file is on; this value can be used for <code>-fstype</code> .
%g	File's group name, or numeric group ID if the group has no name.
%G	File's numeric group ID.
%h	Dirname; the Leading directories of the file's name (all but the last element). If the file name contains no slashes (since it is in the current directory) the %h specifier expands to '..'. For files which are themselves directories and contain a slash (including <code>/</code>), %h expands to the empty string. See the EXAMPLES section for an example.
%H	Starting-point under which file was found.
%i	File's inode number (in decimal).
%k	The amount of disk space used for this file in 1 KB blocks. Since disk space is allocated in multiples of the filesystem block size this is usually greater than %s/1024, but it can also be smaller if the file is a sparse file.
%l	Object of symbolic link (empty string if file is not a symbolic link).
%m	File's permission bits (in octal). This option uses the 'traditional' numbers which most Unix implementations use, but if your particular implementation uses an unusual ordering of octal permissions bits, you will see a difference between the actual value of the file's mode and the output of %m. Normally you will want to have a leading zero on this number, and to do this, you should use the # flag (as in, for example, '%#m').
%M	File's permissions (in symbolic form, as for <code>ls</code>). This directive is supported in findutils 4.2.5 and later.
%n	Number of hard links to file.
%p	File's name.
%P	File's name with the name of the starting-point under which it was found removed.
%s	File's size in bytes.
%S	File's sparseness. This is calculated as (BLOCKSIZE*st_blocks / st_size). The exact value you will get for an ordinary file of a certain length is system-dependent. However, normally sparse files will have values less than 1.0, and files which use indirect blocks may have a value which is greater than 1.0. In general the number of blocks used by a file is file system dependent. The value used for BLOCKSIZE is system-dependent, but is usually 512 bytes. If the file size is zero, the value printed is undefined. On systems which lack support for st_blocks, a file's sparseness is assumed to be 1.0.
%t	File's last modification time in the format returned by the C <code>ctime(3)</code> function.
%Tk	File's last modification time in the format specified by <i>k</i> , which is the same as for %A.
%u	File's user name, or numeric user ID if the user has no name.
%U	File's numeric user ID.
%y	File's type (like in <code>ls -l</code>), U=unknown type (shouldn't happen)
%Y	File's type (like %y), plus follow symbolic links: 'L'=loop, 'N'=nonexistent, '?' for any other error when determining the type of the target of a symbolic link.
%Z	(SELinux only) file's security context.
%{ %[%(%	Reserved for future use.

A '%' character followed by any other character is discarded, but the other character is printed (don't rely on this, as further format characters may be introduced). A '%' at the end of the format argument causes undefined behaviour since there is no following character. In some locales, it may hide your door keys, while in others it may remove the final page from the novel you are

reading.

The %m and %d directives support the #, 0 and + flags, but the other directives do not, even if they print numbers. Numeric directives that do not support these flags include **G**, **U**, **b**, **D**, **k** and **n**. The ‘-’ format flag is supported and changes the alignment of a field from right-justified (which is the default) to left-justified.

See the **UNUSUAL FILENAMES** section for information about how unusual characters in filenames are handled.

- prune True; if the file is a directory, do not descend into it. If **-depth** is given, then **-prune** has no effect. Because **-delete** implies **-depth**, you cannot usefully use **-prune** and **-delete** together. For example, to skip the directory *src/emacs* and all files and directories under it, and print the names of the other files found, do something like this:

```
find . -path ./src/emacs -prune -o -print
```

- quit Exit immediately (with return value zero if no errors have occurred). This is different to **-prune** because **-prune** only applies to the contents of pruned directories, while **-quit** simply makes **find** stop immediately. No child processes will be left running. Any command lines which have been built by **-exec ... +** or **-execdir ... +** are invoked before the program is exited. After **-quit** is executed, no more files specified on the command line will be processed. For example, ‘**find /tmp/foo /tmp/bar -print -quit**’ will print only ‘/tmp/foo’.

One common use of **-quit** is to stop searching the file system once we have found what we want. For example, if we want to find just a single file we can do this:

```
find / -name needle -print -quit
```

OPERATORS

Listed in order of decreasing precedence:

(*expr*) Force precedence. Since parentheses are special to the shell, you will normally need to quote them. Many of the examples in this manual page use backslashes for this purpose: ‘\(...\)' instead of ‘(...)'.

! *expr* True if *expr* is false. This character will also usually need protection from interpretation by the shell.

-not *expr*

Same as ! *expr*, but not POSIX compliant.

expr1 expr2

Two expressions in a row are taken to be joined with an implied **-a**; *expr2* is not evaluated if *expr1* is false.

expr1 -a expr2

Same as *expr1 expr2*.

expr1 -and expr2

Same as *expr1 expr2*, but not POSIX compliant.

expr1 –o *expr2*

Or; *expr2* is not evaluated if *expr1* is true.

expr1 –or *expr2*

Same as *expr1* –o *expr2*, but not POSIX compliant.

expr1 , *expr2*

List; both *expr1* and *expr2* are always evaluated. The value of *expr1* is discarded; the value of the list is the value of *expr2*. The comma operator can be useful for searching for several different types of thing, but traversing the filesystem hierarchy only once. The –fprintf action can be used to list the various matched items into several different output files.

Please note that –a when specified implicitly (for example by two tests appearing without an explicit operator between them) or explicitly has higher precedence than –o. This means that **find . -name afile -o -name bfile -print** will never print *afile*.

UNUSUAL FILENAMES

Many of the actions of **find** result in the printing of data which is under the control of other users. This includes file names, sizes, modification times and so forth. File names are a potential problem since they can contain any character except ‘\0’ and ‘/’. Unusual characters in file names can do unexpected and often undesirable things to your terminal (for example, changing the settings of your function keys on some terminals). Unusual characters are handled differently by various actions, as described below.

–print0, –fprint0

Always print the exact filename, unchanged, even if the output is going to a terminal.

–ls, –fls

Unusual characters are always escaped. White space, backslash, and double quote characters are printed using C-style escaping (for example ‘f’, ‘\”’). Other unusual characters are printed using an octal escape. Other printable characters (for –ls and –fls these are the characters between octal 041 and 0176) are printed as-is.

–printf, –fprintf

If the output is not going to a terminal, it is printed as-is. Otherwise, the result depends on which directive is in use. The directives %D, %F, %g, %G, %H, %Y, and %y expand to values which are not under control of files’ owners, and so are printed as-is. The directives %a, %b, %c, %d, %i, %k, %m, %M, %n, %s, %t, %u and %U have values which are under the control of files’ owners but which cannot be used to send arbitrary data to the terminal, and so these are printed as-is. The directives %f, %h, %l, %p and %P are quoted. This quoting is performed in the same way as for GNU ls. This is not the same quoting mechanism as the one used for –ls and –fls. If you are able to decide what format to use for the output of **find** then it is normally better to use ‘\0’ as a terminator than to use newline, as file names can contain white space and newline characters. The setting of the ‘LC_CTYPE’ environment variable is used to determine which characters need to be quoted.

–print, –fprint

Quoting is handled in the same way as for –printf and –fprintf. If you are using **find** in a script or in a situation where the matched files might have arbitrary names, you should consider using –print0 instead of –print.

The –ok and –okdir actions print the current filename as-is. This may change in a future release.

STANDARDS CONFORMANCE

For closest compliance to the POSIX standard, you should set the `POSIXLY_CORRECT` environment variable. The following options are specified in the POSIX standard (IEEE Std 1003.1-2008, 2016 Edition):

-H This option is supported.

-L This option is supported.

-name This option is supported, but POSIX conformance depends on the POSIX conformance of the system's `fnmatch(3)` library function. As of `findutils`-4.2.2, shell metacharacters ('*', '?' or '[]' for example) match a leading '.', because IEEE PASC interpretation 126 requires this. This is a change from previous versions of `findutils`.

-type Supported. POSIX specifies 'b', 'c', 'd', 'l', 'p', 'f' and 's'. GNU `find` also supports 'D', representing a Door, where the OS provides these. Furthermore, GNU `find` allows multiple types to be specified at once in a comma-separated list.

-ok Supported. Interpretation of the response is according to the 'yes' and 'no' patterns selected by setting the 'LC_MESSAGES' environment variable. When the 'POSIXLY_CORRECT' environment variable is set, these patterns are taken system's definition of a positive (yes) or negative (no) response. See the system's documentation for `nl_langinfo(3)`, in particular YESEXPR and NOEXPR. When 'POSIXLY_CORRECT' is not set, the patterns are instead taken from `find`'s own message catalogue.

-newer

Supported. If the file specified is a symbolic link, it is always dereferenced. This is a change from previous behaviour, which used to take the relevant time from the symbolic link; see the HISTORY section below.

-perm Supported. If the `POSIXLY_CORRECT` environment variable is not set, some mode arguments (for example +a+x) which are not valid in POSIX are supported for backward-compatibility.

Other primaries

The primaries **-atime**, **-ctime**, **-depth**, **-exec**, **-group**, **-links**, **-mtime**, **-nogroup**, **-nouser**, **-ok**, **-path**, **-print**, **-prune**, **-size**, **-user** and **-xdev** are all supported.

The POSIX standard specifies parentheses '(', ')' , negation '!' and the logical AND/OR operators **-a** and **-o**.

All other options, predicates, expressions and so forth are extensions beyond the POSIX standard. Many of these extensions are not unique to GNU `find`, however.

The POSIX standard requires that `find` detects loops:

The `find` utility shall detect infinite loops; that is, entering a previously visited directory that is an ancestor of the last file encountered. When it detects an infinite loop, `find` shall write a diagnostic message to standard error and shall either recover its position in the hierarchy or terminate.

GNU `find` complies with these requirements. The link count of directories which contain entries which are hard links to an ancestor will often be lower than they otherwise should be. This can mean that GNU `find` will sometimes optimise away the visiting of a subdirectory which is actually a link to an ancestor. Since `find` does not actually enter such a subdirectory, it is allowed to avoid emitting a diagnostic message. Although this behaviour may be somewhat confusing, it is unlikely that anybody actually depends on this

behaviour. If the leaf optimisation has been turned off with **-noleaf**, the directory entry will always be examined and the diagnostic message will be issued where it is appropriate. Symbolic links cannot be used to create filesystem cycles as such, but if the **-L** option or the **-follow** option is in use, a diagnostic message is issued when **find** encounters a loop of symbolic links. As with loops containing hard links, the leaf optimisation will often mean that **find** knows that it doesn't need to call *stat()* or *chdir()* on the symbolic link, so this diagnostic is frequently not necessary.

The **-d** option is supported for compatibility with various BSD systems, but you should use the POSIX-compliant option **-depth** instead.

The **POSIXLY_CORRECT** environment variable does not affect the behaviour of the **-regex** or **-iregex** tests because those tests aren't specified in the POSIX standard.

ENVIRONMENT VARIABLES

LANG Provides a default value for the internationalization variables that are unset or null.

LC_ALL

If set to a non-empty string value, override the values of all the other internationalization variables.

LC_COLLATE

The POSIX standard specifies that this variable affects the pattern matching to be used for the **-name** option. GNU find uses the **fnmatch(3)** library function, and so support for 'LC_COLLATE' depends on the system library. This variable also affects the interpretation of the response to **-ok**; while the 'LC_MESSAGES' variable selects the actual pattern used to interpret the response to **-ok**, the interpretation of any bracket expressions in the pattern will be affected by 'LC_COLLATE'.

LC_CTYPE

This variable affects the treatment of character classes used in regular expressions and also with the **-name** test, if the system's **fnmatch(3)** library function supports this. This variable also affects the interpretation of any character classes in the regular expressions used to interpret the response to the prompt issued by **-ok**. The 'LC_CTYPE' environment variable will also affect which characters are considered to be unprintable when filenames are printed; see the section UNUSUAL FILENAMES.

LC_MESSAGES

Determines the locale to be used for internationalised messages. If the 'POSIXLY_CORRECT' environment variable is set, this also determines the interpretation of the response to the prompt made by the **-ok** action.

NLSPATH

Determines the location of the internationalisation message catalogues.

PATH Affects the directories which are searched to find the executables invoked by **-exec**, **-execdir**, **-ok** and **-okdir**.

POSIXLY_CORRECT

Determines the block size used by **-ls** and **-fls**. If **POSIXLY_CORRECT** is set, blocks are units of 512 bytes. Otherwise they are units of 1024 bytes.

Setting this variable also turns off warning messages (that is, implies **-nowarn**) by default, because POSIX requires that apart from the output for **-ok**, all messages printed on stderr are diagnostics and must result in a non-zero exit status.

When `POSIXLY_CORRECT` is not set, `-perm +zzz` is treated just like `-perm /zzz` if `+zzz` is not a valid symbolic mode. When `POSIXLY_CORRECT` is set, such constructs are treated as an error.

When `POSIXLY_CORRECT` is set, the response to the prompt made by the `-ok` action is interpreted according to the system's message catalogue, as opposed to according to `find`'s own message translations.

TZ Affects the time zone used for some of the time-related format directives of `-printf` and `-fprintf`.

EXAMPLES

Simple ‘`find|xargs`‘ approach

- Find files named `core` in or below the directory `/tmp` and delete them.

```
$ find /tmp -name core -type f -print | xargs /bin/rm -f
```

Note that this will work incorrectly if there are any filenames containing newlines, single or double quotes, or spaces.

Safer ‘`find -print0 | xargs -0`‘ approach

- Find files named `core` in or below the directory `/tmp` and delete them, processing filenames in such a way that file or directory names containing single or double quotes, spaces or newlines are correctly handled.

```
$ find /tmp -name core -type f -print0 | xargs -0 /bin/rm -f
```

The `-name` test comes before the `-type` test in order to avoid having to call `stat(2)` on every file.

Note that there is still a race between the time `find` traverses the hierarchy printing the matching filenames, and the time the process executed by `xargs` works with that file.

Executing a command for each file

- Run `file` on every file in or below the current directory.

```
$ find . -type f -exec file '{}' \;
```

Notice that the braces are enclosed in single quote marks to protect them from interpretation as shell script punctuation. The semicolon is similarly protected by the use of a backslash, though single quotes could have been used in that case also.

In many cases, one might prefer the ‘`-exec ... +`’ or better the ‘`-execdir ... +`’ syntax for performance and security reasons.

Traversing the filesystem just once - for 2 different actions

- Traverse the filesystem just once, listing set-user-ID files and directories into `/root/suid.txt` and large files into `/root/big.txt`.

```
$ find / \
  \(-perm -4000 -fprintf /root/suid.txt '%#m %u %p\n'\) , \
  \(-size +100M -fprintf /root/big.txt '%-10s %p\n'\)
```

This example uses the line-continuation character ‘\’ on the first two lines to instruct the shell to continue reading the command on the next line.

Searching files by age

- Search for files in your home directory which have been modified in the last twenty-four hours.

```
$ find $HOME -mtime 0
```

This command works this way because the time since each file was last modified is divided by 24 hours and any remainder is discarded. That means that to match **-mtime 0**, a file will have to have a modification in the past which is less than 24 hours ago.

Searching files by permissions

- Search for files which are executable but not readable.

```
$ find /sbin /usr/sbin -executable ! -readable -print
```

- Search for files which have read and write permission for their owner, and group, but which other users can read but not write to.

```
$ find . -perm 664
```

Files which meet these criteria but have other permissions bits set (for example if someone can execute the file) will not be matched.

- Search for files which have read and write permission for their owner and group, and which other users can read, without regard to the presence of any extra permission bits (for example the executable bit).

```
$ find . -perm -664
```

This will match a file which has mode *0777*, for example.

- Search for files which are writable by somebody (their owner, or their group, or anybody else).

```
$ find . -perm /222
```

- Search for files which are writable by either their owner or their group.

```
$ find . -perm /220
$ find . -perm /u+w,g+w
$ find . -perm /u=w,g=w
```

All three of these commands do the same thing, but the first one uses the octal representation of the file mode, and the other two use the symbolic form. The files don't have to be writable by both the owner and group to be matched; either will do.

- Search for files which are writable by both their owner and their group.

```
$ find . -perm -220
$ find . -perm -g+w,u+w
```

Both these commands do the same thing.

- A more elaborate search on permissions.

```
$ find . -perm -444 -perm /222 ! -perm /111
$ find . -perm -a+r -perm /a+w ! -perm /a+x
```

These two commands both search for files that are readable for everybody (**-perm -444** or **-perm -a+r**), have at least one write bit set (**-perm /222** or **-perm /a+w**) but are not executable for anybody (**! -perm /111** or **! -perm /a+x** respectively).

Pruning - omitting files and subdirectories

- Copy the contents of */source-dir* to */dest-dir*, but omit files and directories named *.snapshot* (and anything in them). It also omits files or directories whose name ends in ‘~’, but not their contents.

```
$ cd /source-dir
$ find . -name .snapshot -prune -o !( ! -name '*~' -print0 ) \
| cpio -pmd0 /dest-dir
```

The construct **-prune -o !(... -print0)** is quite common. The idea here is that the expression before **-prune** matches things which are to be pruned. However, the **-prune** action itself returns true, so the following **-o** ensures that the right hand side is evaluated only for those directories which didn’t get pruned (the contents of the pruned directories are not even visited, so their contents are irrelevant). The expression on the right hand side of the **-o** is in parentheses only for clarity. It emphasises that the **-print0** action takes place only for things that didn’t have **-prune** applied to them. Because the default ‘and’ condition between tests binds more tightly than **-o**, this is the default anyway, but the parentheses help to show what is going on.

- Given the following directory of projects and their associated SCM administrative directories, perform an efficient search for the projects’ roots:

```
$ find repo/ \
  !( -exec test -d '{}/.svn' ';' \
  -or -exec test -d '{}/.git' ';' \
  -or -exec test -d '{}/CVS' ';' \
) -print -prune
```

Sample output:

```
repo/project1/CVS
repo/gnu/project2/.svn
repo/gnu/project3/.svn
repo/gnu/project3/src/.svn
repo/project4/.git
```

In this example, **-prune** prevents unnecessary descent into directories that have already been discovered (for example we do not search *project3/src* because we already found *project3/.svn*), but ensures sibling directories (*project2* and *project3*) are found.

Other useful examples

- Search for several file types.

```
$ find /tmp -type f,d,l
```

Search for files, directories, and symbolic links in the directory */tmp* passing these types as a comma-separated list (GNU extension), which is otherwise equivalent to the longer, yet more portable:

```
$ find /tmp !( -type f -o -type d -o -type l )
```

- Search for files with the particular name *needle* and stop immediately when we find the first one.

```
$ find / -name needle -print -quit
```

- Demonstrate the interpretation of the **%f** and **%h** format directives of the **-printf** action for some corner-cases. Here is an example including some output.

```
$ find . . / /tmp /tmp/TRACE compile compile/64/tests/find -maxdepth 0 -printf '[%h][%f]\n'
[.][.]
[.][..]
[][/]
[][tmp]
[/tmp][TRACE]
[.][compile]
[compile/64/tests][find]
```

EXIT STATUS

find exits with status 0 if all files are processed successfully, greater than 0 if errors occur. This is deliberately a very broad description, but if the return value is non-zero, you should not rely on the correctness of the results of **find**.

When some error occurs, **find** may stop immediately, without completing all the actions specified. For example, some starting points may not have been examined or some pending program invocations for **-exec ... {} +** or **-execdir ... {} +** may not have been performed.

HISTORY

As of findutils-4.2.2, shell metacharacters ('*', '?', '[' or ']' for example) used in filename patterns match a leading '.', because IEEE POSIX interpretation 126 requires this.

As of findutils-4.3.3, **-perm /000** now matches all files instead of none.

Nanosecond-resolution timestamps were implemented in findutils-4.3.3.

As of findutils-4.3.11, the **-delete** action sets **find**'s exit status to a nonzero value when it fails. However, **find** will not exit immediately. Previously, **find**'s exit status was unaffected by the failure of **-delete**.

Feature	Added in	Also occurs in
-newerXY	4.3.3	BSD
-D	4.3.1	
-O	4.3.1	
-readable	4.3.0	
-writable	4.3.0	
-executable	4.3.0	
-regextype	4.2.24	
-exec ... {} +	4.2.12	POSIX
-execdir	4.2.12	BSD
-okdir	4.2.12	
-samefile	4.2.11	
-H	4.2.5	POSIX
-L	4.2.5	POSIX
-P	4.2.5	BSD
-delete	4.2.3	
-quit	4.2.3	
-d	4.2.3	BSD
-wholename	4.2.0	
-iwholename	4.2.0	
-ignore_readdir_race	4.2.0	
-fls	4.0	
-ilname	3.8	
-iname	3.8	
-ipath	3.8	
-iregex	3.8	

The syntax **-perm +MODE** was removed in findutils-4.5.12, in favour of **-perm /MODE**. The **+MODE**

syntax had been deprecated since findutils-4.2.21 which was released in 2005.

NON-BUGS

Operator precedence surprises

The command **find . -name afile -o -name bfile -print** will never print *afile* because this is actually equivalent to **find . -name afile -o \(-name bfile -a -print\)**. Remember that the precedence of **-a** is higher than that of **-o** and when there is no operator specified between tests, **-a** is assumed.

“paths must precede expression” error message

```
$ find . -name *.c -print
find: paths must precede expression
find: possible unquoted pattern after predicate ‘-name’?
```

This happens when the shell could expand the pattern `*.c` to more than one file name existing in the current directory, and passing the resulting file names in the command line to **find** like this:

```
find . -name frcode.c locate.c word_io.c -print
```

That command is of course not going to work, because the **-name** predicate allows exactly one pattern as argument. Instead of doing things this way, you should enclose the pattern in quotes or escape the wildcard, thus allowing **find** to use the pattern with the wildcard during the search for file name matching instead of file names expanded by the parent shell:

```
$ find . -name '*.c' -print
$ find . -name '\*.c' -print
```

BUGS

There are security problems inherent in the behaviour that the POSIX standard specifies for **find**, which therefore cannot be fixed. For example, the **-exec** action is inherently insecure, and **-execdir** should be used instead.

The environment variable **LC_COLLATE** has no effect on the **-ok** action.

A service daemon with D-Bus interface

Documentation > Manual Pages >

firewall-applet

Name

firewall-applet — firewalld applet

Synopsis

```
firewall-applet [OPTIONS...]
```

Description

firewall-applet is a tray applet for firewalld.

Options

firewall-applet does not support any special options.

The following options are supported:

```
-h , --help
```

Prints a short help text and exits.

QSettings

firewall-applet has additional settings to adapt the look and feel. QSettings is used and stores them in `~/.config/firewall/applet.conf`. The file is automatically reloaded if it has been changed and the new settings will immediately be effective.

There is also the global config file `/etc/firewall/applet.conf`, which contains the default values. The settings in this file will be overloaded by settings in the user settings file.

Here is an example `applet.conf` file:

```
[General]
notifications=true
show-inactive=true
```

The following settings are supported:

notifications

The applet shows notifications if enabled. This setting can be enabled also in the applet with the "Enable Notifications" checkbox in the right mouse menu.

This setting defaults to `false`.

If notifications are shown for these actions if enabled:

- Connection to firewalld established
- Connection to firewalld lost
- Firewall has been reloaded
- Default zone has been changed
- Panic mode has been enabled or disabled
- Activation, deactivation or change of zones bound to interfaces
- Activation, deactivation or change of zones bound to sources addresses

show-inactive

Show applet also if firewalld is not running. If firewalld has been stopped or is not running the applet will be hidden and not visible in the applet tray. Enable this setting to see the applet all the time for example to be sure that the firewall is active.

This setting defaults to `false`.

shields-up

The shields-up zone name to be used if shields-up is enabled.

This setting defaults to '`block`'.

shields-down

The shields-down zone name to be used if shields-up has been deactivated again.

This setting defaults to '`public`'.

blink

If enabled, the applet icon blinks in these cases:

- Connection to firewalld lost
- Panic mode has been enabled or disabled

This setting defaults to `false`.

blink-count

The number of blinks if `blink` is enabled.

This setting defaults to `5`.

Documentation > Manual Pages >

firewall-cmd

Name

firewall-cmd — firewalld command line client

Synopsis

```
firewall-cmd [OPTIONS...]
```

Description

firewall-cmd is the command line client of the firewalld daemon. It provides an interface to manage the runtime and permanent configurations.

The runtime configuration in firewalld is separated from the permanent configuration. This means that things can get changed in the runtime or permanent configuration.

Options

Sequence options are the options that can be specified multiple times, the exit code is 0 if there is at least one item that succeeded. The `ALREADY_ENABLED` (11), `NOT_ENABLED` (12) and also `ZONE_ALREADY_SET` (16) errors are treated as succeeded. If there are issues while parsing the items, then these are treated as warnings and will not change the result as long as there is a succeeded one. Without any succeeded item, the exit code will depend on the error codes. If there is exactly one error code, then this is used. If there are more than one then `UNKNOWN_ERROR` (254) will be used.

The following options are supported:

General Options

`-h`, `--help`

Prints a short help text and exits.

`-V`, `--version`

Print the version string of firewalld. This option is not combinable with other options.

`-q`, `--quiet`

Do not print status messages.

Status Options

--state

Check whether the firewalld daemon is active (i.e. running). Returns an exit code 0 if it is active, `RUNNING_BUT_FAILED` if failure occurred on startup, `NOT_RUNNING` otherwise. See the section called “Exit Codes”. This will also print the state to `STDOUT`.

--reload

Reload firewall rules and keep state information. Current permanent configuration will become new runtime configuration, i.e. all runtime only changes done until reload are lost with reload if they have not been also in permanent configuration.

Note: If `FlushAllOnReload=no`, runtime changes applied via the direct interface are not affected and will therefore stay in place until firewalld daemon is restarted completely. For `FlushAllOnReload`, see [firewalld.conf\(5\)](#).

--complete-reload

Reload firewall completely, even netfilter kernel modules. This will most likely terminate active connections, because state information is lost. This option should only be used in case of severe firewall problems. For example if there are state information problems that no connection can be established with correct firewall rules.

Note: If `FlushAllOnReload=no`, runtime changes applied via the direct interface are not affected and will therefore stay in place until firewalld daemon is restarted completely. For `FlushAllOnReload`, see [firewalld.conf\(5\)](#).

--runtime-to-permanent

Save active runtime configuration and overwrite permanent configuration with it. The way this is supposed to work is that when configuring firewalld you do runtime changes only and once you're happy with the configuration and you tested that it works the way you want, you save the configuration to disk.

--check-config

Run checks on the permanent configuration. This includes XML validity and semantics.

Log Denied Options

--get-log-denied

Print the log denied setting.

--set-log-denied = `value`

Add logging rules right before reject and drop rules in the INPUT, FORWARD and OUTPUT chains for the default rules and also final reject and drop rules in zones for the configured link-

layer packet type. The possible values are: `all`, `unicast`, `broadcast`, `multicast` and `off`. The default setting is `off`, which disables the logging.

This is a runtime and permanent change and will also reload the firewall to be able to add the logging rules.

Permanent Options

`--permanent`

The permanent option `--permanent` can be used to set options permanently. These changes are not effective immediately, only after service restart/reload or system reboot. Without the `--permanent` option, a change will only be part of the runtime configuration.

If you want to make a change in runtime and permanent configuration, use the same call with and without the `--permanent` option.

The `--permanent` option can be optionally added to all options further down where it is supported.

Zone Options

`--get-default-zone`

Print default zone for connections and interfaces.

`--set-default-zone = zone`

Set default zone for connections and interfaces where no zone has been selected. Setting the default zone changes the zone for the connections or interfaces, that are using the default zone.

This is a runtime and permanent change.

`--get-active-zones`

Print currently active zones altogether with interfaces and sources used in these zones. Active zones are zones, that have a binding to an interface or source. The output format is:

```

zone1
  interfaces: interface1 interface2 ...
  sources: source1 ...
zone2
  interfaces: interface3 ...
zone3
  sources: source2 ...

```

If there are no interfaces or sources bound to the zone, the corresponding line will be omitted.

`[--permanent] --get-zones`

Print predefined zones as a space separated list.

[--permanent] --get-services

Print predefined services as a space separated list.

[--permanent] --get-icmptypes

Print predefined icmptypes as a space separated list.

[--permanent] --get-zone-of-interface = *interface*

Print the name of the zone the *interface* is bound to or no zone.

[--permanent] --get-zone-of-source = *source* [/ *mask*] || *MAC* |ipset: *ipset*

Print the name of the zone the source is bound to or no zone.

[--permanent] --info-zone= *zone*

Print information about the zone *zone*. The output format is:

```
zone
  interfaces: interface1 ...
  sources: source1 ...
  services: service1 ...
  ports: port1 ...
  protocols: protocol1 ...
  forward-ports:
    forward-port1
    ...
  source-ports: source-port1 ...
  icmp-blocks: icmp-type1 ...
  rich rules:
    rich-rule1
    ...
```

[--permanent] --list-all-zones

List everything added for or enabled in all zones. The output format is:

```
zone1
  interfaces: interface1 ...
  sources: source1 ...
  services: service1 ...
  ports: port1 ...
  protocols: protocol1 ...
  forward-ports:
    forward-port1
    ...
  icmp-blocks: icmp-type1 ...
  rich rules:
    rich-rule1
```

..
..
`--permanent --new-zone = zone`

Add a new permanent and empty zone.

Zone names must be alphanumeric and may additionally include characters: '_' and '-'.

`--permanent --new-zone-from-file = filename [--name = zone]`

Add a new permanent zone from a prepared zone file with an optional name override.

`--permanent --delete-zone = zone`

Delete an existing permanent zone.

`--permanent --load-zone-defaults = zone`

Load zone default settings or report NO_DEFAULTS error.

`--permanent --path-zone= zone`

Print path of the zone configuration file.

Policy Options

`[--permanent] --get-policies`

Print predefined policies as a space separated list.

`[--permanent] --info-policy = policy`

Print information about the policy `policy`.

`[--permanent] --list-all-policies`

List everything added for or enabled in all policies.

`--permanent --new-policy = policy`

Add a new permanent policy.

Policy names must be alphanumeric and may additionally include characters: '_' and '-'.

`--permanent --new-policy-from-file = filename [--name = policy]`

Add a new permanent policy from a prepared policy file with an optional name override.

`--permanent --path-policy = policy`

Print path of the policy configuration file.

`--permanent --delete-policy = policy`

Delete an existing permanent policy.

`--permanent --load-policy-defaults = policy`

Load the shipped defaults for a policy. Only applies to policies shipped with firewalld. Does not apply to user defined policies.

Options to Adapt and Query Zones and Policies

Options in this section affect only one particular zone or policy. If used with `--zone = zone` or `--policy = policy` option, they affect the specified zone or policy. If both options are omitted, they affect the default zone (see `--get-default-zone`).

`[--permanent] [--zone = zone] [--policy = policy] --list-all`

List everything added or enabled.

`--permanent [--zone = zone] [--policy = policy] --get-target`

Get the target.

`--permanent [--zone = zone] [--policy = policy] --set-target = target`

Set the target.

For zones `target` is one of: `default`, `ACCEPT`, `DROP`, `REJECT`

For policies `target` is one of: `CONTINUE`, `ACCEPT`, `DROP`, `REJECT`

`default` is similar to `REJECT`, but it implicitly allows ICMP packets.

`--permanent [--zone = zone] [--policy = policy] --set-description = description`

Set description.

`--permanent [--zone = zone] [--policy = policy] --get-description`

Print description.

`--permanent [--zone = zone] [--policy = policy] --set-short = description`

Set short description.

`--permanent [--zone = zone] [--policy = policy] --get-short`

Print short description.

`[--permanent] [--zone = zone] [--permanent] [--policy = policy] --list-services`

List services added as a space separated list.

`[--permanent] [--zone = zone] [--permanent] [--policy = policy] --add-service = service [--timeout = timeval]`

Add a service. This option can be specified multiple times. If a timeout is supplied, the rule will be active for the specified amount of time and will be removed automatically afterwards. `timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

The service is one of the firewalld provided services. To get a list of the supported services, use **firewall-cmd --get-services**.

The `--timeout` option is not combinable with the `--permanent` option.

Note: Some services define connection tracking helpers. Helpers that may operate in client mode (e.g. tftp) must be added to an outbound policy instead of a zone to take effect for clients. Otherwise the helper will not be applied to the outbound traffic. The related traffic, as defined by the connection tracking helper, on the return path (ingress) will be allowed by the stateful firewall rules.

An example of an outbound policy for connection tracking helpers:

```
# firewall-cmd --permanent --new-policy clientConntrack
# firewall-cmd --permanent --policy clientConntrack --add-ingress-zone HOST
# firewall-cmd --permanent --policy clientConntrack --add-egress-zone ANY
# firewall-cmd --permanent --policy clientConntrack --add-service tftp

[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-
service = service
```

Remove a service. This option can be specified multiple times.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-
service = service
```

Return whether `service` has been added. Returns 0 if true, 1 otherwise.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --list-ports
```

List ports added as a space separated list. A port is of the form `portid[-portid]/protocol`, it can be either a port and protocol pair or a port range with a protocol.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-port = portid [-
portid]/protocol [ --timeout = timeval ]
```

Add the port. This option can be specified multiple times. If a timeout is supplied, the rule will be active for the specified amount of time and will be removed automatically afterwards. `timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

The port can either be a single port number or a port range `portid - portid`. The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

The `--timeout` option is not combinable with the `--permanent` option.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-
port = portid [-portid]/protocol
```

Remove the port. This option can be specified multiple times.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-
port = portid [- portid ]/ protocol
```

Return whether the port has been added. Returns 0 if true, 1 otherwise.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --list-protocols
```

List protocols added as a space separated list.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-
protocol = protocol [ --timeout = timeval ]
```

Add the protocol. This option can be specified multiple times. If a timeout is supplied, the rule will be active for the specified amount of time and will be removed automatically afterwards.

`timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

The protocol can be any protocol supported by the system. Please have a look at `/etc/protocols` for supported protocols.

The `--timeout` option is not combinable with the `--permanent` option.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-
protocol = protocol
```

Remove the protocol. This option can be specified multiple times.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-
protocol = protocol
```

Return whether the protocol has been added. Returns 0 if true, 1 otherwise.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --list-source-ports
```

List source ports added as a space separated list. A port is of the form `portid [- portid]/ protocol`.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-source-
port = portid [- portid ]/ protocol [ --timeout = timeval ]
```

Add the source port. This option can be specified multiple times. If a timeout is supplied, the rule will be active for the specified amount of time and will be removed automatically afterwards.

`timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

The port can either be a single port number or a port range `portid - portid`. The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

The `--timeout` option is not combinable with the `--permanent` option.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-source-
port = portid [- portid ]/ protocol
```

Remove the source port. This option can be specified multiple times.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-source-port = portid [- portid] / protocol
```

Return whether the source port has been added. Returns 0 if true, 1 otherwise.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --list-icmp-blocks
```

List Internet Control Message Protocol (ICMP) type blocks added as a space separated list.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-icmp-block = icmptype [ --timeout = timeval ]
```

Add an ICMP block for `icmptype`. This option can be specified multiple times. If a timeout is supplied, the rule will be active for the specified amount of time and will be removed automatically afterwards. `timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

The `icmptype` is the one of the icmp types firewalld supports. To get a listing of supported icmp types: **firewall-cmd --get-icmptypes**

The `--timeout` option is not combinable with the `--permanent` option.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-icmp-block = icmptype
```

Remove the ICMP block for `icmptype`. This option can be specified multiple times.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-icmp-block = icmptype
```

Return whether an ICMP block for `icmptype` has been added. Returns 0 if true, 1 otherwise.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --list-forward-ports
```

List IPv4 forward ports added as a space separated list.

For IPv6 forward ports, please use the rich language.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-forward-port = port=portid [- portid]:proto=protocol[:toport=portid [- portid]] [:toaddr=address [/ mask]] [ --timeout = timeval ]
```

Add the IPv4 forward port. This option can be specified multiple times. If a timeout is supplied, the rule will be active for the specified amount of time and will be removed automatically afterwards. `timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

The port can either be a single port number `portid` or a port range `portid - portid`. The protocol can either be `tcp`, `udp`, `sctp` or `dccp`. The destination address is a simple IP address.

The `--timeout` option is not combinable with the `--permanent` option.

For *IPv6* forward ports, please use the rich language.

Note: IP forwarding will be implicitly enabled if `toaddr` is specified.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-forward-
port =port= portid [- portid ]:proto= protocol [:toport= portid [- portid ]]
[:toaddr= address [/ mask ]]
```

Remove the *IPv4* forward port. This option can be specified multiple times.

For *IPv6* forward ports, please use the rich language.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-forward-
port =port= portid [- portid ]:proto= protocol [:toport= portid [- portid ]]
[:toaddr= address [/ mask ]]
```

Return whether the *IPv4* forward port has been added. Returns 0 if true, 1 otherwise.

For *IPv6* forward ports, please use the rich language.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-masquerade [ --
timeout = timeval ]
```

Enable *IPv4* masquerade. If a timeout is supplied, masquerading will be active for the specified amount of time. `timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`. Masquerading is useful if the machine is a router and machines connected over an interface in another zone should be able to use the first connection.

The `--timeout` option is not combinable with the `--permanent` option.

For *IPv6* masquerading, please use the rich language.

Note: IP forwarding will be implicitly enabled.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-masquerade
```

Disable *IPv4* masquerade. If the masquerading was enabled with a timeout, it will be disabled also.

For *IPv6* masquerading, please use the rich language.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-masquerade
```

Return whether *IPv4* masquerading has been enabled. Returns 0 if true, 1 otherwise.

For *IPv6* masquerading, please use the rich language.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --list-rich-rules
```

List rich language rules added as a newline separated list.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --add-rich-
rule='rule' [ --timeout = timeval ]
```

Add rich language rule '`rule`'. This option can be specified multiple times. If a timeout is supplied, the `rule` will be active for the specified amount of time and will be removed automatically afterwards. `timeval` is either a number (of seconds) or number followed by one of characters `s` (seconds), `m` (minutes), `h` (hours), for example `20m` or `1h`.

For the rich language rule syntax, please have a look at [firewalld.richlanguage\(5\)](#).

The `--timeout` option is not combinable with the `--permanent` option.

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --remove-rich-
rule='rule'
```

Remove rich language rule '`rule`'. This option can be specified multiple times.

For the rich language rule syntax, please have a look at [firewalld.richlanguage\(5\)](#).

```
[ --permanent ] [ --zone = zone ] [ --permanent ] [ --policy = policy ] --query-rich-
rule='rule'
```

Return whether a rich language rule '`rule`' has been added. Returns 0 if true, 1 otherwise.

For the rich language rule syntax, please have a look at [firewalld.richlanguage\(5\)](#).

Options to Adapt and Query Zones

Options in this section affect only one particular zone. If used with `--zone = zone` option, they affect the specified zone. If the option is omitted, they affect default zone (see `--get-default-zone`).

```
[ --permanent ] [ --zone = zone ] --add-icmp-block-inversion
```

Enable ICMP block inversion.

```
[ --permanent ] [ --zone = zone ] --remove-icmp-block-inversion
```

Disable ICMP block inversion.

```
[ --permanent ] [ --zone = zone ] --query-icmp-block-inversion
```

Return whether ICMP block inversion is enabled. Returns 0 if true, 1 otherwise.

```
[ --permanent ] [ --zone = zone ] --add-forward
```

Enable intra zone forwarding.

```
[ --permanent ] [ --zone = zone ] --remove-forward
```

Disable intra zone forwarding.

```
[ --permanent ] [ --zone = zone ] --query-forward
```

Return whether intra zone forwarding is enabled. Returns 0 if true, 1 otherwise.

Options to Adapt and Query Policies

Options in this section affect only one particular policy. It's required to specify `--policy = policy` with these options.

`--permanent` `--policy = policy` `--get-priority`

Get the priority.

`--permanent` `--policy = policy` `--set-priority = priority`

Set the priority. The priority determines the relative ordering of policies. This is an integer value between -32768 and 32767 where -1 is the default value for new policies and 0 is reserved for internal use.

If a priority is < 0, then the policy's rules will execute before all rules in all zones.

If a priority is > 0, then the policy's rules will execute after all rules in all zones.

`[--permanent] --policy = policy` `--list-ingress-zones`

List ingress zones added as a space separated list.

`[--permanent] --policy = policy` `--add-ingress-zone = zone`

Add an ingress zone. This option can be specified multiple times.

The ingress zone is one of the firewalld provided zones or one of the pseudo-zones: HOST, ANY.

HOST is used for traffic originating from the host machine, i.e. the host running firewalld.

ANY is used for traffic originating from any zone. This can be thought of as a wild card for zones. However it does not include traffic originating from the host machine - use HOST for that.

`[--permanent] --policy = policy` `--remove-ingress-zone = zone`

Remove an ingress zone. This option can be specified multiple times.

`[--permanent] --policy = policy` `--query-ingress-zone = zone`

Return whether `zone` has been added. Returns 0 if true, 1 otherwise.

`[--permanent] --policy = policy` `--list-egress-zones`

List egress zones added as a space separated list.

`[--permanent] --policy = policy` `--add-egress-zone = zone`

Add an egress zone. This option can be specified multiple times.

The egress zone is one of the firewalld provided zones or one of the pseudo-zones: HOST, ANY.

For clarification on HOST and ANY see option `--add-ingress-zone`.

`[--permanent] --policy = policy` `--remove-egress-zone = zone`

Remove an egress zone. This option can be specified multiple times.

```
[ --permanent ] [ --policy = policy ] [ --query-egress-zone = zone ]
```

Return whether *zone* has been added. Returns 0 if true, 1 otherwise.

Options to Handle Bindings of Interfaces

Binding an interface to a zone means that this zone settings are used to restrict traffic via the interface.

Options in this section affect only one particular zone. If used with `--zone = zone` option, they affect the zone *zone*. If the option is omitted, they affect default zone (see `--get-default-zone`).

For a list of predefined zones use **firewall-cmd --get-zones**.

An interface name is a string up to 16 characters long, that may not contain ' ', '/', '!' and '*'.

```
[ --permanent ] [ --zone = zone ] [ --list-interfaces ]
```

List interfaces that are bound to zone *zone* as a space separated list. If zone is omitted, default zone will be used.

```
[ --permanent ] [ --zone = zone ] [ --add-interface = interface ]
```

Bind interface *interface* to zone *zone*. If zone is omitted, default zone will be used.

If the interface is under control of NetworkManager, it is at first connected to change the zone for the connection that is using the interface. If this fails, the zone binding is created in firewalld and the limitations below apply. For interfaces that are not under control of NetworkManager, firewalld tries to change the ZONE setting in the ifcfg file, if the file exists.

As a end user you don't need this in most cases, because NetworkManager (or legacy network service) adds interfaces into zones automatically (according to `ZONE=` option from ifcfg-*interface* file) if `NM_CONTROLLED=no` is not set. You should do it only if there's no /etc/sysconfig/network-scripts/ifcfg-*interface* file. If there is such file and you add interface to zone with this `--add-interface` option, make sure the zone is the same in both cases, otherwise the behaviour would be undefined. Please also have a look at the **firewalld(1)** man page in the `Concepts` section. For permanent association of interface with a zone, see also 'How to set or change a zone for a connection?' in **firewalld.zones(5)**.

```
[ --permanent ] [ --zone = zone ] [ --change-interface = interface ]
```

If the interface is under control of NetworkManager, it is at first connected to change the zone for the connection that is using the interface. If this fails, the zone binding is created in firewalld and the limitations below apply. For interfaces that are not under control of NetworkManager, firewalld tries to change the ZONE setting in the ifcfg file, if the file exists.

Change zone the interface `interface` is bound to to zone `zone`. It's basically `--remove-interface` followed by `--add-interface`. If the interface has not been bound to a zone before, it behaves like `--add-interface`. If zone is omitted, default zone will be used.

```
[ --permanent ] [ --zone = zone ] --query-interface = interface
```

Query whether interface `interface` is bound to zone `zone`. Returns 0 if true, 1 otherwise.

```
[ --permanent ] --remove-interface = interface
```

If the interface is under control of NetworkManager, it is at first connected to change the zone for the connection that is using the interface. If this fails, the zone binding is created in firewalld and the limitations below apply.

For the addition or change of interfaces that are not under control of NetworkManager: firewalld tries to change the ZONE setting in the ifcfg file, if an ifcfg file exists that is using the interface.

Only for the removal of interfaces that are not under control of NetworkManager: firewalld is not trying to change the ZONE setting in the ifcfg file. This is needed to make sure that an ifdown of the interface will not result in a reset of the zone setting to the default zone. Only the zone binding is then removed in firewalld then.

Remove binding of interface `interface` from zone it was previously added to.

Options to Handle Bindings of Sources

Binding a source to a zone means that this zone settings will be used to restrict traffic from this source.

A source address or address range is either an IP address or a network IP address with a mask for IPv4 or IPv6 or a MAC address or an ipset with the ipset: prefix. For IPv4, the mask can be a network mask or a plain number. For IPv6 the mask is a plain number. The use of host names is not supported.

Options in this section affect only one particular zone. If used with `--zone = zone` option, they affect the zone `zone`. If the option is omitted, they affect default zone (see `--get-default-zone`).

For a list of predefined zones use **firewall-cmd** `[--permanent] --get-zones`.

```
[ --permanent ] [ --zone = zone ] --list-sources
```

List sources that are bound to zone `zone` as a space separated list. If zone is omitted, default zone will be used.

```
[ --permanent ] [ --zone = zone ] --add-source = source [/ mask ]|MAC|ipset: ipset
```

Bind the source to zone `zone`. If zone is omitted, default zone will be used.

```
[ --zone = zone ] --change-source = source [/ mask ]|MAC|ipset: ipset
```

Change zone the source is bound to to zone `zone`. It's basically `--remove-source` followed by `--add-source`. If the source has not been bound to a zone before, it behaves like `--add-source`. If zone is omitted, default zone will be used.

`[--permanent] [--zone = zone] --query-source = source [/ mask]| MAC |ipset: ipset`

Query whether the source is bound to the zone `zone`. Returns 0 if true, 1 otherwise.

`[--permanent] --remove-source = source [/ mask]| MAC |ipset: ipset`

Remove binding of the source from zone it was previously added to.

IPSet Options

`--get-ipset-types`

Print the supported ipset types.

`--permanent --new-ipset = ipset --type = type [--family = inet | inet6] [--option = key [= value]]`

Add a new permanent and empty ipset with specifying the type and optional the family and options like `timeout`, `hashsize` and `maxelem`. For more information please have a look at `ipset(8)` man page.

ipset names must be alphanumeric and may additionally include characters: '_' and '-'.

`--permanent --new-ipset-from-file = filename [--name = ipset]`

Add a new permanent ipset from a prepared ipset file with an optional name override.

`--permanent --delete-ipset = ipset`

Delete an existing permanent ipset.

`--permanent --load-ipset-defaults = ipset`

Load ipset default settings or report NO_DEFAULTS error.

`[--permanent] --info-ipset= ipset`

Print information about the ipset `ipset`. The output format is:

```

ipset
type: type
options: option1[=value1] ...
entries: entry1 ...

```

`[--permanent] --get-ipsets`

Print predefined ipsets as a space separated list.

`--permanent --ipset = ipset --set-description = description`

Set new description to ipset

`--permanent` `--ipset = ipset` `--get-description`

Print description for ipset

`--permanent` `--ipset = ipset` `--set-short = description`

Set short description to ipset

`--permanent` `--ipset = ipset` `--get-short`

Print short description for ipset

[`--permanent`] `--ipset = ipset` `--add-entry = entry`

Add a new entry to the ipset.

Adding an entry to an ipset with option `timeout` is permitted, but these entries are not tracked by firewalld.

[`--permanent`] `--ipset = ipset` `--remove-entry = entry`

Remove an entry from the ipset.

[`--permanent`] `--ipset = ipset` `--query-entry = entry`

Return whether the entry has been added to an ipset. Returns 0 if true, 1 otherwise.

Querying an ipset with a timeout will yield an error. Entries are not tracked for ipsets with a timeout.

[`--permanent`] `--ipset = ipset` `--get-entries`

List all entries of the ipset.

[`--permanent`] `--ipset = ipset` `--add-entries-from-file = filename`

Add a new entries to the ipset from the file. For all entries that are listed in the file but already in the ipset, a warning will be printed.

The file should contain an entry per line. Lines starting with an hash or semicolon are ignored. Also empty lines.

[`--permanent`] `--ipset = ipset` `--remove-entries-from-file = filename`

Remove existing entries from the ipset from the file. For all entries that are listed in the file but not in the ipset, a warning will be printed.

The file should contain an entry per line. Lines starting with an hash or semicolon are ignored. Also empty lines.

`--permanent` `--path-ipset= ipset`

Print path of the ipset configuration file.

Service Options

Options in this section affect only one particular service.

`[--permanent] --info-service= service`

Print information about the service `service`. The output format is:

```
service
ports: port1 ..
protocols: protocol1 ..
source-ports: source-port1 ..
helpers: helper1 ..
destination: ipv1 : address1 ..
```

The following options are only usable in the permanent configuration.

`--permanent --new-service= service`

Add a new permanent and empty service.

Service names must be alphanumeric and may additionally include characters: '_' and '-'.

`--permanent --new-service-from-file= filename [--name= service]`

Add a new permanent service from a prepared service file with an optional name override.

`--permanent --delete-service= service`

Delete an existing permanent service.

`--permanent --load-service-defaults= service`

Load service default settings or report NO_DEFAULTS error.

`--permanent --path-service= service`

Print path of the service configuration file.

`--permanent --service= service --set-description= description`

Set new description to service

`--permanent --service= service --get-description`

Print description for service

`--permanent --service= service --set-short= description`

Set short description to service

`--permanent --service= service --get-short`

Print short description for service

`--permanent --service= service --add-port= portid[-portid]/protocol`

Add a new port to the permanent service.

`--permanent --service= service --remove-port= portid[-portid]/protocol`

Remove a port from the permanent service.

```
--permanent --service = service --query-port = portid[-portid]/protocol
```

Return whether the port has been added to the permanent service.

```
--permanent --service = service --get-ports
```

List ports added to the permanent service.

```
--permanent --service = service --add-protocol = protocol
```

Add a new protocol to the permanent service.

```
--permanent --service = service --remove-protocol = protocol
```

Remove a protocol from the permanent service.

```
--permanent --service = service --query-protocol = protocol
```

Return whether the protocol has been added to the permanent service.

```
--permanent --service = service --get-protocols
```

List protocols added to the permanent service.

```
--permanent --service = service --add-source-port = portid[-portid]/protocol
```

Add a new source port to the permanent service.

```
--permanent --service = service --remove-source-port = portid[-portid]/protocol
```

Remove a source port from the permanent service.

```
--permanent --service = service --query-source-port = portid[-portid]/protocol
```

Return whether the source port has been added to the permanent service.

```
--permanent --service = service --get-source-ports
```

List source ports added to the permanent service.

```
--permanent --service = service --add-helper = helper
```

Add a new helper to the permanent service.

```
--permanent --service = service --remove-helper = helper
```

Remove a helper from the permanent service.

```
--permanent --service = service --query-helper = helper
```

Return whether the helper has been added to the permanent service.

```
--permanent --service = service --get-service-helpers
```

List helpers added to the permanent service.

```
--permanent --service = service --set-destination = ipv:address[/mask]
```

Set destination for *ipv* to *address*[/*mask*] in the permanent service.

`--permanent --service = service --remove-destination = ipv`

Remove the destination for *ipv* from the permanent service.

`--permanent --service = service --query-destination = ipv : address [/ mask]`

Return whether the destination *ipv* to *address[/mask]* has been set in the permanent service.

`--permanent --service = service --get-destinations`

List destinations added to the permanent service.

`--permanent --service = service --add-include = service`

Add a new include to the permanent service.

`--permanent --service = service --remove-include = service`

Remove a include from the permanent service.

`--permanent --service = service --query-include = service`

Return whether the include has been added to the permanent service.

`--permanent --service = service --get-includes`

List includes added to the permanent service.

Helper Options

Options in this section affect only one particular helper.

`[--permanent] --info-helper= helper`

Print information about the helper *helper*. The output format is:

```
helper
family: family
module: module
ports: port1 ..
```

The following options are only usable in the permanent configuration.

`--permanent --new-helper = helper --module = nf_conntrack_module [--family = ipv4 | ipv6]`

Add a new permanent helper with module and optionally family defined.

Helper names must be alphanumeric and may additionally include characters: '-'.

`--permanent --new-helper-from-file = filename [--name = helper]`

Add a new permanent helper from a prepared helper file with an optional name override.

`--permanent --delete-helper = helper`

Delete an existing permanent helper.

`--permanent --load-helper-defaults = helper`

Load helper default settings or report NO_DEFAULTS error.

`--permanent --path-helper= helper`

Print path of the helper configuration file.

`[--permanent] --get-helpers`

Print predefined helpers as a space separated list.

`--permanent --helper = helper --set-description = description`

Set new description to helper

`--permanent --helper = helper --get-description`

Print description for helper

`--permanent --helper = helper --set-short = description`

Set short description to helper

`--permanent --helper = helper --get-short`

Print short description for helper

`--permanent --helper = helper --add-port = portid[- portid]/ protocol`

Add a new port to the permanent helper.

`--permanent --helper = helper --remove-port = portid[- portid]/ protocol`

Remove a port from the permanent helper.

`--permanent --helper = helper --query-port = portid[- portid]/ protocol`

Return whether the port has been added to the permanent helper.

`--permanent --helper = helper --get-ports`

List ports added to the permanent helper.

`--permanent --helper = helper --set-module = description`

Set module description for helper

`--permanent --helper = helper --get-module`

Print module description for helper

`--permanent --helper = helper --set-family = description`

Set family description for helper

`--permanent --helper = helper --get-family`

Print family description of helper

Internet Control Message Protocol (ICMP) type Options

Options in this section affect only one particular icmp type.

```
[ --permanent ] --info-icmptype= icmptype
```

Print information about the icmp type *icmptype*. The output format is:

```
icmptype
```

```
destination: ipv1 ..
```

The following options are only usable in the permanent configuration.

```
--permanent --new-icmptype= icmptype
```

Add a new permanent and empty icmptype.

ICMP type names must be alphanumeric and may additionally include characters: '_' and '-'.

```
--permanent --new-icmptype-from-file= filename [ --name= icmptype ]
```

Add a new permanent icmptype from a prepared icmptype file with an optional name override.

```
--permanent --delete-icmptype= icmptype
```

Delete an existing permanent icmptype.

```
--permanent --load-icmptype-defaults= icmptype
```

Load icmptype default settings or report NO_DEFAULTS error.

```
--permanent --icmptype= icmptype --set-description= description
```

Set new description to icmptype

```
--permanent --icmptype= icmptype --get-description
```

Print description for icmptype

```
--permanent --icmptype= icmptype --set-short= description
```

Set short description to icmptype

```
--permanent --icmptype= icmptype --get-short
```

Print short description for icmptype

```
--permanent --icmptype= icmptype --add-destination= ipv
```

Enable destination for ipv in permanent icmptype. ipv is one of *ipv4* or *ipv6*.

```
--permanent --icmptype= icmptype --remove-destination= ipv
```

Disable destination for ipv in permanent icmptype. ipv is one of *ipv4* or *ipv6*.

```
--permanent --icmptype= icmptype --query-destination= ipv
```

Return whether destination for ipv is enabled in permanent icmptype. ipv is one of *ipv4* or *ipv6*.

`--permanent` `--icmptype = icmptype` `--get-destinations`

List destinations in permanent icmptype.

`--permanent` `--path-icmptype= icmptype`

Print path of the icmptype configuration file.

Direct Options

DEPRECATED

The direct interface has been deprecated. It will be removed in a future release. It is superseded by policies, see [firewalld.policies\(5\)](#).

The direct options give a more direct access to the firewall. These options require user to know basic iptables concepts, i.e. `table` (filter/mangle/nat/...), `chain` (INPUT/OUTPUT/FORWARD/...), `commands` (-A/-D/-I/...), `parameters` (-p/-s/-d/-j/...) and `targets` (ACCEPT/DROP/REJECT/...).

Direct options should be used only as a last resort when it's not possible to use for example `--add-service = service` or `--add-rich-rule ='rule'`.

Warning: Direct rules behavior is different depending on the value of `FirewallBackend`. See [CAVEATS](#) in [firewalld.direct\(5\)](#).

The first argument of each option has to be `ipv4` or `ipv6` or `eb`. With `ipv4` it will be for IPv4 ([iptables\(8\)](#)), with `ipv6` for IPv6 ([ip6tables\(8\)](#)) and with `eb` for ethernet bridges ([ebtables\(8\)](#)).

`[--permanent] --direct --get-all-chains`

Get all chains added to all tables. This option concerns only chains previously added with `--direct --add-chain`.

`[--permanent] --direct --get-chains { ipv4 | ipv6 | eb } table`

Get all chains added to table `table` as a space separated list. This option concerns only chains previously added with `--direct --add-chain`.

`[--permanent] --direct --add-chain { ipv4 | ipv6 | eb } table chain`

Add a new chain with name `chain` to table `table`. Make sure there's no other chain with this name already.

There already exist basic chains to use with direct options, for example `INPUT_direct` chain (see `iptables-save | grep direct` output for all of them). These chains are jumped into before chains for zones, i.e. every rule put into `INPUT_direct` will be checked before rules in zones.

`[--permanent] --direct --remove-chain { ipv4 | ipv6 | eb } table chain`

Remove chain with name `chain` from table `table`. Only chains previously added with `--direct --add-chain` can be removed this way.

```
[ --permanent ] --direct --query-chain { ipv4 | ipv6 | eb } table chain
```

Return whether a chain with name `chain` exists in table `table`. Returns 0 if true, 1 otherwise.

This option concerns only chains previously added with `--direct --add-chain`.

```
[ --permanent ] --direct --get-all-rules
```

Get all rules added to all chains in all tables as a newline separated list of the priority and arguments. This option concerns only rules previously added with `--direct --add-rule`.

```
[ --permanent ] --direct --get-rules { ipv4 | ipv6 | eb } table chain
```

Get all rules added to chain `chain` in table `table` as a newline separated list of the priority and arguments. This option concerns only rules previously added with `--direct --add-rule`.

```
[ --permanent ] --direct --add-rule { ipv4 | ipv6 | eb } table chain priority  
args
```

Add a rule with the arguments `args` to chain `chain` in table `table` with priority `priority`.

The `priority` is used to order rules. Priority 0 means add rule on top of the chain, with a higher priority the rule will be added further down. Rules with the same priority are on the same level and the order of these rules is not fixed and may change. If you want to make sure that a rule will be added after another one, use a low priority for the first and a higher for the following.

```
[ --permanent ] --direct --remove-rule { ipv4 | ipv6 | eb } table chain priority  
args
```

Remove a rule with `priority` and the arguments `args` from chain `chain` in table `table`.

Only rules previously added with `--direct --add-rule` can be removed this way.

```
[ --permanent ] --direct --remove-rules { ipv4 | ipv6 | eb } table chain
```

Remove all rules in the chain with name `chain` exists in table `table`. This option concerns only rules previously added with `--direct --add-rule` in this chain.

```
[ --permanent ] --direct --query-rule { ipv4 | ipv6 | eb } table chain priority  
args
```

Return whether a rule with `priority` and the arguments `args` exists in chain `chain` in table `table`. Returns 0 if true, 1 otherwise. This option concerns only rules previously added with `--direct --add-rule`.

```
--direct --passthrough { ipv4 | ipv6 | eb } args
```

Pass a command through to the firewall. `args` can be all **iptables**, **ip6tables** and **ebtables** command line arguments. This command is untracked, which means that firewalld is not able to provide information about this command later on, also not a listing of the untracked passthroughs.

```
[ --permanent ] --direct --get-all-passthroughs
```

Get all passthrough rules as a newline separated list of the ipv value and arguments.

```
[ --permanent ] --direct --get-passthroughs { ipv4 | ipv6 | eb }
```

Get all passthrough rules for the ipv value as a newline separated list of the priority and arguments.

```
[ --permanent ] --direct --add-passthrough { ipv4 | ipv6 | eb } args
```

Add a passthrough rule with the arguments `args` for the ipv value.

```
[ --permanent ] --direct --remove-passthrough { ipv4 | ipv6 | eb } args
```

Remove a passthrough rule with the arguments `args` for the ipv value.

```
[ --permanent ] --direct --query-passthrough { ipv4 | ipv6 | eb } args
```

Return whether a passthrough rule with the arguments `args` exists for the ipv value. Returns 0 if true, 1 otherwise.

Lockdown Options

Local applications or services are able to change the firewall configuration if they are running as root (example: libvirt) or are authenticated using PolicyKit. With this feature administrators can lock the firewall configuration so that only applications on lockdown whitelist are able to request firewall changes.

The lockdown access check limits D-Bus methods that are changing firewall rules. Query, list and get methods are not limited.

The lockdown feature is a very light version of user and application policies for firewalld and is turned off by default.

```
--lockdown-on
```

Enable lockdown. Be careful - if firewall-cmd is not on lockdown whitelist when you enable lockdown you won't be able to disable it again with firewall-cmd, you would need to edit firewalld.conf.

This is a runtime and permanent change.

```
--lockdown-off
```

Disable lockdown.

This is a runtime and permanent change.

```
--query-lockdown
```

Query whether lockdown is enabled. Returns 0 if lockdown is enabled, 1 otherwise.

Lockdown Whitelist Options

The lockdown whitelist can contain `commands`, `contexts`, `users` and `user ids`.

If a command entry on the whitelist ends with an asterisk '*', then all command lines starting with the command will match. If the '*' is not there the absolute command inclusive arguments must match.

Command paths for users are not always the same and depends on the users PATH. Some distributions symlink **/bin** to **/usr/bin** in which case it depends on the order they appear in the PATH environment variable.

The context is the security (SELinux) context of a running application or service. To get the context of a running application use **ps -e --context**.

Warning: If the context is unconfined, then this will open access for more than the desired application.

The lockdown whitelist entries are checked in the following order:

1. `context`

2. `uid`

3. `user`

4. `command`

`[--permanent] --list-lockdown-whitelist-commands`

List all command lines that are on the whitelist.

`[--permanent] --add-lockdown-whitelist-command = command`

Add the `command` to the whitelist.

`[--permanent] --remove-lockdown-whitelist-command = command`

Remove the `command` from the whitelist.

`[--permanent] --query-lockdown-whitelist-command = command`

Query whether the `command` is on the whitelist. Returns 0 if true, 1 otherwise.

`[--permanent] --list-lockdown-whitelist-contexts`

List all contexts that are on the whitelist.

`[--permanent] --add-lockdown-whitelist-context = context`

Add the context `context` to the whitelist.

`[--permanent] --remove-lockdown-whitelist-context = context`

Remove the `context` from the whitelist.

`[--permanent] --query-lockdown-whitelist-context = context`

Query whether the `context` is on the whitelist. Returns 0 if true, 1 otherwise.

`[--permanent] --list-lockdown-whitelist-uids`

List all user ids that are on the whitelist.

`[--permanent] --add-lockdown-whitelist-uid = uid`

Add the user id `uid` to the whitelist.

`[--permanent] --remove-lockdown-whitelist-uid = uid`

Remove the user id `uid` from the whitelist.

`[--permanent] --query-lockdown-whitelist-uid = uid`

Query whether the user id `uid` is on the whitelist. Returns 0 if true, 1 otherwise.

`[--permanent] --list-lockdown-whitelist-users`

List all user names that are on the whitelist.

`[--permanent] --add-lockdown-whitelist-user = user`

Add the user name `user` to the whitelist.

`[--permanent] --remove-lockdown-whitelist-user = user`

Remove the user name `user` from the whitelist.

`[--permanent] --query-lockdown-whitelist-user = user`

Query whether the user name `user` is on the whitelist. Returns 0 if true, 1 otherwise.

Panic Options

`--panic-on`

Enable panic mode. All incoming and outgoing packets are dropped, active connections will expire. Enable this only if there are serious problems with your network environment. For example if the machine is getting hacked in.

This is a runtime only change.

`--panic-off`

Disable panic mode. After disabling panic mode established connections might work again, if panic mode was enabled for a short period of time.

This is a runtime only change.

`--query-panic`

Returns 0 if panic mode is enabled, 1 otherwise.

Examples

For more examples see <http://fedoraproject.org/wiki/FirewallID>

Example 1

Enable http service in default zone. This is runtime only change, i.e. effective until restart.

```
firewall-cmd --add-service=http
```

Example 2

Enable port 443/tcp immediately and permanently in default zone. To make the change effective immediately and also after restart we need two commands. The first command makes the change in runtime configuration, i.e. makes it effective immediately, until restart. The second command makes the change in permanent configuration, i.e. makes it effective after restart.

```
firewall-cmd --add-port=443/tcp
firewall-cmd --permanent --add-port=443/tcp
```

Exit Codes

On success 0 is returned. On failure the output is red colored and exit code is either 2 in case of wrong command-line option usage or one of the following error codes in other cases:

String	Code
ALREADY_ENABLED	11
NOT_ENABLED	12

firewall-config

Name

firewall-config — firewalld GUI configuration tool

Synopsis

```
firewall-config [OPTIONS...]
```

Description

firewall-config is a GUI configuration tool for firewalld.

Options

firewall-config does not support any special options. The only options that can be used are the general options that Gtk uses for Gtk application initialization. For more information on these options, please have a look at the runtime documentation for Gtk.

The following options are supported:

```
-h , --help
```

Prints a short help text and exits.

Documentation > Manual Pages >

firewalld.conf

Name

`firewalld.conf` — firewalld configuration file

Synopsis

```
/etc/firewalld/firewalld.conf
```

Description

`firewalld.conf` is loaded by firewalld during the initialization process. The file contains the basic configuration options for firewalld.

Options

These are the options that can be set in the config file:

`DefaultZone`

This sets the default zone for connections or interfaces if the zone is not selected or specified by NetworkManager, initscripts or command line tool. The default zone is public.

`MinimalMark`

Deprecated. This option is ignored and no longer used. Marks are no longer used internally.

`CleanupModulesOnExit`

Setting this option to yes or true unloads all firewall-related kernel modules when firewalld is stopped. The default value is no or false.

`CleanupOnExit`

If firewalld stops, it cleans up all firewall rules. Setting this option to no or false leaves the current firewall rules untouched. The default value is yes or true.

`Lockdown`

If this option is enabled, firewall changes with the D-Bus interface will be limited to applications that are listed in the lockdown whitelist (see [firewalld.lockdown-whitelist\(5\)](#)). The default value is no or

false.

IPv6_rpfilter

If this option is enabled (it is by default), reverse path filter test on a packet for IPv6 is performed. If a reply to the packet would be sent via the same interface that the packet arrived on, the packet will match and be accepted, otherwise dropped. For IPv4 the rp_filter is controlled using sysctl.

Note: This feature has a performance impact. In most cases the impact is not enough to cause a noticeable difference. It requires route lookups and its execution occurs before the established connections fast path. As such it can have a significant performance impact if there is a lot of traffic. It's enabled by default for security, but can be disabled if performance is a concern.

IndividualCalls

If this option is disabled (it is by default), combined -restore calls are used and not individual calls to apply changes to the firewall. The use of individual calls increases the time that is needed to apply changes and to start the daemon, but is good for debugging as error messages are more specific.

LogDenied

Add logging rules right before reject and drop rules in the INPUT, FORWARD and OUTPUT chains for the default rules and also final reject and drop rules in zones for the configured link-layer packet type. The possible values are: `all`, `unicast`, `broadcast`, `multicast` and `off`. The default setting is `off`, which disables the logging.

AutomaticHelpers

Deprecated. This option is ignored and no longer used.

FirewallBackend

Selects the firewall backend implementation. Possible values are; `nftables` (default), or `iptables`. This applies to all firewalld primitives. The only exception is direct and passthrough rules which always use the traditional iptables, ip6tables, and ebtables backends.

Note: The iptables backend is deprecated. It will be removed in a future release.

FlushAllOnReload

Flush all runtime rules on a reload. In previous releases some runtime configuration was retained during a reload, namely; interface to zone assignment, and direct rules. This was confusing to users. To get the old behavior set this to "no". Defaults to "yes".

RFC3964_IPv4

As per RFC 3964, filter IPv6 traffic with 6to4 destination addresses that correspond to IPv4 addresses that should not be routed over the public internet. Defaults to "yes".

AllowZoneDrifting

Deprecated. This option is ignored and no longer used.

Documentation > Manual Pages >

firewalld.policies

Name

`firewalld.policies` — firewalld policies

Description

What is a policy?

A policy applies a set of rules to traffic flowing between zones (see [zones\(5\)](#)). The policy affects traffic in a stateful unidirectional manner, e.g. zoneA to zoneB. This allows asynchronous filtering policies.

A policy's relationship to zones is defined by assigning a set of ingress zones and a set of egress zones. For example, if the set of ingress zones contains "public" and the set of egress zones contains "internal" then the policy will affect all traffic flowing from the "public" zone to the "internal" zone. However, since policies are unidirectional it will not apply to traffic flowing from "internal" to "public". Note that the ingress set and egress set can contain multiple zones.

Active Policies

Policies only become active if all of the following are true.

- The ingress zones list contain at least one regular zone or a single symbolic zone.
- The egress zones list contain at least one regular zone or a single symbolic zone.
- For non symbolic zones, the zone must be active. That is, it must have interfaces or sources assigned to it.

If the policy is not active then the policy has no effect.

Symbolic Zones

Regular zones are not enough to express every form of packet filtering. For example there is no zone to represent traffic flowing to or from the host running firewalld. As such, there are some symbolic zones to fill these gaps. However, symbolic zones are unique in that they're the only zone

allowed in the ingress or egress zone sets. For example, you cannot use "public" and "HOST" in the ingress zones.

Symbolic zones:

1. HOST

This symbolic zone is for traffic flowing to or from the host running firewalld. This corresponds to netfilter (iptables/nftables) chains INPUT and OUTPUT.

- If used in the egress zones list it will apply to traffic on the INPUT chain.
- If used in the ingress zones list it will apply to traffic on the OUTPUT chain.

2. ANY

This symbolic zone behaves like a wildcard for the ingress and egress zones. With the exception that it does not include "HOST". It's useful if you want a policy to apply to every zone.

- If used in the ingress zones list it will apply for traffic originating from any zone.
- If used in the egress zones list it will apply for traffic destined to any zone.

Predefined Policies

firewalld ships with some predefined policies. These may or may not be active by default. For details see the description of each policy.

- allow-host-ipv6

Similarity to Zones

Policies are similar to zones in that they are an attachment point for firewalld's primitives: services, ports, forward ports, etc. This is not a coincidence. Policies are a generalization of how zones have traditionally achieved filtering. In fact, in modern firewalld zones are internally implemented as a set of policies.

The main difference between policies and zones is that policies allow filtering in all directions: input, output, and forwarding. With a couple of exceptions zones only allow input filtering which is sufficient for an end station firewalling. However, for network level filtering or filtering on behalf of virtual machines and containers something more flexible, i.e. policies, are needed.

A service daemon with D-Bus interface

Documentation > Manual Pages >

firewalld.policy

Name

firewalld.policy — firewalld policy configuration files

Synopsis

```
/etc/firewalld/policies/policy.xml
```

```
/usr/lib/firewalld/policies/policy.xml
```

Description

A firewalld policy configuration file contains the information for a policy. These are the policy descriptions, services, ports, protocols, icmp-blocks, masquerade, forward-ports and rich language rules in an XML file format. The file name has to be `policy_name.xml` where length of `policy_name` is currently limited to 17 chars.

This is the structure of a policy configuration file:

```
<?xml version="1.0" encoding="utf-8"?>
<policy [version="versionstring" ] [target="CONTINUE|ACCEPT|REJECT|DROP"]
[priority="priority"]>
  [ <ingress-zone name="zone" /> ]
  [ <egress-zone name="zone" /> ]

  [ <short>short description</short> ]
  [ <description>description</description> ]
  [ <service name="string" /> ]
  [ <port port="portid[-portid]" protocol="tcp|udp|sctp|dccp"/> ]
  [ <protocol value="protocol" /> ]
  [ <icmp-block name="string" /> ]
  [ <masquerade/> ]
  [ <forward-port port="portid[-portid]" protocol="tcp|udp|sctp|dccp" [to-
  port="portid[-portid]" ] [to-addr="IP address" /> ]
```

```
[ <source-port port="portid[-portid]" protocol="tcp|udp|sctp|dccp"/> ]
[

    <rule [family="ipv4|ipv6"] [priority="priority" ]>
        [ <source address="address[/mask] |mac="MAC" |ipset="ipset" 
[invert="True"]/> ]
            [ <destination address="address[/mask] |ipset="ipset" 
[invert="True"]/> ]
                [
                    <service name="string" /> |
                    <port port="portid[-portid]" protocol="tcp|udp|sctp|dccp"/> |
                    <protocol value="protocol" /> |
                    <icmp-block name="icmptype" /> |
                    <icmp-type name="icmptype" /> |
                    <masquerade /> |
                    <forward-port port="portid[-portid]" protocol="tcp|udp|sctp|dccp"
[to-port="portid[-portid]" ] [to-addr="address"]/>
                ]
                [
                    <log [prefix="prefix text" ]
[level="emerg|alert|crit|err|warn|notice|info|debug"]> [<limit
value="rate / duration" />] </log> |
                    <nflog [group="group id" ] [prefix="prefix text" ] [queue-
size="threshold" ]> [<limit value="rate / duration" />] </nflog>
                ]
                [
                    <audit> [<limit value="rate / duration" />] </audit> ]
                [
                    <accept> [<limit value="rate / duration" />] </accept> |
                    <reject [type="rejecttype" ]> [<limit value="rate / duration" />]
</reject> |
                    <drop> [<limit value="rate / duration" />] </drop> |
                    <mark set="mark[/mask]> [<limit value="rate / duration" />]
</mark>
                ]
            </rule>
        ]
    
```

```
</policy>
```

The config can contain these tags and attributes. Some of them are mandatory, others optional.

policy

The mandatory policy start and end tag defines the policy. This tag can only be used once in a policy configuration file. There are optional attributes for policy:

`version="string"`

To give the policy a version.

target="`CONTINUE` | `ACCEPT` | `REJECT` | `DROP`"

Can be used to accept, reject or drop every packet that doesn't match any rule (port, service, etc.). The `CONTINUE` is the default and used for policies that are non-terminal.

ingress-zone

An optional element that can be used several times. It can be the name of a firewalld zone or one of the symbolic zones: HOST, ANY. See [firewalld.policies\(5\)](#) for information about symbolic zones.

egress-zone

An optional element that can be used several times. It can be the name of a firewalld zone or one of the symbolic zones: HOST, ANY. See [firewalld.policies\(5\)](#) for information about symbolic zones.

short

Is an optional start and end tag and is used to give a more readable name.

description

Is an optional start and end tag to have a description.

service

Is an optional empty-element tag and can be used several times to have more than one service entry enabled. A service entry has exactly one attribute:

name="`string`"

The name of the service to be enabled. To get a list of valid service names `firewall-cmd --get-services` can be used.

port

Is an optional empty-element tag and can be used several times to have more than one port entry. All attributes of a port entry are mandatory:

port="`portid` [- `portid`]"

The port can either be a single port number `portid` or a port range `portid - portid`.

protocol="`tcp` | `udp` | `sctp` | `dccp`"

The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

protocol

Is an optional empty-element tag and can be used several times to have more than one protocol entry. All protocol has exactly one attribute:

`value="string"`

The protocol can be any protocol supported by the system. Please have a look at </etc/protocols> for supported protocols.

icmp-block

Is an optional empty-element tag and can be used several times to have more than one icmp-block entry. Each icmp-block tag has exactly one mandatory attribute:

`name="string"`

The name of the Internet Control Message Protocol (ICMP) type to be blocked. To get a list of valid ICMP types **firewall-cmd --get-icmptypes** can be used.

tcp-mss-clamp

Is an optional empty-element tag and can be used several times. If left empty maximum segment size is set to 'pmtu'. This tag has exactly one optional attribute:

`value="string"`

Value can set maximum segment size to 'pmtu' (Path Maximum Transmission Unit) or a user-defined value that is greater than or equal to 536.

masquerade

Is an optional empty-element tag. It can be used only once. If it's present masquerading is enabled.

forward-port

Is an optional empty-element tag and can be used several times to have more than one port or packet forward entry. There are mandatory and also optional attributes for forward ports:

Mandatory attributes:

The local port and protocol to be forwarded.

`port="portid [-portid]"`

The port can either be a single port number `portid` or a port range `portid - portid`.

`protocol="tcp | udp | sctp | dccp"`

The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

Optional attributes:

The destination of the forward. For local forwarding add `to-port` only. For remote forwarding add `to-addr` and use `to-port` optionally if the destination port on the destination machine should be different.

`to-port="portid [- portid]"`

The destination port or port range to forward to. If omitted, the value of the `port=` attribute will be used altogether with the `to-addr` attribute.

`to-addr="address"`

The destination IP address either for IPv4 or IPv6.

`source-port`

Is an optional empty-element tag and can be used several times to have more than one source port entry. All attributes of a source port entry are mandatory:

`port="portid [- portid]"`

The port can either be a single port number `portid` or a port range `portid - portid`.

`protocol="tcp | udp | sctp | dccp"`

The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

`rule`

Is an optional element tag and can be used several times to have more than one rich language rule entry.

The general rule structure:

```
<rule [family="ipv4|ipv6"] [priority="priority"]>
    [ <source address="address [/mask]" | mac="MAC" | ipset="ipset"
[invert="True"]/> ]
    [ <destination address="address [/mask]" | ipset="ipset" [invert="True"]/>
]
    [
        <service name="string"/> |
        <port port="portid [- portid]" protocol="tcp|udp|sctp|dccp"/> |
        <protocol value="protocol"/> |
        <icmp-block name="icmptype"/> |
        <icmp-type name="icmptype"/> |
        <masquerade/> |
        <forward-port port="portid [- portid]" protocol="tcp|udp|sctp|dccp" [to-
port="portid [- portid]" [to-addr="address"]]/> |
        <source-port port="portid [- portid]" protocol="tcp|udp|sctp|dccp"/> |
    ]

```

```

<log [prefix="prefix text"] [level="emerg|alert|crit|err|warn|notice|info|debug"] > [<limit value="rate / duration" />] </log> |
    <nflog [group="group id"] [prefix="prefix text"] [queue-size="threshold"]> [<limit value="rate / duration" />] </nflog>
]
[ <audit> [<limit value="rate / duration" />] </audit> ]
[
    <accept> [<limit value="rate / duration" />] </accept> |
    <reject [type="rejecttype"]> [<limit value="rate / duration" />]
</reject> |
    <drop> [<limit value="rate / duration" />] </drop> |
    <mark set="mark [ / mask]"> [<limit value="rate / duration" />] </mark>
]
</rule>

```

Rule structure for source black or white listing:

```

<rule [family="ipv4|ipv6"] [priority="priority"]>
    <source address="address [ / mask] | mac="MAC" | ipset="ipset" [invert="True" ]/>
    [
        <log [prefix="prefix text"] [level="emerg|alert|crit|err|warn|notice|info|debug"] > [<limit value="rate / duration" />] </log> |
            <nflog [group="group id"] [prefix="prefix text"] [queue-size="threshold"]> [<limit value="rate / duration" />] </nflog>
        ]
        [ <audit> [<limit value="rate / duration" />] </audit> ]
        <accept> [<limit value="rate / duration" />] </accept> |
        <reject [type="rejecttype"]> [<limit value="rate / duration" />] </reject> |
        <drop> [<limit value="rate / duration" />] </drop>
    ]
</rule>

```

For a full description on rich language rules, please have a look at [firewalld.richlanguage\(5\)](#).

A service daemon with D-Bus interface

Documentation > Manual Pages >

firewalld.service

Name

firewalld.service — firewalld service configuration files

Synopsis

```
/etc/firewalld/services/service.xml  
/usr/lib/firewalld/services/service.xml
```

Description

A firewalld service configuration file provides the information of a service entry for firewalld. The most important configuration options are ports, modules and destination addresses.

This example configuration file shows the structure of a service configuration file:

```
<?xml version="1.0" encoding="utf-8"?>  
<service>  
  <short> My Service </short>  
  <description> description </description>  
  <port port=" 137 " protocol=" tcp " />  
  <protocol value=" igmp " />  
  <module name=" nf_conntrack_netbios_ns " />  
  <destination ipv4=" 224.0.0.251 " ipv6=" ff02::fb " />  
  <include service=" ssdp " />  
  <helper name=" ftp " />  
</service>
```

Options

The config can contain these tags and attributes. Some of them are mandatory, others optional.

service

The mandatory service start and end tag defines the service. This tag can only be used once in a service configuration file. There are optional attributes for services:

`version="string"`

To give the service a version.

short

Is an optional start and end tag and is used to give an service a more readable name.

description

Is an optional start and end tag to have a description for a service.

port

Is an optional empty-element tag and can be used several times to have more than one port entry.

All attributes of a port entry are mandatory:

`port="string"`

The port `string` can be a single port number or a port range `portid - portid` or also empty to match a protocol only.

`protocol="string"`

The protocol value can either be `tcp`, `udp`, `sctp` or `dccp`.

For compatibility with older firewalld versions, it is possible to add protocols with the port option where the port is empty. With the addition of native protocol support in the service, this is not needed anymore. These entries will automatically be converted to protocols. With the next modification of the service file, the entries will be listed as protocols.

protocol

Is an optional empty-element tag and can be used several times to have more than one protocol entry. A protocol entry has exactly one attribute:

`value="string"`

The protocol can be any protocol supported by the system. Please have a look at `/etc/protocols` for supported protocols.

source-port

Is an optional empty-element tag and can be used several times to have more than one source port entry. All attributes of a source port entry are mandatory:

`port="string"`

The port `string` can be a single port number or a port range `portid - portid`.

`protocol="string"`

The protocol value can either be `tcp`, `udp`, `sctp` or `dccp`.

module

This element is deprecated. Please use helper described below in **the section called “helper”**.

destination

Is an optional empty-element tag and can be used only once. The destination specifies the destination network as a network IP address (optional with /mask), or a plain IP address. The use of hostnames is not recommended, because these will only be resolved at service activation and transmitted to the kernel. For more information in this element, please have a look at `--destination` in [iptables\(8\)](#) and [ip6tables\(8\)](#).

`ipv4="address [/mask]"`

The IPv4 destination address with optional mask.

`ipv6="address [/mask]"`

The IPv6 destination address with optional mask.

include

Is an optional empty-element tag and can be used several times to have more than one include entry. An include entry has exactly one attribute:

`service="string"`

The include can be any service supported by firewalld.

Warning:Firewalld will only check that the included service is a valid service if it's applied to a zone.

helper

Is an optional empty-element tag and can be used several times to have more than one helper entry. An helper entry has exactly one attribute:

`name="string"`

The helper can be any helper supported by firewalld.

A service daemon with D-Bus interface

Documentation > Manual Pages >

firewalld.zone

Name

firewalld.zone — firewalld zone configuration files

Synopsis

```
/etc/firewalld/zones/zone.xml
```

```
/usr/lib/firewalld/zones/zone.xml
```

Description

A firewalld zone configuration file contains the information for a zone. These are the zone description, services, ports, protocols, icmp-blocks, masquerade, forward-ports, intra-zone forwarding and rich language rules in an XML file format. The file name has to be `zone_name.xml` where length of `zone_name` is currently limited to 17 chars.

This is the structure of a zone configuration file:

```
<?xml version="1.0" encoding="utf-8"?>
<zone [version="versionstring" ] [target="ACCEPT|%%REJECT%%|DROP"]>
    [ <interface name="string" /> ]
    [ <source address="address [/mask] " |mac="MAC" |ipset="ipset" /> ]
    [ <icmp-block-inversion/> ]
    [ <forward/> ]

    [ <short> short description </short> ]
    [ <description> description </description> ]
    [ <service name="string" /> ]
    [ <port port="portid [-portid] " protocol="tcp|udp|sctp|dccp"/> ]
    [ <protocol value="protocol" /> ]
    [ <icmp-block name="string" /> ]
    [ <masquerade/> ]
    [ <forward-port port="portid [-portid] " protocol="tcp|udp|sctp|dccp" [to-
```

```

port=" [portid][-portid]" ] [to-addr=" [IP address]" ]/> ]
[ <source-port port=" [portid][-portid]" protocol="tcp|udp|sctp|dccp"/> ]
[
    <rule [family="ipv4|ipv6"] [priority=" priority "]>
        [ <source address=" address [/ mask]" |mac=" MAC " |ipset=" ipset "
[invert=" True "]/> ]
            [ <destination address=" address [/ mask]" |ipset=" ipset "
[invert=" True "]/> ]
                [
                    <service name=" string "/> |
                    <port port=" [portid][-portid]" protocol="tcp|udp|sctp|dccp"/> |
                    <protocol value=" protocol "/> |
                    <icmp-block name=" icmptype "/> |
                    <icmp-type name=" icmptype "/> |
                    <masquerade/> |
                    <forward-port port=" [portid][-portid]" protocol="tcp|udp|sctp|dccp"
[to-port=" [portid][-portid]" ] [to-addr=" address "]/>
                ]
                [
                    <log [prefix=" prefix text "]
[level="emerg|alert|crit|err|warn|notice|info|debug"]> [<limit
value=" rate / duration " />] </log> |
                        <nflog [group=" group id "] [prefix=" prefix text "] [queue-
size=" threshold "]> [<limit value=" rate / duration " />] </nflog>
                    ]
                    [ <audit> [<limit value=" rate / duration " />] </audit> ]
                    [
                        <accept> [<limit value=" rate / duration " />] </accept> |
                        <reject [type=" rejecttype "]> [<limit value=" rate / duration " />]
</reject> |
                            <drop> [<limit value=" rate / duration " />] </drop> |
                            <mark set=" mark [/ mask ]"> [<limit value=" rate / duration " />]
</mark>
                        ]
                    </rule>
                ]
            
```

</zone>

The config can contain these tags and attributes. Some of them are mandatory, others optional.

zone

The mandatory zone start and end tag defines the zone. This tag can only be used once in a zone configuration file. There are optional attributes for zones:

`version="string"`

To give the zone a version.

`target="ACCEPT | %%REJECT%% | DROP"`

Can be used to accept, reject or drop every packet that doesn't match any rule (port, service, etc.). The `ACCEPT` target is used in `trusted` zone to accept every packet not matching any rule. The `%%REJECT%%` target is used in `block` zone to reject (with default firewalld reject type) every packet not matching any rule. The `DROP` target is used in `drop` zone to drop every packet not matching any rule. If the target is not specified, every packet not matching any rule will be rejected.

interface

Is an optional empty-element tag and can be used several times. It can be used to bind an interface to a zone. You don't need this for NetworkManager-managed interfaces, because NetworkManager binds interfaces to zones automatically. See also 'How to set or change a zone for a connection?' in [firewalld.zones\(5\)](#). You can use it as a fallback mechanism for interfaces that can't be managed via NetworkManager. An interface entry has exactly one attribute:

`name="string"`

The name of the interface to be bound to the zone.

source

Is an optional empty-element tag and can be used several times. It can be used to bind a source address, address range, a MAC address or an ipset to a zone. A source entry has exactly one of these attributes:

`address="address [/mask]"`

The source is either an IP address or a network IP address with a mask for IPv4 or IPv6. The network family (IPv4/IPv6) will be automatically discovered. For IPv4, the mask can be a network mask or a plain number. For IPv6 the mask is a plain number. The use of host names is not supported.

`mac="MAC"`

The source is a MAC address. It must be of the form XX:XX:XX:XX:XX:XX.

`ipset="ipset"`

The source is an ipset.

icmp-block-inversion

Is an optional empty-element tag and can be used only once in a zone configuration. This flag inverts the icmp block handling. Only enabled ICMP types are accepted and all others are rejected in the zone.

forward

Is an optional empty-element tag and can be used only once in a zone configuration. This flag enables intra-zone forwarding. When enabled, packets will be forwarded between interfaces or sources within a zone, even if the zone's target is not set to `ACCEPT`.

short

Is an optional start and end tag and is used to give a more readable name.

description

Is an optional start and end tag to have a description.

service

Is an optional empty-element tag and can be used several times to have more than one service entry enabled. A service entry has exactly one attribute:

`name="string"`

The name of the service to be enabled. To get a list of valid service names `firewall-cmd --get-services` can be used.

port

Is an optional empty-element tag and can be used several times to have more than one port entry. All attributes of a port entry are mandatory:

`port="portid [-portid]"`

The port can either be a single port number `portid` or a port range `portid - portid`.

`protocol="tcp | udp | sctp | dccp"`

The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

protocol

Is an optional empty-element tag and can be used several times to have more than one protocol entry. All protocol has exactly one attribute:

`value="string"`

The protocol can be any protocol supported by the system. Please have a look at `/etc/protocols` for supported protocols.

icmp-block

Is an optional empty-element tag and can be used several times to have more than one icmp-block entry. Each icmp-block tag has exactly one mandatory attribute:

`name="string"`

The name of the Internet Control Message Protocol (ICMP) type to be blocked. To get a list of valid ICMP types **firewall-cmd --get-icmptypes** can be used.

tcp-mss-clamp

Is an optional empty-element tag and can be used several times. If left empty maximum segment size is set to 'pmtu'. This tag has exactly one optional attribute:

`value="string"`

Value can set maximum segment size to 'pmtu' (Path Maximum Transmission Unit) or a user-defined value that is greater than or equal to 536.

masquerade

Is an optional empty-element tag. It can be used only once. If it's present masquerading is enabled.

forward-port

Is an optional empty-element tag and can be used several times to have more than one port or packet forward entry. There are mandatory and also optional attributes for forward ports:

Mandatory attributes:

The local port and protocol to be forwarded.

`port="portid [-portid]"`

The port can either be a single port number `portid` or a port range `portid - portid`.

`protocol="tcp | udp | sctp | dccp"`

The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

Optional attributes:

The destination of the forward. For local forwarding add `to-port` only. For remote forwarding add `to-addr` and use `to-port` optionally if the destination port on the destination machine should be different.

`to-port="portid [-portid]"`

The destination port or port range to forward to. If omitted, the value of the `port=` attribute will be used altogether with the `to-addr` attribute.

`to-addr="address"`

The destination IP address either for IPv4 or IPv6.

source-port

Is an optional empty-element tag and can be used several times to have more than one source port entry. All attributes of a source port entry are mandatory:

`port="portid [-portid]"`

The port can either be a single port number `portid` or a port range `portid - portid`.

`protocol="tcp | udp | sctp | dccp"`

The protocol can either be `tcp`, `udp`, `sctp` or `dccp`.

rule

Is an optional element tag and can be used several times to have more than one rich language rule entry.

The general rule structure:

```
<rule [family="ipv4|ipv6"] [priority="priority"]>
    [ <source address="address [/mask]" | mac="MAC" | ipset="ipset"
    [invert="True"] /> ]
    [ <destination address="address [/mask]" | ipset="ipset" [invert="True"] />
    ]
    [
        <service name="string" /> |
        <port port="portid [-portid]" protocol="tcp|udp|sctp|dccp" /> |
        <protocol value="protocol" /> |
        <icmp-block name="icmptype" /> |
        <icmp-type name="icmptype" /> |
        <masquerade /> |
        <forward-port port="portid [-portid]" protocol="tcp|udp|sctp|dccp" [to-
port="portid [-portid]" ] [to-addr="address"] /> |
        <source-port port="portid [-portid]" protocol="tcp|udp|sctp|dccp" /> |
    ]
    [
        <log [prefix="prefix text"] [level="emerg|alert|crit|err|warn|notice|info|debug"]> [<limit
value="rate / duration" />] </log> |
        <nflog [group="group id"] [prefix="prefix text"] [queue-
size="threshold"]> [<limit value="rate / duration" />] </nflog>
    ]
    [ <audit> [<limit value="rate / duration" />] </audit> ]
    [
        <accept> [<limit value="rate / duration" />] </accept> |
        <reject [type="rejecttype"]> [<limit value="rate / duration" />]
```

```

</reject> |
    <drop> [<limit value="rate / duration" />] </drop> |
    <mark set="mark [/ mask" /> [<limit value="rate / duration" />] </mark>
]
</rule>

```

Rule structure for source black or white listing:

```

<rule [family="ipv4|ipv6"] [priority="priority"]>
    <source address="address [/ mask" |mac="MAC" |ipset="ipset"|
[invert="True"]/>
    [
        <log [prefix="prefix text"]|
[level="emerg|alert|crit|err|warn|notice|info|debug"]> [<limit
value="rate / duration" />] </log> |
        <nflog [group="group id" ] [prefix="prefix text"] [queue-
size="threshold" ]> [<limit value="rate / duration" />] </nflog>
    ]
    [ <audit> [<limit value="rate / duration" />] </audit> ]
    <accept> [<limit value="rate / duration" />] </accept> |
    <reject [type="rejecttype"]> [<limit value="rate / duration" />] </reject> |
    <drop> [<limit value="rate / duration" />] </drop>
</rule>

```

For a full description on rich language rules, please have a look at [firewalld.richlanguage\(5\)](#).

A service daemon with D-Bus interface

Documentation > Manual Pages >

firewalld

Name

firewalld — Dynamic Firewall Manager

Synopsis

```
firewalld [OPTIONS...]
```

Description

firewalld provides a dynamically managed firewall with support for network/firewall zones to define the trust level of network connections or interfaces. It has support for IPv4, IPv6 firewall settings and for ethernet bridges and has a separation of runtime and permanent configuration options. It also supports an interface for services or applications to add firewall rules directly.

Options

These are the command line options of firewalld:

```
-h , --help
```

Prints a short help text and exits.

```
--default-config
```

Path to firewalld default configuration. This usually defaults to `/usr/lib/firewalld`.

```
--debug [= level]
```

Set the debug level for firewalld to `level`. The range of the debug level is 1 (lowest level) to 10 (highest level). The debug output will be written to the firewalld log file specified by `--log-file`.

```
--debug-gc
```

Print garbage collector leak information. The collector runs every 10 seconds and if there are leaks, it prints information about the leaks.

```
--log-target
```

Define the output target to which log messages are written. In mixed mode, Firewalld writes info-level log messages to syslog. Debug messages are written to a file (see the `--log-file` parameter).

Info messages also go to stdout and stderr. The syslog, file or console modes write all messages to the one configured target only.

--log-file

Define the file where debug messages are written to. The default file is `/var/log/firewalld`.

--nofork

Turn off daemon forking. Force firewalld to run as a foreground process instead of as a daemon in the background.

--nopid

Disable writing pid file. By default the program will write a pid file. If the program is invoked with this option it will not check for an existing server process.

--system-config

Path to firewalld system (user) configuration. This usually defaults to `/etc/firewalld`.

Concepts

firewalld has a D-Bus interface for firewall configuration of services and applications. It also has a command line client for the user. Services or applications already using D-Bus can request changes to the firewall with the D-Bus interface directly. For more information on the firewalld D-Bus interface, please have a look at [firewalld.dbus\(5\)](#).

firewalld provides support for zones, predefined services and ICMP types and has a separation of runtime and permanent configuration options. Permanent configuration is loaded from XML files in `/usr/lib/firewalld` (`--default-config`) or `/etc/firewalld` (`--system-config`) (see [the section called “Directories”](#)).

If NetworkManager is not in use and firewalld gets started after the network is already up, the connections and manually created interfaces are not bound to the zone specified in the ifcfg file. The interfaces will automatically be handled by the default zone. firewalld will also not get notified about network device renames. All this also applies to interfaces that are not controlled by NetworkManager if `NM_CONTROLLED=no` is set.

You can add these interfaces to a zone with `firewall-cmd --permanent --zone=zone --add-interface=interface`. If there is a `/etc/sysconfig/network-scripts/ifcfg-interface` file, firewalld tries to change the `ZONE=zone` setting in this file.

If firewalld gets reloaded, it will restore the interface bindings that were in place before reloading to keep interface bindings stable in the case of NetworkManager uncontrolled interfaces. This mechanism is not possible in the case of a firewalld service restart.

It is essential to keep the `ZONE=` setting in the ifcfg file consistent to the binding in firewalld in the case of NetworkManager uncontrolled interfaces.

Zones

A network or firewall zone defines the trust level of the interface used for a connection. There are several pre-defined zones provided by firewalld. Zone configuration options and generic information about zones are described in [firewalld.zone\(5\)](#)

Services

A service can be a list of local ports, protocols and destinations and additionally also a list of firewall helper modules automatically loaded if a service is enabled. Service configuration options and generic information about services are described in [firewalld.service\(5\)](#). The use of predefined services makes it easier for the user to enable and disable access to a service.

ICMP types

The Internet Control Message Protocol (ICMP) is used to exchange information and also error messages in the Internet Protocol (IP). ICMP types can be used in firewalld to limit the exchange of these messages. For more information, please have a look at [firewalld.icmptype\(5\)](#).

Runtime configuration

Runtime configuration is the actual active configuration and is not permanent. After reload/restart of the service or a system reboot, runtime settings will be gone if they haven't been also in permanent configuration.

Permanent configuration

The permanent configuration is stored in config files and will be loaded and become new runtime configuration with every machine boot or service reload/restart.

Direct interface

DEPRECATED

The direct interface has been deprecated. It will be removed in a future release. It is superseded by policies, see [firewalld.policies\(5\)](#).

The direct interface is mainly used by services or applications to add specific firewall rules. It requires basic knowledge of ip(6)tables concepts (tables, chains, commands, parameters, targets).

Directories

firewalld supports two configuration directories:

Default/Fallback configuration in `/usr/lib/firewalld` (`--default-config`)

This directory contains the default and fallback configuration provided by firewalld for icmptypes, services and zones. The files provided with the firewalld package should not get changed and the changes are gone with an update of the firewalld package. Additional `icmptypes`, `services` and `zones` can be provided with packages or by creating files.

System configuration settings in `/etc/firewalld` (`--system-config`)

The system or user configuration stored here is either created by the system administrator or by customization with the configuration interface of firewalld or by hand. The files will overload the default configuration files.

To manually change settings of pre-defined icmptypes, zones or services, copy the file from the default configuration directory to the corresponding directory in the system configuration directory and change it accordingly.

For more information on icmptypes, please have a look at the `firewalld.icmptype(5)` man page, for services at `firewalld.service(5)` and for zones at `firewalld.zone(5)`.

SIGNALS

Currently only SIGHUP is supported.

SIGHUP

Reloads the complete firewall configuration. You can also use `firewall-cmd --reload`. All runtime configuration settings will be restored. Permanent configuration will change according to options defined in the configuration files.

NAME

free – Display amount of free and used memory in the system

SYNOPSIS

free [*options*]

DESCRIPTION

free displays the total amount of free and used physical and swap memory in the system, as well as the buffers and caches used by the kernel. The information is gathered by parsing /proc/meminfo. The displayed columns are:

total Total installed memory (MemTotal and SwapTotal in /proc/meminfo)
used Used memory (calculated as **total** - **free** - **buffers** - **cache**)
free Unused memory (MemFree and SwapFree in /proc/meminfo)
shared Memory used (mostly) by tmpfs (Shmem in /proc/meminfo)
buffers Memory used by kernel buffers (Buffers in /proc/meminfo)
cache Memory used by the page cache and slabs (Cached and SReclaimable in /proc/meminfo)
buff/cache

Sum of **buffers** and **cache**

available

Estimation of how much memory is available for starting new applications, without swapping. Unlike the data provided by the **cache** or **free** fields, this field takes into account page cache and also that not all reclaimable memory slabs will be reclaimed due to items being in use (MemAvailable in /proc/meminfo, available on kernels 3.14, emulated on kernels 2.6.27+, otherwise the same as **free**)

OPTIONS**-b, --bytes**

Display the amount of memory in bytes.

-k, --kibi

Display the amount of memory in kibibytes. This is the default.

-m, --mebi

Display the amount of memory in mebibytes.

-g, --gibi

Display the amount of memory in gibibytes.

--tebi

Display the amount of memory in tebibytes.

--pebi

Display the amount of memory in pebibytes.

--kilo

Display the amount of memory in kilobytes. Implies --si.

--mega

Display the amount of memory in megabytes. Implies --si.

--giga

Display the amount of memory in gigabytes. Implies --si.

--tera

Display the amount of memory in terabytes. Implies --si.

--peta

Display the amount of memory in petabytes. Implies --si.

-h, --human

Show all output fields automatically scaled to shortest three digit unit and display the units of print out. Following units are used.

B = bytes

Ki = kibibyte

Mi = mebibyte

Gi = gibibyte
Ti = tebibyte
Pi = pebibyte

If unit is missing, and you have exbibyte of RAM or swap, the number is in tebibytes and columns might not be aligned with header.

-w, --wide

Switch to the wide mode. The wide mode produces lines longer than 80 characters. In this mode **buffers** and **cache** are reported in two separate columns.

-c, --count *count*

Display the result *count* times. Requires the **-s** option.

-l, --lohi

Show detailed low and high memory statistics.

-s, --seconds *delay*

Continuously display the result *delay* seconds apart. You may actually specify any floating point number for *delay* using either . or , for decimal point. **usleep(3)** is used for microsecond resolution delay times.

--si Use kilo, mega, giga etc (power of 1000) instead of kibi, mebi, gibi (power of 1024).**-t, --total**

Display a line showing the column totals.

--help Print help.**-V, --version**

Display version information.

FILES

/proc/meminfo
memory information

BUGS

The value for the **shared** column is not available from kernels before 2.6.32 and is displayed as zero.

Please send bug reports to
[<procps@freelists.org>](mailto:procps@freelists.org)

NAME

malloc, free, calloc, realloc, reallocarray – allocate and free dynamic memory

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <stdlib.h>
void *malloc(size_t size);
void free(void *ptr);
void *calloc(size_t nmemb, size_t size);
void *realloc(void *ptr, size_t size);
void *reallocarray(void *ptr, size_t nmemb, size_t size);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros(7)**):

```
reallocarray():
Since glibc 2.29:
    _DEFAULT_SOURCE
glibc 2.28 and earlier:
    _GNU_SOURCE
```

DESCRIPTION**malloc()**

The **malloc()** function allocates *size* bytes and returns a pointer to the allocated memory. *The memory is not initialized.* If *size* is 0, then **malloc()** returns a unique pointer value that can later be successfully passed to **free()**. (See "Nonportable behavior" for portability issues.)

free()

The **free()** function frees the memory space pointed to by *ptr*, which must have been returned by a previous call to **malloc()** or related functions. Otherwise, or if *ptr* has already been freed, undefined behavior occurs. If *ptr* is NULL, no operation is performed.

calloc()

The **calloc()** function allocates memory for an array of *nmemb* elements of *size* bytes each and returns a pointer to the allocated memory. The memory is set to zero. If *nmemb* or *size* is 0, then **calloc()** returns a unique pointer value that can later be successfully passed to **free()**.

If the multiplication of *nmemb* and *size* would result in integer overflow, then **calloc()** returns an error. By contrast, an integer overflow would not be detected in the following call to **malloc()**, with the result that an incorrectly sized block of memory would be allocated:

```
malloc(nmemb * size);
```

realloc()

The **realloc()** function changes the size of the memory block pointed to by *ptr* to *size* bytes. The contents of the memory will be unchanged in the range from the start of the region up to the minimum of the old and new sizes. If the new size is larger than the old size, the added memory will *not* be initialized.

If *ptr* is NULL, then the call is equivalent to **malloc(size)**, for all values of *size*.

If *size* is equal to zero, and *ptr* is not NULL, then the call is equivalent to **free(ptr)** (but see "Nonportable behavior" for portability issues).

Unless *ptr* is NULL, it must have been returned by an earlier call to **malloc** or related functions. If the area pointed to was moved, a **free(ptr)** is done.

reallocarray()

The **reallocarray()** function changes the size of (and possibly moves) the memory block pointed to by *ptr* to be large enough for an array of *nmemb* elements, each of which is *size* bytes. It is equivalent to the call

```
realloc(ptr, nmemb * size);
```

However, unlike that **realloc()** call, **reallocarray()** fails safely in the case where the multiplication would

overflow. If such an overflow occurs, **reallocarray()** returns an error.

RETURN VALUE

The **malloc()**, **calloc()**, **realloc()**, and **reallocarray()** functions return a pointer to the allocated memory, which is suitably aligned for any type that fits into the requested size or less. On error, these functions return NULL and set *errno*. Attempting to allocate more than **PTRDIFF_MAX** bytes is considered an error, as an object that large could cause later pointer subtraction to overflow.

The **free()** function returns no value, and preserves *errno*.

The **realloc()** and **reallocarray()** functions return NULL if *ptr* is not NULL and the requested size is zero; this is not considered an error. (See "Nonportable behavior" for portability issues.) Otherwise, the returned pointer may be the same as *ptr* if the allocation was not moved (e.g., there was room to expand the allocation in-place), or different from *ptr* if the allocation was moved to a new address. If these functions fail, the original block is left untouched; it is not freed or moved.

ERRORS

calloc(), **malloc()**, **realloc()**, and **reallocarray()** can fail with the following error:

ENOMEM

Out of memory. Possibly, the application hit the **RLIMIT_AS** or **RLIMIT_DATA** limit described in **getrlimit(2)**.

VERSIONS

reallocarray() was added in glibc 2.26.

malloc() and related functions rejected sizes greater than **PTRDIFF_MAX** starting in glibc 2.30.

free() preserved *errno* starting in glibc 2.33.

ATTRIBUTES

For an explanation of the terms used in this section, see **attributes(7)**.

Interface	Attribute	Value
malloc() , free() , calloc() , realloc()	Thread safety	MT-Safe

STANDARDS

malloc(), **free()**, **calloc()**, **realloc()**: POSIX.1-2001, POSIX.1-2008, C99.

reallocarray() is a nonstandard extension that first appeared in OpenBSD 5.6 and FreeBSD 11.0.

NOTES

By default, Linux follows an optimistic memory allocation strategy. This means that when **malloc()** returns non-NULL there is no guarantee that the memory really is available. In case it turns out that the system is out of memory, one or more processes will be killed by the OOM killer. For more information, see the description of */proc/sys/vm/overcommit_memory* and */proc/sys/vm/oom_adj* in **proc(5)**, and the Linux kernel source file *Documentation/vm/overcommit-accounting.rst*.

Normally, **malloc()** allocates memory from the heap, and adjusts the size of the heap as required, using **sbrk(2)**. When allocating blocks of memory larger than **MMAP_THRESHOLD** bytes, the glibc **malloc()** implementation allocates the memory as a private anonymous mapping using **mmap(2)**. **MMAP_THRESHOLD** is 128 kB by default, but is adjustable using **mallopt(3)**. Prior to Linux 4.7 allocations performed using **mmap(2)** were unaffected by the **RLIMIT_DATA** resource limit; since Linux 4.7, this limit is also enforced for allocations performed using **mmap(2)**.

To avoid corruption in multithreaded applications, mutexes are used internally to protect the memory-management data structures employed by these functions. In a multithreaded application in which threads simultaneously allocate and free memory, there could be contention for these mutexes. To scalably handle memory allocation in multithreaded applications, glibc creates additional *memory allocation arenas* if mutex contention is detected. Each arena is a large region of memory that is internally allocated by the system (using **brk(2)** or **mmap(2)**), and managed with its own mutexes.

If your program uses a private memory allocator, it should do so by replacing **malloc()**, **free()**, **calloc()**, and

realloc(). The replacement functions must implement the documented glibc behaviors, including *errno* handling, size-zero allocations, and overflow checking; otherwise, other library routines may crash or operate incorrectly. For example, if the replacement *free()* does not preserve *errno*, then seemingly unrelated library routines may fail without having a valid reason in *errno*. Private memory allocators may also need to replace other glibc functions; see "Replacing malloc" in the glibc manual for details.

Crashes in memory allocators are almost always related to heap corruption, such as overflowing an allocated chunk or freeing the same pointer twice.

The **malloc()** implementation is tunable via environment variables; see **mallopt(3)** for details.

Nonportable behavior

The behavior of these functions when the requested size is zero is glibc specific; other implementations may return NULL without setting *errno*, and portable POSIX programs should tolerate such behavior. See **realloc(3p)**.

POSIX requires memory allocators to set *errno* upon failure. However, the C standard does not require this, and applications portable to non-POSIX platforms should not assume this.

Portable programs should not use private memory allocators, as POSIX and the C standard do not allow replacement of **malloc()**, **free()**, **calloc()**, and **realloc()**.

EXAMPLES

```
#include <err.h>
#include <stddef.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define MALLOCARRAY(n, type) ((type *) my_mallocarray(n, sizeof(type)))
#define MALLOC(type)          MALLOCARRAY(1, type)

static inline void *my_mallocarray(size_t nmemb, size_t size);

int
main(void)
{
    char *p;

    p = MALLOCARRAY(32, char);
    if (p == NULL)
        err(EXIT_FAILURE, "malloc");

    strlcpy(p, "foo", 32);
    puts(p);
}

static inline void *
my_mallocarray(size_t nmemb, size_t size)
{
    return reallocarray(NULL, nmemb, size);
}
```

NAME

alloc_hugepages, free_hugepages – allocate or free huge pages

SYNOPSIS

```
void *syscall(SYS_alloc_hugepages, int key, void *addr[.len], size_t len,
              int prot, int flag);
int syscall(SYS_free_hugepages, void *addr);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of **syscall**(2).

DESCRIPTION

The system calls **alloc_hugepages()** and **free_hugepages()** were introduced in Linux 2.5.36 and removed again in Linux 2.5.54. They existed only on i386 and ia64 (when built with **CONFIG_HUGETLB_PAGE**). In Linux 2.4.20, the syscall numbers exist, but the calls fail with the error **ENOSYS**.

On i386 the memory management hardware knows about ordinary pages (4 KiB) and huge pages (2 or 4 MiB). Similarly ia64 knows about huge pages of several sizes. These system calls serve to map huge pages into the process's memory or to free them again. Huge pages are locked into memory, and are not swapped.

The *key* argument is an identifier. When zero the pages are private, and not inherited by children. When positive the pages are shared with other applications using the same *key*, and inherited by child processes.

The *addr* argument of **free_hugepages()** tells which page is being freed: it was the return value of a call to **alloc_hugepages()**. (The memory is first actually freed when all users have released it.) The *addr* argument of **alloc_hugepages()** is a hint, that the kernel may or may not follow. Addresses must be properly aligned.

The *len* argument is the length of the required segment. It must be a multiple of the huge page size.

The *prot* argument specifies the memory protection of the segment. It is one of **PR_O_T_READ**, **PROT_WRITE**, **PROT_EXEC**.

The *flag* argument is ignored, unless *key* is positive. In that case, if *fla g* is **IPC_CREAT**, then a new huge page segment is created when none with the given key existed. If this flag is not set, then **ENOENT** is returned when no segment with the given key exists.

RETURN VALUE

On success, **alloc_hugepages()** returns the allocated virtual address, and **free_hugepages()** returns zero. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS**ENOSYS**

The system call is not supported on this kernel.

FILES

/proc/sys/vm/nr_hugepages

Number of configured hugetlb pages. This can be read and written.

/proc/meminfo

Gives info on the number of configured hugetlb pages and on their size in the three variables **HugePages_Total**, **HugePages_Free**, **Hugepagesize**.

STANDARDS

These extinct system calls were specific to Linux on Intel processors.

NOTES

These system calls are gone; they existed only in Linux 2.5.36 through to Linux 2.5.54. Now the hugetlfs filesystem can be used instead. Memory backed by huge pages (if the CPU supports them) is obtained by using **mmap**(2) to map files in this virtual filesystem.

The maximal number of huge pages can be specified using the **hugepages=** boot parameter.

NAME

fsck – check and repair a Linux filesystem

SYNOPSIS

fsck [**-lsAVRTMNP**] [**-r [fd]**] [**-C [fd]**] [**-t fstype**] [*filesystem...*] [**--**] [*fs-specific-options*]

DESCRIPTION

fsck is used to check and optionally repair one or more Linux filesystems. *filesystem* can be a device name (e.g., */dev/hdc1*, */dev/sdb2*), a mount point (e.g., */*, */usr*, */home*), or an filesystem label or UUID specifier (e.g., *UUID=868abf6-88c5-4a83-98b8-bfc24057f7bd* or *LABEL=root*). Normally, the **fsck** program will try to handle filesystems on different physical disk drives in parallel to reduce the total amount of time needed to check all of them.

If no filesystems are specified on the command line, and the **-A** option is not specified, **fsck** will default to checking filesystems in */etc/fstab* serially. This is equivalent to the **-As** options.

The exit status returned by **fsck** is the sum of the following conditions:

0	No errors
1	Filesystem errors corrected
2	System should be rebooted
4	Filesystem errors left uncorrected
8	Operational error
16	Usage or syntax error
32	Checking canceled by user request
128	Shared-library error

The exit status returned when multiple filesystems are checked is the bit-wise OR of the exit statuses for each filesystem that is checked.

In actuality, **fsck** is simply a front-end for the various filesystem checkers (**fsck.fstype**) available under Linux. The filesystem-specific checker is searched for in the **PATH** environment variable. If the **PATH** is undefined then fallback to */sbin*.

Please see the filesystem-specific checker manual pages for further details.

OPTIONS

-l

Create an exclusive **flock**(2) lock file (*/run/fsck/<diskname>.lock*) for whole-disk device. This option can be used with one device only (this means that **-A** and **-l** are mutually exclusive). This option is recommended when more **fsck** instances are executed in the same time. The option is ignored when

used for multiple devices or for non-rotating disks. **fsck** does not lock underlying devices when executed to check stacked devices (e.g. MD or DM) – this feature is not implemented yet.

-r [fd]

Report certain statistics for each **fsck** when it completes. These statistics include the exit status, the maximum run set size (in kilobytes), the elapsed all-clock time and the user and system CPU time used by the **fsck** run. For example:

```
/dev/sda1: status 0, rss 92828, real 4.002804, user 2.677592, sys 0.86186
```

GUI front-ends may specify a file descriptor *fd*, in which case the progress bar information will be sent to that file descriptor in a machine parseable format. For example:

```
/dev/sda1 0 92828 4.002804 2.677592 0.86186
```

-s

Serialize **fsck** operations. This is a good idea if you are checking multiple filesystems and the checkers are in an interactive mode. (Note: **e2fsck(8)** runs in an interactive mode by default. To make **e2fsck(8)** run in a non-interactive mode, you must either specify the **-p** or **-a** option, if you wish for errors to be corrected automatically, or the **-n** option if you do not.)

-t fslist

Specifies the type(s) of filesystem to be checked. When the **-A** flag is specified, only filesystems that match *fslist* are checked. The *fslist* parameter is a comma-separated list of filesystems and options specifiers. All of the filesystems in this comma-separated list may be prefixed by a negation operator '**no**' or '**!**', which requests that only those filesystems not listed in *fslist* will be checked. If none of the filesystems in *fslist* is prefixed by a negation operator, then only those listed filesystems will be checked.

Options specifiers may be included in the comma-separated *fslist*. They must have the format **opts=fs-option**. If an options specifier is present, then only filesystems which contain *fs-option* in their mount options field of */etc/fstab* will be checked. If the options specifier is prefixed by a negation operator, then only those filesystems that do not have *fs-option* in their mount options field of */etc/fstab* will be checked.

For example, if **opts=ro** appears in *fslist*, then only filesystems listed in */etc/fstab* with the **ro** option will be checked.

For compatibility with Mandrake distributions whose boot scripts depend upon an unauthorized UI change to the **fsck** program, if a filesystem type of **loop** is found in *fslist*, it is treated as if **opts=loop** were specified as an argument to the **-t** option.

Normally, the filesystem type is deduced by searching for *filesys* in the */etc/fstab* file and using the corresponding entry. If the type cannot be deduced, and there is only a single filesystem given as an argument to the **-t** option, **fsck** will use the specified filesystem type. If this type is not available, then the default filesystem type (currently ext2) is used.

-A

Walk through the */etc/fstab* file and try to check all filesystems in one run. This option is typically used from the */etc/rc* system initialization file, instead of multiple commands for checking a single filesystem.

The root filesystem will be checked first unless the **-P** option is specified (see below). After that, filesystems will be checked in the order specified by the *fs_passno* (the sixth) field in the */etc/fstab* file.

Filesystems with a *fs_passno* value of 0 are skipped and are not checked at all. Filesystems with a *fs_passno* value of greater than zero will be checked in order, with filesystems with the lowest *fs_passno* number being checked first. If there are multiple filesystems with the same pass number, **fsck** will attempt to check them in parallel, although it will avoid running multiple filesystem checks on the same physical disk.

fsck does not check stacked devices (RAIDs, dm-crypt, ...) in parallel with any other device. See below for **FSCK_FORCE_ALL_PARALLEL** setting. The /sys filesystem is used to determine dependencies between devices.

Hence, a very common configuration in /etc/fstab files is to set the root filesystem to have a *fs_passno* value of 1 and to set all other filesystems to have a *fs_passno* value of 2. This will allow **fsck** to automatically run filesystem checkers in parallel if it is advantageous to do so. System administrators might choose not to use this configuration if they need to avoid multiple filesystem checks running in parallel for some reason – for example, if the machine in question is short on memory so that excessive paging is a concern.

fsck normally does not check whether the device actually exists before calling a filesystem specific checker. Therefore non-existing devices may cause the system to enter filesystem repair mode during boot if the filesystem specific checker returns a fatal error. The /etc/fstab mount option **nofail** may be used to have **fsck** skip non-existing devices. **fsck** also skips non-existing devices that have the special filesystem type **auto**.

-C [fd]

Display completion/progress bars for those filesystem checkers (currently only for ext[234]) which support them. **fsck** will manage the filesystem checkers so that only one of them will display a progress bar at a time. GUI front-ends may specify a file descriptor *fd*, in which case the progress bar information will be sent to that file descriptor.

-M

Do not check mounted filesystems and return an exit status of 0 for mounted filesystems.

-N

Don't execute, just show what would be done.

-P

When the **-A** flag is set, check the root filesystem in parallel with the other filesystems. This is not the safest thing in the world to do, since if the root filesystem is in doubt things like the **e2fsck(8)** executable might be corrupted! This option is mainly provided for those sysadmins who don't want to repartition the root filesystem to be small and compact (which is really the right solution).

-R

When checking all filesystems with the **-A** flag, skip the root filesystem. (This is useful in case the root filesystem has already been mounted read-write.)

-T

Don't show the title on startup.

-V

Produce verbose output, including all filesystem-specific commands that are executed.

-?, --help

Display help text and exit.

--version

Display version information and exit.

FILESYSTEM SPECIFIC OPTIONS

Options which are not understood by fsck are passed to the filesystem-specific checker!

These options **must** not take arguments, as there is no way for **fsck** to be able to properly guess which options take arguments and which don't.

Options and arguments which follow the **--** are treated as filesystem-specific options to be passed to the filesystem-specific checker.

Please note that **fsck** is not designed to pass arbitrarily complicated options to filesystem-specific checkers. If you're doing something complicated, please just execute the filesystem-specific checker directly. If you pass **fsck** some horribly complicated options and arguments, and it doesn't do what you expect, **don't bother reporting it as a bug**. You're almost certainly doing something that you shouldn't be doing with **fsck**. Options to different filesystem-specific **fsck**'s are not standardized.

ENVIRONMENT

The **fsck** program's behavior is affected by the following environment variables:

FSCK_FORCE_ALL_PARALLEL

If this environment variable is set, **fsck** will attempt to check all of the specified filesystems in parallel, regardless of whether the filesystems appear to be on the same device. (This is useful for RAID systems or high-end storage systems such as those sold by companies such as IBM or EMC.) Note that the *fs_passno* value is still used.

FSCK_MAX_INST

This environment variable will limit the maximum number of filesystem checkers that can be running at one time. This allows configurations which have a large number of disks to avoid **fsck** starting too many filesystem checkers at once, which might overload CPU and memory resources available on the system. If this value is zero, then an unlimited number of processes can be spawned. This is currently the default, but future versions of **fsck** may attempt to automatically determine how many filesystem checks can be run based on gathering accounting data from the operating system.

PATH

The **PATH** environment variable is used to find filesystem checkers.

FSTAB_FILE

This environment variable allows the system administrator to override the standard location of the */etc/fstab* file. It is also useful for developers who are testing **fsck**.

LIBBLKID_DEBUG=all

enables libblkid debug output.

LIBMOUNT_DEBUG=all

enables libmount debug output.

FILES

/etc/fstab

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

The **fsck** command is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

fsck.btrfs – do nothing, successfully

SYNOPSIS

fsck.btrfs [**-aApy**] [<*device*>...]

DESCRIPTION

fsck.btrfs is a type of utility that should exist for any filesystem and is called during system setup when the corresponding **/etc/fstab** entries contain non-zero value for **fs_passno**, see **fstab(5)** for more.

Traditional filesystems need to run their respective fsck utility in case the filesystem was not unmounted cleanly and the log needs to be replayed before mount. This is not needed for BTRFS. You should set **fs_passno** to 0.

If you wish to check the consistency of a BTRFS filesystem or repair a damaged filesystem, see **btrfs-check(8)**. By default filesystem consistency is checked, the repair mode is enabled via the **--repair** option (use with care!).

OPTIONS

The options are all the same and detect if **fsck.btrfs** is executed in non-interactive mode and exits with success, otherwise prints a message about btrfs check.

EXIT STATUS

There are two possible exit codes returned:

0

No error

8

Operational error, eg. device does not exist

FILES

/etc/fstab

NAME

fsck.exfat – check an exFAT filesystem

SYNOPSIS

fsck.exfat [**-a**] [**-n**] [**-r**] [**-v**] [**-y**] [**-v**] *device*
fsck.exfat **-V**

DESCRIPTION

fsck.exfat checks an exFAT filesystem and repairs the filesystem depending on the options passed.

OPTIONS

- a** This option does the same thing as the **-p** option. It is provided for backwards compatibility only; it is suggested that people use **-p** option whenever possible.
- n** Check the filesystem but do not attempt to repair the filesystem.
- p** Repair the filesystem without user interaction if it can be done safely.
- r** Repair the filesystem interactively.
- v** Prints verbose debugging information while checking the exFAT filesystem.
- V** Prints the version number and exits.
- y** Repair the filesystem answering yes to all questions.

NAME

e2fsck – check a Linux ext2/ext3/ext4 file system

SYNOPSIS

```
e2fsck [ -pacnyrdfkvtDFV ] [ -b superblock ] [ -B blocksize ] [ -I|-L bad_blocks_file ] [ -C fd ] [ -j external-journal ] [ -E extended_options ] [ -z undo_file ] device
```

DESCRIPTION

e2fsck is used to check the ext2/ext3/ext4 family of file systems. For ext3 and ext4 file systems that use a journal, if the system has been shut down uncleanly without any errors, normally, after replaying the committed transactions in the journal, the file system should be marked as clean. Hence, for file systems that use journaling, **e2fsck** will normally replay the journal and exit, unless its superblock indicates that further checking is required.

device is a block device (e.g., */dev/sdc1*) or file containing the file system.

Note that in general it is not safe to run **e2fsck** on mounted file systems. The only exception is if the **-n** option is specified, and **-c**, **-I**, or **-L** options are *not* specified. However, even if it is safe to do so, the results printed by **e2fsck** are not valid if the file system is mounted. If **e2fsck** asks whether or not you should check a file system which is mounted, the only correct answer is “no”. Only experts who really know what they are doing should consider answering this question in any other way.

If **e2fsck** is run in interactive mode (meaning that none of **-y**, **-n**, or **-p** are specified), the program will ask the user to fix each problem found in the file system. A response of ‘y’ will fix the error; ‘n’ will leave the error unfixed; and ‘a’ will fix the problem and all subsequent problems; pressing Enter will proceed with the default response, which is printed before the question mark. Pressing Control-C terminates **e2fsck** immediately.

OPTIONS

- a** This option does the same thing as the **-p** option. It is provided for backwards compatibility only; it is suggested that people use **-p** option whenever possible.
- b** *superblock*
Instead of using the normal superblock, use an alternative superblock specified by *superblock*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system’s blocksize, the number of blocks per group, and features such as **sparse_super**.
Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system’s layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).
If an alternative superblock is specified and the file system is not opened read-only, **e2fsck** will make sure that the primary superblock is updated appropriately upon completion of the file system check.
- B** *blocksize*
Normally, **e2fsck** will search for the superblock at various different block sizes in an attempt to find the appropriate block size. This search can be fooled in some cases. This option forces **e2fsck** to only try locating the superblock at a particular blocksize. If the superblock is not found, **e2fsck** will terminate with a fatal error.
- c** This option causes **e2fsck** to use **badblocks(8)** program to do a read-only scan of the device in order to find any bad blocks. If any bad blocks are found, they are added to the bad block inode to prevent them from being allocated to a file or directory. If this option is specified twice, then the bad block scan will be done using a non-destructive read-write test.
- C** *fd* This option causes **e2fsck** to write completion information to the specified file descriptor so that the progress of the file system check can be monitored. This option is typically used by programs which are running **e2fsck**. If the file descriptor number is negative, then absolute value of the file descriptor will be used, and the progress information will be suppressed initially. It can later be enabled by sending the **e2fsck** process a SIGUSR1 signal. If the file descriptor specified is 0,

e2fsck will print a completion bar as it goes about its business. This requires that e2fsck is running on a video console or terminal.

- d** Print debugging output (useless unless you are debugging **e2fsck**).
- D** Optimize directories in file system. This option causes e2fsck to try to optimize all directories, either by re-indexing them if the file system supports directory indexing, or by sorting and compressing directories for smaller directories, or for file systems using traditional linear directories.

Even without the **-D** option, **e2fsck** may sometimes optimize a few directories --- for example, if directory indexing is enabled and a directory is not indexed and would benefit from being indexed, or if the index structures are corrupted and need to be rebuilt. The **-D** option forces all directories in the file system to be optimized. This can sometimes make them a little smaller and slightly faster to search, but in practice, you should rarely need to use this option.

The **-D** option will detect directory entries with duplicate names in a single directory, which e2fsck normally does not enforce for performance reasons.

-E extended_options

Set e2fsck extended options. Extended options are comma separated, and may take an argument using the equals ('=') sign. The following options are supported:

ea_ver=extended_attribute_version

Set the version of the extended attribute blocks which **e2fsck** will require while checking the file system. The version number may be 1 or 2. The default extended attribute version format is 2.

journal_only

Only replay the journal if required, but do not perform any further checks or repairs.

fragcheck

During pass 1, print a detailed report of any discontiguous blocks for files in the file system.

discard

Attempt to discard free blocks and unused inode blocks after the full file system check (discarding blocks is useful on solid state devices and sparse / thin-provisioned storage). Note that discard is done in pass 5 AFTER the file system has been fully checked and only if it does not contain recognizable errors. However there might be cases where **e2fsck** does not fully recognize a problem and hence in this case this option may prevent you from further manual data recovery.

nodiscard

Do not attempt to discard free blocks and unused inode blocks. This option is exactly the opposite of discard option. This is set as default.

no_optimize_extents

Do not offer to optimize the extent tree by eliminating unnecessary width or depth. This can also be enabled in the options section of **/etc/e2fsck.conf**.

optimize_extents

Offer to optimize the extent tree by eliminating unnecessary width or depth. This is the default unless otherwise specified in **/etc/e2fsck.conf**.

inode_count_fullmap

Trade off using memory for speed when checking a file system with a large number of hard-linked files. The amount of memory required is proportional to the number of inodes in the file system. For large file systems, this can be gigabytes of memory. (For example, a 40TB file system with 2.8 billion inodes will consume an additional 5.7 GB memory if this optimization is

enabled.) This optimization can also be enabled in the options section of */etc/e2fsck.conf*.

no_inode_count_fullmap

Disable the **inode_count_fullmap** optimization. This is the default unless otherwise specified in */etc/e2fsck.conf*.

readahead_kb

Use this many KiB of memory to pre-fetch metadata in the hopes of reducing e2fsck runtime. By default, this is set to the size of two block groups' inode tables (typically 4MiB on a regular ext4 file system); if this amount is more than 1/50th of total physical memory, readahead is disabled. Set this to zero to disable readahead entirely.

bmap2extent

Convert block-mapped files to extent-mapped files.

fixes_only

Only fix damaged metadata; do not optimize htree directories or compress extent trees. This option is incompatible with the -D and -E bmap2extent options.

check_encoding

Force verification of encoded filenames in case-insensitive directories. This is the default mode if the file system has the strict flag enabled.

unshare_blocks

If the file system has shared blocks, with the shared blocks read-only feature enabled, then this will unshare all shared blocks and unset the read-only feature bit. If there is not enough free space then the operation will fail. If the file system does not have the read-only feature bit, but has shared blocks anyway, then this option will have no effect. Note when using this option, if there is no free space to clone blocks, there is no prompt to delete files and instead the operation will fail.

Note that **unshare_blocks** implies the "-f" option to ensure that all passes are run. Additionally, if "-n" is also specified, e2fsck will simulate trying to allocate enough space to deduplicate. If this fails, the exit code will be non-zero.

-f Force checking even if the file system seems clean.

-F Flush the file system device's buffer caches before beginning. Only really useful for doing **e2fsck** time trials.

-j *external-journal*

Set the pathname where the external-journal for this file system can be found.

-k When combined with the **-c** option, any existing bad blocks in the bad blocks list are preserved, and any new bad blocks found by running **badblocks(8)** will be added to the existing bad blocks list.

-l *filename*

Add the block numbers listed in the file specified by *filename* to the list of bad blocks. The format of this file is the same as the one generated by the **badblocks(8)** program. Note that the block numbers are based on the blocksize of the file system. Hence, **badblocks(8)** must be given the blocksize of the file system in order to obtain correct results. As a result, it is much simpler and safer to use the **-c** option to **e2fsck**, since it will assure that the correct parameters are passed to the **badblocks** program.

-L *filename*

Set the bad blocks list to be the list of blocks specified by *filename*. (This option is the same as the **-l** option, except the bad blocks list is cleared before the blocks listed in the file are added to

the bad blocks list.)

- n** Open the file system read-only, and assume an answer of ‘no’ to all questions. Allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-p** or **-y** options.
- p** Automatically repair (“preen”) the file system. This option will cause **e2fsck** to automatically fix any file system problems that can be safely fixed without human intervention. If **e2fsck** discloses a problem which may require the system administrator to take additional corrective action, **e2fsck** will print a description of the problem and then exit with the value 4 logically or’ed into the exit code. (See the **EXIT CODE** section.) This option is normally used by the system’s boot scripts. It may not be specified at the same time as the **-n** or **-y** options.
- r** This option does nothing at all; it is provided only for backwards compatibility.
- t** Print timing statistics for **e2fsck**. If this option is used twice, additional timing statistics are printed on a pass by pass basis.
- v** Verbose mode.
- V** Print version information and exit.
- y** Assume an answer of ‘yes’ to all questions; allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-n** or **-p** options.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the **undo_file** argument, the undo file will be written to a file named **e2fsck-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable.

WARNING: The undo file cannot be used to recover from a power or system crash.

EXIT CODE

The exit code returned by **e2fsck** is the sum of the following conditions:

0	– No errors
1	– File system errors corrected
2	– File system errors corrected, system should be rebooted
4	– File system errors left uncorrected
8	– Operational error
16	– Usage or syntax error
32	– E2fsck canceled by user request
128	– Shared library error

SIGNALS

The following signals have the following effect when sent to **e2fsck**.

SIGUSR1

This signal causes **e2fsck** to start displaying a completion bar or emitting progress information. (See discussion of the **-C** option.)

SIGUSR2

This signal causes **e2fsck** to stop displaying a completion bar or emitting progress information.

REPORTING BUGS

Almost any piece of software will have bugs. If you manage to find a file system which causes **e2fsck** to crash, or which **e2fsck** is unable to repair, please report it to the author.

Please include as much information as possible in your bug report. Ideally, include a complete transcript of the **e2fsck** run, so I can see exactly what error messages are displayed. (Make sure the messages printed by **e2fsck** are in English; if your system has been configured so that **e2fsck**’s messages have been translated

into another language, please set the the **LC_ALL** environment variable to **C** so that the transcript of e2fsck's output will be useful to me.) If you have a writable file system where the transcript can be stored, the **script(1)** program is a handy way to save the output of **e2fsck** to a file.

It is also useful to send the output of **dumpe2fs(8)**. If a specific inode or inodes seems to be giving **e2fsck** trouble, try running the **debugfs(8)** command and send the output of the **stat(1u)** command run on the relevant inode(s). If the inode is a directory, the **debugfs** *dump* command will allow you to extract the contents of the directory inode, which can sent to me after being first run through **uuencode(1)**. The most useful data you can send to help reproduce the bug is a compressed raw image dump of the file system, generated using **e2image(8)**. See the **e2image(8)** man page for more details.

Always include the full version string which **e2fsck** displays when it is run, so I know which version you are running.

ENVIRONMENT

E2FSCK_CONFIG

Determines the location of the configuration file (see **e2fsck.conf(5)**).

AUTHOR

This version of **e2fsck** was written by Theodore Ts'o <tytso@mit.edu>.

NAME

e2fsck – check a Linux ext2/ext3/ext4 file system

SYNOPSIS

```
e2fsck [ -pacnyrdfkvtDFV ] [ -b superblock ] [ -B blocksize ] [ -I|-L bad_blocks_file ] [ -C fd ] [ -j external-journal ] [ -E extended_options ] [ -z undo_file ] device
```

DESCRIPTION

e2fsck is used to check the ext2/ext3/ext4 family of file systems. For ext3 and ext4 file systems that use a journal, if the system has been shut down uncleanly without any errors, normally, after replaying the committed transactions in the journal, the file system should be marked as clean. Hence, for file systems that use journaling, **e2fsck** will normally replay the journal and exit, unless its superblock indicates that further checking is required.

device is a block device (e.g., */dev/sdc1*) or file containing the file system.

Note that in general it is not safe to run **e2fsck** on mounted file systems. The only exception is if the **-n** option is specified, and **-c**, **-I**, or **-L** options are *not* specified. However, even if it is safe to do so, the results printed by **e2fsck** are not valid if the file system is mounted. If **e2fsck** asks whether or not you should check a file system which is mounted, the only correct answer is “no”. Only experts who really know what they are doing should consider answering this question in any other way.

If **e2fsck** is run in interactive mode (meaning that none of **-y**, **-n**, or **-p** are specified), the program will ask the user to fix each problem found in the file system. A response of ‘y’ will fix the error; ‘n’ will leave the error unfixed; and ‘a’ will fix the problem and all subsequent problems; pressing Enter will proceed with the default response, which is printed before the question mark. Pressing Control-C terminates **e2fsck** immediately.

OPTIONS

- a** This option does the same thing as the **-p** option. It is provided for backwards compatibility only; it is suggested that people use **-p** option whenever possible.
- b** *superblock*
Instead of using the normal superblock, use an alternative superblock specified by *superblock*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system’s blocksize, the number of blocks per group, and features such as **sparse_super**.
Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system’s layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).
If an alternative superblock is specified and the file system is not opened read-only, **e2fsck** will make sure that the primary superblock is updated appropriately upon completion of the file system check.
- B** *blocksize*
Normally, **e2fsck** will search for the superblock at various different block sizes in an attempt to find the appropriate block size. This search can be fooled in some cases. This option forces **e2fsck** to only try locating the superblock at a particular blocksize. If the superblock is not found, **e2fsck** will terminate with a fatal error.
- c** This option causes **e2fsck** to use **badblocks(8)** program to do a read-only scan of the device in order to find any bad blocks. If any bad blocks are found, they are added to the bad block inode to prevent them from being allocated to a file or directory. If this option is specified twice, then the bad block scan will be done using a non-destructive read-write test.
- C** *fd* This option causes **e2fsck** to write completion information to the specified file descriptor so that the progress of the file system check can be monitored. This option is typically used by programs which are running **e2fsck**. If the file descriptor number is negative, then absolute value of the file descriptor will be used, and the progress information will be suppressed initially. It can later be enabled by sending the **e2fsck** process a SIGUSR1 signal. If the file descriptor specified is 0,

e2fsck will print a completion bar as it goes about its business. This requires that e2fsck is running on a video console or terminal.

- d** Print debugging output (useless unless you are debugging **e2fsck**).
- D** Optimize directories in file system. This option causes e2fsck to try to optimize all directories, either by re-indexing them if the file system supports directory indexing, or by sorting and compressing directories for smaller directories, or for file systems using traditional linear directories.

Even without the **-D** option, **e2fsck** may sometimes optimize a few directories --- for example, if directory indexing is enabled and a directory is not indexed and would benefit from being indexed, or if the index structures are corrupted and need to be rebuilt. The **-D** option forces all directories in the file system to be optimized. This can sometimes make them a little smaller and slightly faster to search, but in practice, you should rarely need to use this option.

The **-D** option will detect directory entries with duplicate names in a single directory, which e2fsck normally does not enforce for performance reasons.

-E extended_options

Set e2fsck extended options. Extended options are comma separated, and may take an argument using the equals ('=') sign. The following options are supported:

ea_ver=extended_attribute_version

Set the version of the extended attribute blocks which **e2fsck** will require while checking the file system. The version number may be 1 or 2. The default extended attribute version format is 2.

journal_only

Only replay the journal if required, but do not perform any further checks or repairs.

fragcheck

During pass 1, print a detailed report of any discontiguous blocks for files in the file system.

discard

Attempt to discard free blocks and unused inode blocks after the full file system check (discarding blocks is useful on solid state devices and sparse / thin-provisioned storage). Note that discard is done in pass 5 AFTER the file system has been fully checked and only if it does not contain recognizable errors. However there might be cases where **e2fsck** does not fully recognize a problem and hence in this case this option may prevent you from further manual data recovery.

nodiscard

Do not attempt to discard free blocks and unused inode blocks. This option is exactly the opposite of discard option. This is set as default.

no_optimize_extents

Do not offer to optimize the extent tree by eliminating unnecessary width or depth. This can also be enabled in the options section of **/etc/e2fsck.conf**.

optimize_extents

Offer to optimize the extent tree by eliminating unnecessary width or depth. This is the default unless otherwise specified in **/etc/e2fsck.conf**.

inode_count_fullmap

Trade off using memory for speed when checking a file system with a large number of hard-linked files. The amount of memory required is proportional to the number of inodes in the file system. For large file systems, this can be gigabytes of memory. (For example, a 40TB file system with 2.8 billion inodes will consume an additional 5.7 GB memory if this optimization is

enabled.) This optimization can also be enabled in the options section of */etc/e2fsck.conf*.

no_inode_count_fullmap

Disable the **inode_count_fullmap** optimization. This is the default unless otherwise specified in */etc/e2fsck.conf*.

readahead_kb

Use this many KiB of memory to pre-fetch metadata in the hopes of reducing e2fsck runtime. By default, this is set to the size of two block groups' inode tables (typically 4MiB on a regular ext4 file system); if this amount is more than 1/50th of total physical memory, readahead is disabled. Set this to zero to disable readahead entirely.

bmap2extent

Convert block-mapped files to extent-mapped files.

fixes_only

Only fix damaged metadata; do not optimize htree directories or compress extent trees. This option is incompatible with the -D and -E bmap2extent options.

check_encoding

Force verification of encoded filenames in case-insensitive directories. This is the default mode if the file system has the strict flag enabled.

unshare_blocks

If the file system has shared blocks, with the shared blocks read-only feature enabled, then this will unshare all shared blocks and unset the read-only feature bit. If there is not enough free space then the operation will fail. If the file system does not have the read-only feature bit, but has shared blocks anyway, then this option will have no effect. Note when using this option, if there is no free space to clone blocks, there is no prompt to delete files and instead the operation will fail.

Note that **unshare_blocks** implies the "-f" option to ensure that all passes are run. Additionally, if "-n" is also specified, e2fsck will simulate trying to allocate enough space to deduplicate. If this fails, the exit code will be non-zero.

-f Force checking even if the file system seems clean.

-F Flush the file system device's buffer caches before beginning. Only really useful for doing **e2fsck** time trials.

-j *external-journal*

Set the pathname where the external-journal for this file system can be found.

-k When combined with the **-c** option, any existing bad blocks in the bad blocks list are preserved, and any new bad blocks found by running **badblocks(8)** will be added to the existing bad blocks list.

-l *filename*

Add the block numbers listed in the file specified by *filename* to the list of bad blocks. The format of this file is the same as the one generated by the **badblocks(8)** program. Note that the block numbers are based on the blocksize of the file system. Hence, **badblocks(8)** must be given the blocksize of the file system in order to obtain correct results. As a result, it is much simpler and safer to use the **-c** option to **e2fsck**, since it will assure that the correct parameters are passed to the **badblocks** program.

-L *filename*

Set the bad blocks list to be the list of blocks specified by *filename*. (This option is the same as the **-l** option, except the bad blocks list is cleared before the blocks listed in the file are added to

the bad blocks list.)

- n** Open the file system read-only, and assume an answer of ‘no’ to all questions. Allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-p** or **-y** options.
- p** Automatically repair (“preen”) the file system. This option will cause **e2fsck** to automatically fix any file system problems that can be safely fixed without human intervention. If **e2fsck** discovers a problem which may require the system administrator to take additional corrective action, **e2fsck** will print a description of the problem and then exit with the value 4 logically or’ed into the exit code. (See the **EXIT CODE** section.) This option is normally used by the system’s boot scripts. It may not be specified at the same time as the **-n** or **-y** options.
- r** This option does nothing at all; it is provided only for backwards compatibility.
- t** Print timing statistics for **e2fsck**. If this option is used twice, additional timing statistics are printed on a pass by pass basis.
- v** Verbose mode.
- V** Print version information and exit.
- y** Assume an answer of ‘yes’ to all questions; allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-n** or **-p** options.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the **undo_file** argument, the undo file will be written to a file named **e2fsck-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable.

WARNING: The undo file cannot be used to recover from a power or system crash.

EXIT CODE

The exit code returned by **e2fsck** is the sum of the following conditions:

0	– No errors
1	– File system errors corrected
2	– File system errors corrected, system should be rebooted
4	– File system errors left uncorrected
8	– Operational error
16	– Usage or syntax error
32	– E2fsck canceled by user request
128	– Shared library error

SIGNALS

The following signals have the following effect when sent to **e2fsck**.

SIGUSR1

This signal causes **e2fsck** to start displaying a completion bar or emitting progress information. (See discussion of the **-C** option.)

SIGUSR2

This signal causes **e2fsck** to stop displaying a completion bar or emitting progress information.

REPORTING BUGS

Almost any piece of software will have bugs. If you manage to find a file system which causes **e2fsck** to crash, or which **e2fsck** is unable to repair, please report it to the author.

Please include as much information as possible in your bug report. Ideally, include a complete transcript of the **e2fsck** run, so I can see exactly what error messages are displayed. (Make sure the messages printed by **e2fsck** are in English; if your system has been configured so that **e2fsck**’s messages have been translated

into another language, please set the the **LC_ALL** environment variable to **C** so that the transcript of e2fsck's output will be useful to me.) If you have a writable file system where the transcript can be stored, the **script(1)** program is a handy way to save the output of **e2fsck** to a file.

It is also useful to send the output of **dumpe2fs(8)**. If a specific inode or inodes seems to be giving **e2fsck** trouble, try running the **debugfs(8)** command and send the output of the **stat(1u)** command run on the relevant inode(s). If the inode is a directory, the **debugfs** *dump* command will allow you to extract the contents of the directory inode, which can sent to me after being first run through **uuencode(1)**. The most useful data you can send to help reproduce the bug is a compressed raw image dump of the file system, generated using **e2image(8)**. See the **e2image(8)** man page for more details.

Always include the full version string which **e2fsck** displays when it is run, so I know which version you are running.

ENVIRONMENT

NAME

e2fsck – check a Linux ext2/ext3/ext4 file system

SYNOPSIS

```
e2fsck [ -pacnyrdfkvtDFV ] [ -b superblock ] [ -B blocksize ] [ -I|-L bad_blocks_file ] [ -C fd ] [ -j external-journal ] [ -E extended_options ] [ -z undo_file ] device
```

DESCRIPTION

e2fsck is used to check the ext2/ext3/ext4 family of file systems. For ext3 and ext4 file systems that use a journal, if the system has been shut down uncleanly without any errors, normally, after replaying the committed transactions in the journal, the file system should be marked as clean. Hence, for file systems that use journaling, **e2fsck** will normally replay the journal and exit, unless its superblock indicates that further checking is required.

device is a block device (e.g., */dev/sdc1*) or file containing the file system.

Note that in general it is not safe to run **e2fsck** on mounted file systems. The only exception is if the **-n** option is specified, and **-c**, **-I**, or **-L** options are *not* specified. However, even if it is safe to do so, the results printed by **e2fsck** are not valid if the file system is mounted. If **e2fsck** asks whether or not you should check a file system which is mounted, the only correct answer is “no”. Only experts who really know what they are doing should consider answering this question in any other way.

If **e2fsck** is run in interactive mode (meaning that none of **-y**, **-n**, or **-p** are specified), the program will ask the user to fix each problem found in the file system. A response of ‘y’ will fix the error; ‘n’ will leave the error unfixed; and ‘a’ will fix the problem and all subsequent problems; pressing Enter will proceed with the default response, which is printed before the question mark. Pressing Control-C terminates **e2fsck** immediately.

OPTIONS

- a** This option does the same thing as the **-p** option. It is provided for backwards compatibility only; it is suggested that people use **-p** option whenever possible.
- b** *superblock*
Instead of using the normal superblock, use an alternative superblock specified by *superblock*. This option is normally used when the primary superblock has been corrupted. The location of backup superblocks is dependent on the file system’s blocksize, the number of blocks per group, and features such as **sparse_super**.
Additional backup superblocks can be determined by using the **mke2fs** program using the **-n** option to print out where the superblocks exist, supposing **mke2fs** is supplied with arguments that are consistent with the file system’s layout (e.g. blocksize, blocks per group, **sparse_super**, etc.).
If an alternative superblock is specified and the file system is not opened read-only, **e2fsck** will make sure that the primary superblock is updated appropriately upon completion of the file system check.
- B** *blocksize*
Normally, **e2fsck** will search for the superblock at various different block sizes in an attempt to find the appropriate block size. This search can be fooled in some cases. This option forces **e2fsck** to only try locating the superblock at a particular blocksize. If the superblock is not found, **e2fsck** will terminate with a fatal error.
- c** This option causes **e2fsck** to use **badblocks(8)** program to do a read-only scan of the device in order to find any bad blocks. If any bad blocks are found, they are added to the bad block inode to prevent them from being allocated to a file or directory. If this option is specified twice, then the bad block scan will be done using a non-destructive read-write test.
- C** *fd* This option causes **e2fsck** to write completion information to the specified file descriptor so that the progress of the file system check can be monitored. This option is typically used by programs which are running **e2fsck**. If the file descriptor number is negative, then absolute value of the file descriptor will be used, and the progress information will be suppressed initially. It can later be enabled by sending the **e2fsck** process a SIGUSR1 signal. If the file descriptor specified is 0,

e2fsck will print a completion bar as it goes about its business. This requires that e2fsck is running on a video console or terminal.

- d** Print debugging output (useless unless you are debugging **e2fsck**).
- D** Optimize directories in file system. This option causes e2fsck to try to optimize all directories, either by re-indexing them if the file system supports directory indexing, or by sorting and compressing directories for smaller directories, or for file systems using traditional linear directories.

Even without the **-D** option, **e2fsck** may sometimes optimize a few directories --- for example, if directory indexing is enabled and a directory is not indexed and would benefit from being indexed, or if the index structures are corrupted and need to be rebuilt. The **-D** option forces all directories in the file system to be optimized. This can sometimes make them a little smaller and slightly faster to search, but in practice, you should rarely need to use this option.

The **-D** option will detect directory entries with duplicate names in a single directory, which e2fsck normally does not enforce for performance reasons.

-E extended_options

Set e2fsck extended options. Extended options are comma separated, and may take an argument using the equals ('=') sign. The following options are supported:

ea_ver=extended_attribute_version

Set the version of the extended attribute blocks which **e2fsck** will require while checking the file system. The version number may be 1 or 2. The default extended attribute version format is 2.

journal_only

Only replay the journal if required, but do not perform any further checks or repairs.

fragcheck

During pass 1, print a detailed report of any discontiguous blocks for files in the file system.

discard

Attempt to discard free blocks and unused inode blocks after the full file system check (discarding blocks is useful on solid state devices and sparse / thin-provisioned storage). Note that discard is done in pass 5 AFTER the file system has been fully checked and only if it does not contain recognizable errors. However there might be cases where **e2fsck** does not fully recognize a problem and hence in this case this option may prevent you from further manual data recovery.

nodiscard

Do not attempt to discard free blocks and unused inode blocks. This option is exactly the opposite of discard option. This is set as default.

no_optimize_extents

Do not offer to optimize the extent tree by eliminating unnecessary width or depth. This can also be enabled in the options section of **/etc/e2fsck.conf**.

optimize_extents

Offer to optimize the extent tree by eliminating unnecessary width or depth. This is the default unless otherwise specified in **/etc/e2fsck.conf**.

inode_count_fullmap

Trade off using memory for speed when checking a file system with a large number of hard-linked files. The amount of memory required is proportional to the number of inodes in the file system. For large file systems, this can be gigabytes of memory. (For example, a 40TB file system with 2.8 billion inodes will consume an additional 5.7 GB memory if this optimization is

enabled.) This optimization can also be enabled in the options section of */etc/e2fsck.conf*.

no_inode_count_fullmap

Disable the **inode_count_fullmap** optimization. This is the default unless otherwise specified in */etc/e2fsck.conf*.

readahead_kb

Use this many KiB of memory to pre-fetch metadata in the hopes of reducing e2fsck runtime. By default, this is set to the size of two block groups' inode tables (typically 4MiB on a regular ext4 file system); if this amount is more than 1/50th of total physical memory, readahead is disabled. Set this to zero to disable readahead entirely.

bmap2extent

Convert block-mapped files to extent-mapped files.

fixes_only

Only fix damaged metadata; do not optimize htree directories or compress extent trees. This option is incompatible with the -D and -E bmap2extent options.

check_encoding

Force verification of encoded filenames in case-insensitive directories. This is the default mode if the file system has the strict flag enabled.

unshare_blocks

If the file system has shared blocks, with the shared blocks read-only feature enabled, then this will unshare all shared blocks and unset the read-only feature bit. If there is not enough free space then the operation will fail. If the file system does not have the read-only feature bit, but has shared blocks anyway, then this option will have no effect. Note when using this option, if there is no free space to clone blocks, there is no prompt to delete files and instead the operation will fail.

Note that **unshare_blocks** implies the "-f" option to ensure that all passes are run. Additionally, if "-n" is also specified, e2fsck will simulate trying to allocate enough space to deduplicate. If this fails, the exit code will be non-zero.

-f Force checking even if the file system seems clean.

-F Flush the file system device's buffer caches before beginning. Only really useful for doing **e2fsck** time trials.

-j *external-journal*

Set the pathname where the external-journal for this file system can be found.

-k When combined with the **-c** option, any existing bad blocks in the bad blocks list are preserved, and any new bad blocks found by running **badblocks(8)** will be added to the existing bad blocks list.

-l *filename*

Add the block numbers listed in the file specified by *filename* to the list of bad blocks. The format of this file is the same as the one generated by the **badblocks(8)** program. Note that the block numbers are based on the blocksize of the file system. Hence, **badblocks(8)** must be given the blocksize of the file system in order to obtain correct results. As a result, it is much simpler and safer to use the **-c** option to **e2fsck**, since it will assure that the correct parameters are passed to the **badblocks** program.

-L *filename*

Set the bad blocks list to be the list of blocks specified by *filename*. (This option is the same as the **-l** option, except the bad blocks list is cleared before the blocks listed in the file are added to

the bad blocks list.)

- n** Open the file system read-only, and assume an answer of ‘no’ to all questions. Allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-p** or **-y** options.
- p** Automatically repair (“preen”) the file system. This option will cause **e2fsck** to automatically fix any file system problems that can be safely fixed without human intervention. If **e2fsck** discovers a problem which may require the system administrator to take additional corrective action, **e2fsck** will print a description of the problem and then exit with the value 4 logically or’ed into the exit code. (See the **EXIT CODE** section.) This option is normally used by the system’s boot scripts. It may not be specified at the same time as the **-n** or **-y** options.
- r** This option does nothing at all; it is provided only for backwards compatibility.
- t** Print timing statistics for **e2fsck**. If this option is used twice, additional timing statistics are printed on a pass by pass basis.
- v** Verbose mode.
- V** Print version information and exit.
- y** Assume an answer of ‘yes’ to all questions; allows **e2fsck** to be used non-interactively. This option may not be specified at the same time as the **-n** or **-p** options.

-z undo_file

Before overwriting a file system block, write the old contents of the block to an undo file. This undo file can be used with **e2undo(8)** to restore the old contents of the file system should something go wrong. If the empty string is passed as the **undo_file** argument, the undo file will be written to a file named **e2fsck-device.e2undo** in the directory specified via the **E2FSPROGS_UNDO_DIR** environment variable.

WARNING: The undo file cannot be used to recover from a power or system crash.

EXIT CODE

The exit code returned by **e2fsck** is the sum of the following conditions:

0	– No errors
1	– File system errors corrected
2	– File system errors corrected, system should be rebooted
4	– File system errors left uncorrected
8	– Operational error
16	– Usage or syntax error
32	– E2fsck canceled by user request
128	– Shared library error

SIGNALS

The following signals have the following effect when sent to **e2fsck**.

SIGUSR1

This signal causes **e2fsck** to start displaying a completion bar or emitting progress information. (See discussion of the **-C** option.)

SIGUSR2

This signal causes **e2fsck** to stop displaying a completion bar or emitting progress information.

REPORTING BUGS

Almost any piece of software will have bugs. If you manage to find a file system which causes **e2fsck** to crash, or which **e2fsck** is unable to repair, please report it to the author.

Please include as much information as possible in your bug report. Ideally, include a complete transcript of the **e2fsck** run, so I can see exactly what error messages are displayed. (Make sure the messages printed by **e2fsck** are in English; if your system has been configured so that **e2fsck**’s messages have been translated

into another language, please set the the **LC_ALL** environment variable to **C** so that the transcript of e2fsck's output will be useful to me.) If you have a writable file system where the transcript can be stored, the **script(1)** program is a handy way to save the output of **e2fsck** to a file.

It is also useful to send the output of **dumpe2fs(8)**. If a specific inode or inodes seems to be giving **e2fsck** trouble, try running the **debugfs(8)** command and send the output of the **stat(1u)** command run on the relevant inode(s). If the inode is a directory, the **debugfs** *dump* command will allow you to extract the contents of the directory inode, which can sent to me after being first run through **uuencode(1)**. The most useful data you can send to help reproduce the bug is a compressed raw image dump of the file system, generated using **e2image(8)**. See the **e2image(8)** man page for more details.

Always include the full version string which **e2fsck** displays when it is run, so I know which version you are running.

ENVIRONMENT

E2FSCK_CONFIG

Determines the location of the configuration file (see **e2fsck.conf(5)**).

AUTHOR

This version of **e2fsck** was written by Theodore Ts'o <tytso@mit.edu>.

NAME

fsck.f2fs – check a Linux F2FS file system

SYNOPSIS

```
fsck.f2fs [ -a enable auto fix ] [ -f enable force fix ] [ -p enable preen mode ] [ -t show stored directory tree ] [ -d debugging-level ] device
```

DESCRIPTION

fsck.f2fs is used to check an f2fs file system (usually in a disk partition). *device* is the special file corresponding to the device (e.g. */dev/sdXX*).

The exit code returned by **fsck.f2fs** is 0 on success and -1 on failure.

OPTIONS

-a enable auto fix

Enable to run file system check only if a bug was reported by the F2FS kernel module. It is disabled by default.

-f enable force fix

Enable to fix all the inconsistency in the partition.

-p enable preen mode

Same as "-a" to support general fsck convention.

-t show stored directory tree

Enable to show every directory entries in the partition.

-d debug-level

Specify the level of debugging options. The default number is 0, which shows basic debugging messages.

AUTHOR

Initial checking code was written by Byoung Geun Kim <bgbg.kim@samsung.com>. Jaegeuk Kim <jaegeuk@kernel.org> reworked most parts of the codes to support fixing any corrupted images.

AVAILABILITY

fsck.f2fs is available from <git://git.kernel.org/pub/scm/linux/kernel/git/jaegeuk/f2fs-tools.git>.

SEE ALSO

mkfs.f2fs(8), **dump.f2fs(8)**, **defrag.f2fs(8)**, **resize.f2fs(8)**, **sload.f2fs(8)**.

NAME

fsck.fat – check and repair MS-DOS FAT filesystems

SYNOPSIS

fsck.fat [*OPTIONS*] *DEVICE*

DESCRIPTION

fsck.fat verifies the consistency of MS-DOS filesystems and optionally tries to repair them.

The following filesystem problems can be corrected (in this order):

- FAT contains invalid cluster numbers. Cluster is changed to EOF.
- File's cluster chain contains a loop. The loop is broken.
- Bad clusters (read errors). The clusters are marked bad and they are removed from files owning them. This check is optional.
- Directories with a large number of bad entries (probably corrupt). The directory can be deleted.
- Files . and .. are non-directories. They can be deleted or renamed.
- Directories . and .. in root directory. They are deleted.
- Bad filenames. They can be renamed.
- Duplicate directory entries. They can be deleted or renamed.
- Directories with non-zero size field. Size is set to zero.
- Directory . does not point to parent directory. The start pointer is adjusted.
- Directory .. does not point to parent of parent directory. The start pointer is adjusted.
- . and .. are not the two first entries in a non-root directory. The entries are created, moving occupied slots if necessary.
- Start cluster number of a file is invalid. The file is truncated.
- File contains bad or free clusters. The file is truncated.
- File's cluster chain is longer than indicated by the size fields. The file is truncated.
- Two or more files share the same cluster(s). All but one of the files are truncated. If the file being truncated is a directory file that has already been read, the filesystem check is restarted after truncation.
- File's cluster chain is shorter than indicated by the size fields. The file is truncated.
- Volume label in root directory or label in boot sector is invalid. Invalid labels are removed.
- Volume label in root directory and label in boot sector are different. Volume label from root directory is copied to boot sector.
- Clusters are marked as used but are not owned by a file. They are marked as free.

Additionally, the following problems are detected, but not repaired:

- Invalid parameters in boot sector

When **fsck.fat** checks a filesystem, it accumulates all changes in memory and performs them only after all checks are complete. This can be disabled with the **-w** option.

Two different variants of the FAT filesystem are supported. Standard is the FAT12, FAT16 and FAT32 filesystems as defined by Microsoft and widely used on hard disks and removable media like USB sticks and SD cards. The other is the legacy Atari variant used on Atari ST.

There are some minor differences in Atari format: Some boot sector fields are interpreted slightly different, and the special FAT entries for end-of-file and bad cluster can be different. Under MS-DOS 0xffff8 is used for EOF and Atari employs 0xffff by default, but both systems recognize all values from 0xffff8–0xffff as end-of-file. MS-DOS uses only 0xffff7 for bad clusters, where on Atari values 0xffff0–0xffff7 are for this

purpose (but the standard value is still 0xffff7).

OPTIONS

-a Automatically repair the filesystem. No user intervention is necessary. Whenever there is more than one method to solve a problem, the least destructive approach is used.

-A Select using the Atari variation of the FAT filesystem if that isn't active already, otherwise select standard FAT filesystem. This is selected by default if **mkfs.fat** is run on 68k Atari Linux.

-b Make read-only boot sector check.

-c PAGE

Use DOS codepage *PAGE* to decode short file names. By default codepage 850 is used.

-d PATH

Delete the specified file. If more than one file with that name exist, the first one is deleted. This option can be given more than once.

-f Salvage unused cluster chains to files. By default, unused clusters are added to the free disk space except in auto mode (**-a**).

-F NUM

Specify FAT table *NUM* for filesystem access. By default value 0 is assumed and then the first uncorrupted FAT table is chosen. Uncorrupted means that FAT table has valid first cluster. If default value 0 is used and all FAT tables are corrupted then **fsck.fat** gives up and does not try to repair FAT filesystem. If non-zero *NUM* value is specified then **fsck.fat** uses FAT table *NUM* for repairing FAT filesystem. If FAT table *NUM* has corrupted first cluster then **fsck.fat** will repair it. In any case, if FAT filesystem has more FAT tables then repaired content of chosen FAT table is copied to other FAT tables. To repair corrupted first cluster it is required to call **fsck.fat** with non-zero *NUM* value.

-l List path names of files being processed.

-n No-operation mode: non-interactively check for errors, but don't write anything to the filesystem.

-p Same as **-a**, for compatibility with other *fsck.

-r Interactively repair the filesystem. The user is asked for advice whenever there is more than one approach to fix an inconsistency. This is the default mode and the option is only retained for backwards compatibility.

-S Consider short (8.3) file names with spaces in the middle to be invalid, like previous versions of this program did. While such file names are not forbidden by the FAT specification, and were never treated as errors by Microsoft file system checking tools, many DOS programs are unable to handle files with such names. Using this option can make them accessible to these programs.

Short file names which *start* with a space are considered invalid regardless of this option's setting.

Previous versions of this program exceptionally treated *EA DATA. SF* and *WP ROOT. SF* as valid short names; using this option does not preserve that exception.

-t Mark unreadable clusters as bad.

-u PATH

Try to undelete the specified file. **fsck.fat** tries to allocate a chain of contiguous unallocated clusters beginning with the start cluster of the undeleted file. This option can be given more than once.

-U Consider lowercase volume and boot label as invalid and allow only uppercase characters. Such labels are forbidden by the FAT specification, but they are widely used by Linux tools. Moreover MS-DOS and Windows systems do not have problems to read them. Therefore volume and boot labels with lowercase characters are by default permitted.

-v Verbose mode. Generates slightly more output.

-V Perform a verification pass. The filesystem check is repeated after the first run. The second pass should never report any fixable errors. It may take considerably longer than the first pass, because the first pass may have generated long list of modifications that have to be scanned for each disk read.

--variant *TYPE*

Create a filesystem of variant *TYPE*. Acceptable values are *standard* and *atari* (in any combination of upper/lower case). See above under DESCRIPTION for the differences.

-w Write changes to disk immediately.

-y Same as **-a** (automatically repair filesystem) for compatibility with other fsck tools.

--help

Display help message describing usage and options then exit.

EXIT STATUS

0 No recoverable errors have been detected.

1 Recoverable errors have been detected or **fsck.fat** has discovered an internal inconsistency.

2 Usage error. **fsck.fat** did not access the filesystem.

FILES

fsck0000.rec, *fsck0001.rec*, ...

When recovering from a corrupted filesystem, **fsck.fat** dumps recovered data into files named *fsckNNNN.rec* in the top level directory of the filesystem.

BUGS

- Does not remove entirely empty directories.
- Should give more diagnostic messages.
- Undeleting files should use a more sophisticated algorithm.

- Volume label in root directory or label in boot sector is invalid. Invalid labels are removed.
- Volume label in root directory and label in boot sector are different. Volume label from root directory is copied to boot sector.
- Clusters are marked as used but are not owned by a file. They are marked as free.

Additionally, the following problems are detected, but not repaired:

- Invalid parameters in boot sector

When **fsck.fat** checks a filesystem, it accumulates all changes in memory and performs them only after all checks are complete. This can be disabled with the **-w** option.

Two different variants of the FAT filesystem are supported. Standard is the FAT12, FAT16 and FAT32 filesystems as defined by Microsoft and widely used on hard disks and removable media like USB sticks and SD cards. The other is the legacy Atari variant used on Atari ST.

There are some minor differences in Atari format: Some boot sector fields are interpreted slightly different, and the special FAT entries for end-of-file and bad cluster can be different. Under MS-DOS 0xffff8 is used for EOF and Atari employs 0xffff by default, but both systems recognize all values from 0xffff8–0xffff as end-of-file. MS-DOS uses only 0xffff7 for bad clusters, where on Atari values 0xffff0–0xffff7 are for this

purpose (but the standard value is still 0xffff7).

OPTIONS

-a Automatically repair the filesystem. No user intervention is necessary. Whenever there is more than one method to solve a problem, the least destructive approach is used.

-A Select using the Atari variation of the FAT filesystem if that isn't active already, otherwise select standard FAT filesystem. This is selected by default if **mkfs.fat** is run on 68k Atari Linux.

-b Make read-only boot sector check.

-c PAGE

Use DOS codepage *PAGE* to decode short file names. By default codepage 850 is used.

-d PATH

Delete the specified file. If more than one file with that name exist, the first one is deleted. This option can be given more than once.

-f Salvage unused cluster chains to files. By default, unused clusters are added to the free disk space except in auto mode (**-a**).

-F NUM

Specify FAT table *NUM* for filesystem access. By default value 0 is assumed and then the first uncorrupted FAT table is chosen. Uncorrupted means that FAT table has valid first cluster. If default value 0 is used and all FAT tables are corrupted then **fsck.fat** gives up and does not try to repair FAT filesystem. If non-zero *NUM* value is specified then **fsck.fat** uses FAT table *NUM* for repairing FAT filesystem. If FAT table *NUM* has corrupted first cluster then **fsck.fat** will repair it. In any case, if FAT filesystem has more FAT tables then repaired content of chosen FAT table is copied to other FAT tables. To repair corrupted first cluster it is required to call **fsck.fat** with non-zero *NUM* value.

-l List path names of files being processed.

-n No-operation mode: non-interactively check for errors, but don't write anything to the filesystem.

-p Same as **-a**, for compatibility with other *fsck.

-r Interactively repair the filesystem. The user is asked for advice whenever there is more than one approach to fix an inconsistency. This is the default mode and the option is only retained for backwards compatibility.

-S Consider short (8.3) file names with spaces in the middle to be invalid, like previous versions of this program did. While such file names are not forbidden by the FAT specification, and were never treated as errors by Microsoft file system checking tools, many DOS programs are unable to handle files with such names. Using this option can make them accessible to these programs.

Short file names which *start* with a space are considered invalid regardless of this option's setting.

Previous versions of this program exceptionally treated *EA DATA. SF* and *WP ROOT. SF* as valid short names; using this option does not preserve that exception.

-t Mark unreadable clusters as bad.

-u PATH

Try to undelete the specified file. **fsck.fat** tries to allocate a chain of contiguous unallocated clusters beginning with the start cluster of the undeleted file. This option can be given more than once.

-U Consider lowercase volume and boot label as invalid and allow only uppercase characters. Such labels are forbidden by the FAT specification, but they are widely used by Linux tools. Moreover MS-DOS and Windows systems do not have problems to read them. Therefore volume and boot labels with lowercase characters are by default permitted.

-v Verbose mode. Generates slightly more output.

-V Perform a verification pass. The filesystem check is repeated after the first run. The second pass should never report any fixable errors. It may take considerably longer than the first pass, because the first pass may have generated long list of modifications that have to be scanned for each disk read.

--variant *TYPE*

Create a filesystem of variant *TYPE*. Acceptable values are *standard* and *atari* (in any combination of upper/lower case). See above under DESCRIPTION for the differences.

-w Write changes to disk immediately.

-y Same as **-a** (automatically repair filesystem) for compatibility with other fsck tools.

--help

Display help message describing usage and options then exit.

EXIT STATUS

0 No recoverable errors have been detected.

1 Recoverable errors have been detected or **fsck.fat** has discovered an internal inconsistency.

2 Usage error. **fsck.fat** did not access the filesystem.

FILES

fsck0000.rec, *fsck0001.rec*, ...

When recovering from a corrupted filesystem, **fsck.fat** dumps recovered data into files named *fsckNNNN.rec* in the top level directory of the filesystem.

BUGS

- Does not remove entirely empty directories.
- Should give more diagnostic messages.
- Undeleting files should use a more sophisticated algorithm.

NAME

fsck.xfs – do nothing, successfully

SYNOPSIS

fsck.xfs [*filesys* ...]

DESCRIPTION

fsck.xfs is called by the generic Linux **fsck(8)** program at startup to check and repair an XFS filesystem. XFS is a journaling filesystem and performs recovery at **mount(8)** time if necessary, so **fsck.xfs** simply exits with a zero exit status.

If you wish to check the consistency of an XFS filesystem, or repair a damaged or corrupt XFS filesystem, see **xfs_repair(8)**.

However, the system administrator can force **fsck.xfs** to run **xfs_repair(8)** at boot time by creating a */forcefsck* file or booting the system with "fsck.mode=force" on the kernel command line.

FILES

/etc/fstab.

SEE ALSO

fsck(8), **fstab(5)**, **xfs(5)**, **xfs_repair(8)**.

NAME

fstab-decode – run a command with fstab-encoded arguments

SYNOPSIS

fstab-decode *COMMAND* [*ARGUMENT* ...]

DESCRIPTION

fstab-decode decodes escapes (such as newline characters and other whitespace) in the specified *ARGUMENT*'s and uses them to run *COMMAND*. The argument escaping uses the same rules as path escaping in */etc/fstab*, */etc/mtab* and */proc/mtab*.

In essence **fstab-decode** can be used anytime we want to pass multiple parameters to a command as a list of command line arguments. It turns output like this:

```
/root  
/mnt/remote-disk  
/home
```

Into one long list of parameters, "/root /mnt/remote-disk /home". This can be useful when trying to work with multiple filesystems at once. For instance, we can use it to umount multiple NFS shares. This program also removes whitespace and other characters which might cause programs such as mount or umount to fail.

EXIT STATUS

fstab-decode exits with status 127 if *COMMAND* can't be run. Otherwise it exits with the status returned by *COMMAND*.

EXAMPLES

The following example reads fstab, finds all instances of VFAT filesystems and prints their mount points (argument 2 in the fstab file). **fstab-decode** then runs the specified program, **umount**, and passes it the list of VFAT mountpoints. This unmounts all VFAT partitions.

```
fstab-decode umount $(awk '$3 == "vfat" { print $2 }' /etc/fstab)
```

SEE ALSO

fstab(5)

NAME

fstab – static information about the filesystems

SYNOPSIS

/etc/fstab

DESCRIPTION

The file **fstab** contains descriptive information about the filesystems the system can mount. **fstab** is only read by programs, and not written; it is the duty of the system administrator to properly create and maintain this file. The order of records in **fstab** is important because **fsck(8)**, **mount(8)**, and **umount(8)** sequentially iterate through **fstab** doing their thing.

Each filesystem is described on a separate line. Fields on each line are separated by tabs or spaces. Lines starting with '#' are comments. Blank lines are ignored.

The following is a typical example of an **fstab** entry:

```
LABEL=t-home2      /home        ext4      defaults,auto_da_alloc      0      2
```

The first field (*fs_spec*).

This field describes the block special device, remote filesystem or filesystem image for loop device to be mounted or swap file or swap partition to be enabled.

For ordinary mounts, it will hold (a link to) a block special device node (as created by **mknod(2)**) for the device to be mounted, like */dev/cdrom* or */dev/sdb7*. For NFS mounts, this field is *<host>:<dir>*, e.g., *knuth.aeb.nl:/*. For filesystems with no storage, any string can be used, and will show up in **df(1)** output, for example. Typical usage is *proc* for **procfs**; *mem*, *none*, or *tmpfs* for **tmpfs**. Other special filesystems, like **udev** and **sysfs**, are typically not listed in **fstab**.

LABEL=<label> or **UUID=<uuid>** may be given instead of a device name. This is the recommended method, as device names are often a coincidence of hardware detection order, and can change when other disks are added or removed. For example, 'LABEL=Boot' or '**UUID=3e6be9de-8139-11d1-9106-a43f08d823a6**'. (Use a filesystem-specific tool like **e2label(8)**, **xfs_admin(8)**, or **fatlabel(8)** to set LABELs on filesystems).

It's also possible to use **PARTUUID=** and **PARTLABEL=**. These partitions identifiers are supported for example for GUID Partition Table (GPT).

See **mount(8)**, **blkid(8)** or **lsblk(8)** for more details about device identifiers.

Note that **mount(8)** uses UUIDs as strings. The string representation of the UUID should be based on lower case characters. But when specifying the volume ID of FAT or NTFS file systems upper case characters are used (e.g **UUID="A40D-85E7"** or **UUID="61DB7756DB7779B3"**).

The second field (*fs_file*).

This field describes the mount point (target) for the filesystem. For swap partitions, this field should be specified as 'none'. If the name of the mount point contains spaces or tabs these can be escaped as '\040' and '\011' respectively.

The third field (*fs_vfstype*).

This field describes the type of the filesystem. Linux supports many filesystem types: ext4, xfs, btrfs, f2fs, vfat, ntfs, hfsplus, tmpfs, sysfs, proc, iso9660, udf, squashfs, nfs, cifs, and many more. For more details, see **mount(8)**.

An entry *swap* denotes a file or partition to be used for swapping, cf. **swapon(8)**. An entry *none* is useful for bind or move mounts.

More than one type may be specified in a comma-separated list.

mount(8) and **umount(8)** support filesystem *subtypes*. The subtype is defined by '.subtype' suffix. For example 'fuse.sshfs'. It's recommended to use subtype notation rather than add any prefix to the first fstab field (for example 'sshfs#example.com' is deprecated).

The fourth field (*fs_mntops*).

This field describes the mount options associated with the filesystem.

It is formatted as a comma-separated list of options. It contains at least the type of mount (**ro** or **rw**), plus any additional options appropriate to the filesystem type (including performance-tuning options). For details, see **mount(8)** or **swapon(8)**.

Basic filesystem-independent options are:

defaults

use default options: rw, suid, dev, exec, auto, nouser, and async.

noauto

do not mount when **mount -a** is given (e.g., at boot time)

user

allow a user to mount

owner

allow device owner to mount

comment

or x-<name> for use by fstab-maintaining programs

nofail

do not report errors for this device if it does not exist.

The fifth field (*fs_freq*).

This field is used by **dump(8)** to determine which filesystems need to be dumped. Defaults to zero (don't dump) if not present.

The sixth field (*fs_passno*).

This field is used by **fsck(8)** to determine the order in which filesystem checks are done at boot time. The root filesystem should be specified with a *fs_passno* of 1. Other filesystems should have a *fs_passno* of 2. Filesystems within a drive will be checked sequentially, but filesystems on different drives will be checked at the same time to utilize parallelism available in the hardware. Defaults to zero (don't check the filesystem) if not present.

FILES

/etc/fstab, <fstab.h>

NOTES

The proper way to read records from **fstab** is to use the routines **getmntent(3)** or **libmount**.

The keyword **ignore** as a filesystem type (3rd field) is no longer supported by the pure libmount based mount utility (since util-linux v2.22).

HISTORY

The ancestor of this **fstab** file format appeared in 4.0BSD.

SEE ALSO

getmntent(3), **fs(5)**, **findmnt(8)**, **mount(8)**, **swapon(8)**

REPORTING BUGS

For bug reports, use the issue tracker at <https://github.com/util-linux/util-linux/issues>.

AVAILABILITY

fstab is part of the util-linux package which can be downloaded from [Linux Kernel Archive](https://www.kernel.org/pub/linux/utils/util-linux/) <<https://www.kernel.org/pub/linux/utils/util-linux/>>.

NAME

tnftp — Internet file transfer program

SYNOPSIS

```
tnftp [ -46AadefginpRtVv? ] [-N netrc] [-o output] [-P port] [-q quittime]
      [ -r retry ] [ -s srcaddr ] [ -T dir,max[,inc] ] [ -x xfersize ]
      [[user@]host [port]] [[user@]host:[path][/]][file://path]
      [ftp://[user[:password]@]host[:port]/path[/][;type=type]]
      [http://[user[:password]@]host[:port]/path]
      [https://[user[:password]@]host[:port]/path] ...
tnftp -u url file ...
```

DESCRIPTION

tnftp is the user interface to the Internet standard File Transfer Protocol. The program allows a user to transfer files to and from a remote network site.

The last five arguments will fetch a file using the FTP or HTTP protocols, or by direct copying, into the current directory. This is ideal for scripts. Refer to **AUTO-FETCHING FILES** below for more information.

Options may be specified at the command line, or to the command interpreter.

- 4 Forces **tnftp** to only use IPv4 addresses.
- 6 Forces **tnftp** to only use IPv6 addresses.
- A Force active mode FTP. By default, **tnftp** will try to use passive mode FTP and fall back to active mode if passive is not supported by the server. This option causes **tnftp** to always use an active connection. It is only useful for connecting to very old servers that do not implement passive mode properly.
- a Causes **tnftp** to bypass normal login procedure, and use an anonymous login instead.
- d Enables debugging.
- e Disables command line editing. This is useful for Emacs ange-ftp mode.
- f Forces a cache reload for transfers that go through the FTP or HTTP proxies.
- g Disables file name globbing.
- i Turns off interactive prompting during multiple file transfers.
- N *netrc* Use *netrc* instead of *~/.netrc*. Refer to **THE .NETRC FILE** for more information.
- n Restraints **tnftp** from attempting “auto-login” upon initial connection for non auto-fetch transfers. If auto-login is enabled, **tnftp** will check the *.netrc* (see below) file in the user’s home directory for an entry describing an account on the remote machine. If no entry exists, **tnftp** will prompt for the remote machine login name (default is the user identity on the local machine), and, if necessary, prompt for a password and an account with which to login. To override the auto-login for auto-fetch transfers, specify the username (and optionally, password) as appropriate.
- o *output* When auto-fetching files, save the contents in *output*. *output* is parsed according to the **FILE NAMING CONVENTIONS** below. If *output* is not ‘-’ or doesn’t start with ‘|’, then only the first file specified will be retrieved into *output*; all other files will be retrieved into the basename of their remote name.

- P port** Sets the port number to *port*.
- p** Enable passive mode operation for use behind connection filtering firewalls. This option has been deprecated as **tnftp** now tries to use passive mode by default, falling back to active mode if the server does not support passive connections.
- q *quittime*** Quit if the connection has stalled for *quittime* seconds.
- R** Restart all non-proxied auto-fetches.
- r *wait*** Retry the connection attempt if it failed, pausing for *wait* seconds.
- s *srcaddr*** Uses *srcaddr* as the local IP address for all connections.
- t** Enables packet tracing.
- T *direction,maximum[,increment]*** Set the maximum transfer rate for *direction* to *maximum* bytes/second, and if specified, the increment to *increment* bytes/second. Refer to **rate** for more information.
- u *url file ...*** Upload files on the command line to *url* where *url* is one of the ‘**ftp://**’ URL types as supported by auto-fetch (with an optional target filename for single file uploads), and *file* is one or more local files to be uploaded.
- v** Disable **verbose** and **progress**, overriding the default of enabled when output is to a terminal.
- vv** Enable **verbose** and **progress**. This is the default if output is to a terminal (and in the case of **progress**, **tnftp** is the foreground process). Forces **tnftp** to show all responses from the remote server, as well as report on data transfer statistics.
- x *xfersize*** Set the size of the socket send and receive buffers to *xfersize*. Refer to **xferbuf** for more information.
- ?** Display help to stdout, and exit.

The client host with which **tnftp** is to communicate may be specified on the command line. If this is done, **tnftp** will immediately attempt to establish a connection to an FTP server on that host; otherwise, **tnftp** will enter its command interpreter and await instructions from the user. When **tnftp** is a waiting commands from the user the prompt **f tp>** is provided to the user. The following commands are recognized by **tnftp**:

- ! [command [args]]**
Invoke an interactive shell on the local machine. If there are arguments, the first is taken to be a command to execute directly, with the rest of the arguments as its arguments.
- \$ macro-name [args]**
Execute the macro *macro-name* that was defined with the **macdef** command. Arguments are passed to the macro unglobbed.
- account [passwd]**
Supply a supplemental password required by a remote system for access to resources once a login has been successfully completed. If no argument is included, the user will be prompted for an account password in a non-echoing input mode.

append *local-file* [*remote-file*]

Append a local file to a file on the remote machine. If *remote-file* is left unspecified, the local file name is used in naming the remote file after being altered by any **ntrans** or **nmap** setting. File transfer uses the current settings for **type**, **format**, **mode**, and **structure**.

ascii Set the file transfer **type** to network ASCII. This is the default type.**bell** Arrange that a bell be sounded after each file transfer command is completed.**binary** Set the file transfer **type** to support binary image transfer.**bye** Terminate the FTP session with the remote server and exit **tnftp**. An end of file will also terminate the session and exit.**case** Toggle remote computer file name case mapping during **get**, **mget** and **mput** commands. When **case** is on (default is off), remote computer file names with all letters in upper case are written in the local directory with the letters mapped to lower case.**cd** *remote-directory*

Change the working directory on the remote machine to *remote-directory*.

cdup Change the remote machine working directory to the parent of the current remote machine working directory.**chmod** *mode* *remote-file*

Change the permission modes of the file *remote-file* on the remote system to *mode*.

close Terminate the FTP session with the remote server, and return to the command interpreter. Any defined macros are erased.**cr** Toggle carriage return stripping during ascii type file retrieval. Records are denoted by a carriage return/linefeed sequence during ascii type file transfer. When **cr** is on (the default), carriage returns are stripped from this sequence to conform with the UNIX single linefeed record delimiter. Records on non-UNIX remote systems may contain single linefeeds; when an ascii type transfer is made, these linefeeds may be distinguished from a record delimiter only when **cr** is off.**debug** [*debug-value*]

Toggle debugging mode. If an optional *debug-value* is specified it is used to set the debugging level. When debugging is on, **tnftp** prints each command sent to the remote machine, preceded by the string -->.

delete *remote-file*

Delete the file *remote-file* on the remote machine.

dir [*remote-path* [*local-file*]]

Print a listing of the contents of a directory on the remote machine. The listing includes any system-dependent information that the server chooses to include; for example, most UNIX systems will produce output from the command **ls -l**. If *remote-path* is left unspecified, the current working directory is used. If interactive prompting is on, **tnftp** will prompt the user to verify that the last argument is indeed the target local file for receiving **dir** output. If no local file is specified, or if *local-file* is ‘-’, the output is sent to the terminal.

disconnect

A synonym for **close**.

edit Toggle command line editing, and context sensitive command and file completion. This is automatically enabled if input is from a terminal, and disabled otherwise.

epsv, epsv4, epsv6

Toggle the use of the extended EPSV and EPRT commands on all IP, IPv4, and IPv6 connections respectively. First tryEPSV/EPRT, and then PASV/PORT. This is enabled by default. If an extended command fails then this option will be temporarily disabled for the duration of the current connection, or until **epsv**, **epsv4**, or **epsv6** is executed again.

exit A synonym for **bye**.

features Display what features the remote server supports (using the FEAT command).

fget *localfile*

Retrieve the files listed in *localfile*, which has one line per filename.

form *format*

Set the file transfer **form** to *format*. The default (and only supported) format is “non-print”.

ftp *host* [*port*]

A synonym for **open**.

gate [*host* [*port*]]

Toggle gate-ftp mode, which used to connect through the TIS FWTK and Gauntlet FTP proxies. This will not be permitted if the gate-ftp server hasn't been set (either explicitly by the user, or from the FTPSERVER environment variable). If*host* is given, then gate-ftp mode will be enabled, and the gate-ftp server will be set to *host*. If*port* is also given, that will be used as the port to connect to on the gate-ftp server.

get *remote-file* [*local-file*]

Retrieve the *remote-file* and store it on the local machine. If the local file name is not specified, it is given the same name it has on the remote machine, subject to alteration by the current **case**, **ntrans**, and **nmap** settings. The current settings for **type**, **form**, **mode**, and **structure** are used while transferring the file.

glob

Toggle filename expansion for **mdelete**, **mget**, **mput**, and **mreget**. If globbing is turned off with **glob**, the file name arguments are taken literally and not expanded. Globbing for **mput** is done as in csh(1). For **mdelete**, **mget**, and **mreget**, each remote file name is expanded separately on the remote machine and the lists are not merged. Expansion of a directory name is likely to be different from expansion of the name of an ordinary file: the exact result depends on the foreign operating system and FTP server, and can be previewed by doing ‘**mls** *remote-files* –’. Note:**mget**, **mput** and **mreget** are not meant to transfer entire directory subtrees of files. That can be done by transferring a **tar**(1) archive of the subtree (in binary mode).

hash [*size*]

Toggle hash-sign (#) printing for each data block transferred. The size of a data block defaults to 1024 bytes. This can be changed by specifying *size* in bytes. Enabling **hash** disables **progress**.

help [*command*]

Print an informative message about the meaning of *command*. If no argument is given, **tnftp** prints a list of the known commands.

idle [*seconds*]

Set the inactivity timer on the remote server to *seconds* seconds. If *seconds* is omitted, the current inactivity timer is printed.

image A synonym for **binary**.

lcd [directory]

Change the working directory on the local machine. If no *directory* is specified, the user's home directory is used.

less file

A synonym for **page**.

lpage local-file

Display *local-file* with the program specified by the **set pager** option.

lpwd

Print the working directory on the local machine.

ls [remote-path [local-file]]

A synonym for **dir**.

macdef macro-name

Define a macro. Subsequent lines are stored as the macro *macro-name*; a null line (consecutive newline characters in a file or carriage returns from the terminal) terminates macro input mode. There is a limit of 16 macros and 4096 total characters in all defined macros. Macro names can be a maximum of 8 characters. Macros are only applicable to the current session they are defined within (or if defined outside a session, to the session invoked with the next **open** command), and remain defined until a **close** command is executed. To invoke a macro, use the **\$** command (see above).

The macro processor interprets '\$' and '\' as special characters. A '\$' followed by a number (or numbers) is replaced by the corresponding argument on the macro invocation command line. A '\$' followed by an 'i' signals the macro processor that the executing macro is to be looped. On the first pass '\$i' is replaced by the first argument on the macro invocation command line, on the second pass it is replaced by the second argument, and so on. A '\' followed by any character is replaced by that character. Use the '\' to prevent special treatment of the '\$'.

mdelete [remote-files]

Delete the *remote-files* on the remote machine.

mdir remote-files local-file

Like **dir**, except multiple remote files may be specified. If interactive prompting is on, **tnftp** will prompt the user to verify that the last argument is indeed the target local file for receiving **mdir** output.

mget remote-files

Expand the *remote-files* on the remote machine and do a **get** for each file name thus produced. See **glob** for details on the filename expansion. Resulting file names will then be processed according to **case**, **ntrans**, and **nmap** settings. Files are transferred into the local working directory, which can be changed with **lcd directory**; new local directories can be created with '! **mkdir directory**'.

mkdir directory-name

Make a directory on the remote machine.

mls remote-files local-file

Like **ls**, except multiple remote files may be specified, and the *local-file* must be specified. If interactive prompting is on, **tnftp** will prompt the user to verify that the last argument is indeed the target local file for receiving **mls** output.

mlsd [remote-path]

Display the contents of *remote-path* (which should default to the current directory if not given) in a machine-parsable form, using MLSD. The format of display can be changed with

‘remopts mlst ...’.

mlst [*remote-path*]
 Display the details about *remote-path* (which should default to the current directory if not given) in a machine-parsable form, using MLST. The format of display can be changed with ‘remopts mlst ...’.

mode *mode-name*
 Set the file transfer **mode** to *mode-name*. The default (and only supported) mode is “stream”.

modtime *remote-file*
 Show the last modification time of the file on the remote machine, in RFC 2822 format.

more *file*
 A synonym for **page**.

mput *local-files*
 Expand wild cards in the list of local files given as arguments and do a **put** for each file in the resulting list. See **glob** for details of filename expansion. Resulting file names will then be processed according to **ntrans** and **nmap** settings.

mreget *remote-files*
 As per **mget**, but performs a **reget** instead of **get**.

msend *local-files*
 A synonym for **mput**.

newer *remote-file* [*local-file*]
 Get the file only if the modification time of the remote file is more recent than the file on the current system. If the file does not exist on the current system, the remote file is considered **newer**. Otherwise, this command is identical to **get**.

nlist [*remote-path* [*local-file*]]
 A synonym for **ls**.

nmap [*inpattern* *outpattern*]
 Set or unset the filename mapping mechanism. If no arguments are specified, the filename mapping mechanism is unset. If arguments are specified, remote filenames are mapped during **mput** commands and **put** commands issued without a specified remote target filename. If arguments are specified, local filenames are mapped during **mget** commands and **get** commands issued without a specified local target filename. This command is useful when connecting to a non- UNIX remote computer with different file naming conventions or practices. The mapping follows the pattern set by *inpattern* and *outpattern*.

inpattern is a template for incoming filenames (which may have already been processed according to the **ntrans** and **case** settings). Variable templating is accomplished by including the sequences ‘\$1’, ‘\$2’, ..., ‘\$9’ in *inpattern*. Use ‘\’ to prevent this special treatment of the ‘\$’ character. All other characters are treated literally, and are used to determine the **nmap** [*inpattern*] variable values. For example, given *inpattern* ‘\$1.\$2’ and the remote file name ‘mydata.data’, ‘\$1’ would have the value ‘mydata’, and ‘\$2’ would have the value ‘data’.

The *outpattern* determines the resulting mapped filename. The sequences ‘\$1’, ‘\$2’, ..., ‘\$9’ are replaced by any value resulting from the *inpattern* template. The sequence ‘\$0’ is replaced by the original filename. Additionally, the sequence “[*seq1*, *seq2*]” is replaced by *seq1* if *seq1* is not a null string; otherwise it is replaced by *seq2*. For example, the command

```
nmap $1.$2.$3 [${1,$2}].[$2,file]
```

would yield the output filename ‘myfile.data’ for input filenames ‘myfile.data’ and ‘myfile.data.old’, ‘myfile.file’ for the input filename ‘myfile’, and ‘myfile myfile’ for the input filename ‘.myfile’. Spaces may be included in *outpattern*, as in the example:

```
nmap $1 sed s/*$// > $1
```

Use the ‘\’ character to prevent special treatment of the ‘\$’, ‘[’, ‘]’, and ‘,’ characters.

ntrans [*inchars* [*outchars*]]

Set or unset the filename character translation mechanism. If no arguments are specified, the filename character translation mechanism is unset. If arguments are specified, characters in remote filenames are translated during **mput** commands and **put** commands issued without a specified remote target filename. If arguments are specified, characters in local filenames are translated during **mget** commands and **get** commands issued without a specified local target filename. This command is useful when connecting to a non- UNIX remote computer with different file naming conventions or practices. Characters in a filename matching a character in *inchars* are replaced with the corresponding character in *outchars*. If the character’s position in *inchars* is longer than the length of *outchars*, the character is deleted from the file name.

open *host* [*port*]

Establish a connection to the specified *host* FTP server. An optional port number may be supplied, in which case, **tnftp** will attempt to contact an FTP server at that port. If the **set auto-login** option is on (default), **tnftp** will also attempt to automatically log the user in to the FTP server (see below).

page *file*

Retrieve *file* and display with the program specified by the **set pager** option.

passive [*auto*]

Toggle passive mode (if no arguments are given). If *auto* is given, act as if **FTPMODE** is set to ‘auto’. If passive mode is turned on (default), **tnftp** will send a PASV command for all data connections instead of a PORT command. The PASV command requests that the remote server open a port for the data connection and return the address of that port. The remote server listens on that port and the client connects to it. When using the more traditional PORT command, the client listens on a port and sends that address to the remote server, who connects back to it. Passive mode is useful when using **tnftp** through a gateway router or host that controls the directionality of traffic. (Note that though FTP servers are required to support the PASV command by RFC 1123, some do not.)

pdir [*remote-path*]

Perform **dir** [*remote-path*], and display the result with the program specified by the **set pager** option.

pls [*remote-path*]

Perform **ls** [*remote-path*], and display the result with the program specified by the **set pager** option.

pmlsd [*remote-path*]

Perform **mlsd** [*remote-path*], and display the result with the program specified by the **set pager** option.

preserve Toggle preservation of modification times on retrieved files.

progress Toggle display of transfer progress bar. The progress bar will be disabled for a transfer that has *local-file* as ‘-’ or a command that starts with ‘|’. Refer to FILE N AMING CONVENTIONS for more information. Enabling **progress** disables **hash**.

prompt Toggle interactive prompting. Interactive prompting occurs during multiple file transfers to allow the user to selectively retrieve or store files. If prompting is turned off (default is on), any **mget** or **mput** will transfer all files, and any **mdelete** will delete all files.

When prompting is on, the following commands are available at a prompt:

- a** Answer ‘yes’ to the current file, and automatically answer ‘yes’ to any remaining files for the current command.
- n** Answer ‘no’, and do not transfer the file.
- p** Answer ‘yes’ to the current file, and turn off prompt mode (as is “prompt off” had been given).
- q** Terminate the current operation.
- y** Answer ‘yes’, and transfer the file.
- ?** Display a help message.

Any other response will answer ‘yes’ to the current file.

proxy *ftp-command*

Execute an FTP command on a secondary control connection. This command allows simultaneous connection to two remote FTP servers for transferring files between the two servers. The first **proxy** command should be an **open**, to establish the secondary control connection. Enter the command ‘proxy ?’ to see other FTP commands executable on the secondary connection. The following commands behave differently when prefaced by **proxy**: **open** will not define new macros during the auto-login process, **close** will not erase existing macro definitions, **get** and **mget** transfer files from the host on the primary control connection to the host on the secondary control connection, and **put**, **mput**, and **append** transfer files from the host on the secondary control connection to the host on the primary control connection. Third party file transfers depend upon support of the FTP protocol PASV command by the server on the secondary control connection.

put *local-file* [*remote-file*]

Store a local file on the remote machine. If *remote-file* is left unspecified, the local file name is used after processing according to any **ntrans** or **nmap** settings in naming the remote file. File transfer uses the current settings for **type**, **format**, **mode**, and **structure**.

pwd

Print the name of the current working directory on the remote machine.

quit

A synonym for **bye**.

quote [*arg* . . .]

The arguments specified are sent, verbatim, to the remote FTP server.

rate *direction* [*maximum* [*increment*]]

Throttle the maximum transfer rate to *maximum* bytes/second. If *maximum* is 0, disable the throttle.

direction may be one of:

all Both directions.
get Incoming transfers.
put Outgoing transfers.

maximum can be modified on the fly by *increment* bytes (default: 1024) each time a given signal is received:

SIGUSR1 Increment *maximum* by *increment* bytes.

SIGUSR2 Decrement *maximum* by *increment* bytes. The result must be a positive number.

If *maximum* is not supplied, the current throttle rates are displayed.

Note: **rate** is not yet implemented for ascii mode transfers.

rcvbuf *size*

Set the size of the socket receive buffer to *size*.

recv *remote-file* [*local-file*]

A synonym for **get**.

reget *remote-file* [*local-file*]

reget acts like **get**, except that if *local-file* exists and is smaller than *remote-file*, *local-file* is presumed to be a partially transferred copy of *remote-file* and the transfer is continued from the apparent point of failure. This command is useful when transferring very large files over networks that are prone to dropping connections.

remopts *command* [*command-options*]

Set options on the remote FTP server for *command* to *command-options* (whose absence is handled on a command-specific basis). Remote FTP commands known to support options include: MLST (used for MLSD and MLST).

rename [*from* [*to*]]

Rename the file *from* on the remote machine, to the file *to*.

reset

Clear reply queue. This command re-synchronizes command/reply sequencing with the remote FTP server. Resynchronization may be necessary following a violation of the FTP protocol by the remote server.

restart *marker*

Restart the immediately following **get** or **put** at the indicated *marker*. On UNIX systems, *marker* is usually a byte offset into the file.

rhelp [*command-name*]

Request help from the remote FTP server. If a *command-name* is specified it is supplied to the server as well.

rmdir *directory-name*

Delete a directory on the remote machine.

rstatus [*remote-file*]

With no arguments, show status of remote machine. If *remote-file* is specified, show status of *remote-file* on remote machine.

runique

Toggle storing of files on the local system with unique filenames. If a file already exists with a name equal to the target local filename for a **get** or **mget** command, a ‘.1’ is appended to the name. If the resulting name matches another existing file, a ‘.2’ is appended to the original name. If this process continues up to .99, an error message is printed, and the transfer does not take place. The generated unique filename will be reported. Note that **runique** will not

affect local files generated from a shell command (see below). The default value is off.

send *local-file* [*remote-file*]
A synonym for **put**.

sendport Toggle the use of PORT commands. By default, **tnftp** will attempt to use a PORT command when establishing a connection for each data transfer. The use of PORT commands can prevent delays when performing multiple file transfers. If the PORT command fails, **tnftp** will use the default data port. When the use of PORT commands is disabled, no attempt will be made to use PORT commands for each data transfer. This is useful for certain FTP implementations which do ignore PORT commands but, incorrectly, indicate they've been accepted.

set [*option value*]

Set *option* to *value*. If *option* and *value* are not given, display all of the options and their values. The currently supported options are:

anonpass	Defaults to \$FTPANONPASS
ftp_proxy	Defaults to \$ftp_proxy.
http_proxy	Defaults to \$http_proxy.
https_proxy	Defaults to \$https_proxy.
no_proxy	Defaults to \$no_proxy.
pager	Defaults to \$PAGER.
prompt	Defaults to \$FTPPROMPT.
rprompt	Defaults to \$FTPRPROMPT.

site [*arg . . .*]

The arguments specified are sent, verbatim, to the remote FTP server as a SITE command.

size *remote-file*

Return size of *remote-file* on remote machine.

sndbuf *size*

Set the size of the socket send buffer to *size*.

status Show the current status of **tnftp**.

struct *struct-name*

Set the file transfer *structure* to *struct-name*. The default (and only supported) structure is "file".

sunique Toggle storing of files on remote machine under unique file names. The remote FTP server must support FTP protocol STOU command for successful completion. The remote server will report unique name. Default value is off.

system Show the type of operating system running on the remote machine.

tenex Set the file transfer type to that needed to talk to TENEX machines.

throttle A synonym for **rate**.

trace Toggle packet tracing.

type [*type-name*]

Set the file transfer **type** to *type-name*. If no type is specified, the current type is printed. The default type is network ASCII.

umask [*newmask*]

Set the default umask on the remote server to *newmask*. If *newmask* is omitted, the current umask is printed.

unset *option*

Unset *option*. Refer to **set** for more information.

usage *command*

Print the usage message for *command*.

user *user-name* [*password* [*account*]]

Identify yourself to the remote FTP server. If the *password* is not specified and the server requires it, **tnftp** will prompt the user for it (after disabling local echo). If an *account* field is not specified, and the FTP server requires it, the user will be prompted for it. If an *account* field is specified, an account command will be relayed to the remote server after the login sequence is completed if the remote server did not require it for logging in. Unless **tnftp** is invoked with “auto-login” disabled, this process is done automatically on initial connection to the FTP server.

verbose Toggle verbose mode. In verbose mode, all responses from the FTP server are displayed to the user. In addition, if verbose is on, when a file transfer completes, statistics regarding the efficiency of the transfer are reported. By default, verbose is on.

xferbuf *size*

Set the size of the socket send and receive buffers to *size*.

? [*command*]

A synonym for **help**.

Command arguments which have embedded spaces may be quoted with quote ‘"’ marks.

Commands which toggle settings can take an explicit **on** or **off** argument to force the setting appropriately.

Commands which take a byte count as an argument (e.g., **hash**, **rate**, and **xferbuf**) support an optional suffix on the argument which changes the interpretation of the argument. Supported suffixes are:

- b Causes no modification. (Optional)
- k Kilo; multiply the argument by 1024
- m Mega; multiply the argument by 1048576
- g Giga; multiply the argument by 1073741824

If **tnftp** receives a SIGINFO (see the **status** argument of **stty(1)**) or SIGQUIT signal whilst a transfer is in progress, the current transfer rate statistics will be written to the standard error output, in the same format as the standard completion message.

AUTO-FETCHING FILES

In addition to standard commands, this version of **tnftp** supports an auto-fetch feature. To enable auto-fetch, simply pass the list of hostnames/files on the command line.

The following formats are valid syntax for an auto-fetch element:

[*user@host* : [*path*] [/]
“Classic” FTP format.

If *path* contains a glob character and globbing is enabled, (see **glob**), then the equivalent of ‘**mget path**’ is performed.

If the directory component of *path* contains no globbing characters, it is stored locally with the name basename (see **basename(1)**) of **path**, in the current directory. Otherwise, the full remote name is used as the local name, relative to the local root directory.

ftp://[user[:password]@]host[:port]/path[/][;type=type]

An FTP URL, retrieved using the FTP protocol if **set ftp_proxy** isn't defined. Otherwise, transfer the URL using HTTP via the proxy defined in **set http_proxy**. If **set ftp_proxy** isn't defined and *user* is given, login as *user*. In this case, use *password* if supplied, otherwise prompt the user for one.

If a suffix of ‘;type=A’ or ‘;type=I’ is supplied, then the transfer type will take place as ascii or binary (respectively). The default transfer type is binary.

In order to be compliant with RFC 3986, **tnftp** interprets the *path* part of an ‘**ftp://**’ auto-fetch URL as follows:

- The ‘/’ immediately after the *host[:port]* is interpreted as a separator before the *path*, and not as part of the *path* itself.
- The *path* is interpreted as a ‘/’-separated list of name components. For all but the last such component, **tnftp** performs the equivalent of a **cd** command. For the last path component, **tnftp** performs the equivalent of a **get** command.
- Empty name components, which result from ‘//’ within the *path*, or from an extra ‘/’ at the beginning of the *path*, will cause the equivalent of a **cd** command without a directory name. This is unlikely to be useful.
- Any ‘%XX’ codes (perRFC 3986) within the path components are decoded, with XX representing a character code in hexadecimal. This decoding takes place after the *path* has been split into components, but before each component is used in the equivalent of a **cd** or **get** command. Some often-used codes are ‘%2F’ (which represents ‘/’) and ‘%7E’ (which represents ‘~’).

The above interpretation has the following consequences:

- The path is interpreted relative to the default login directory of the specified user or of the ‘anonymous’ user. If the / directory is required, use a leading path of ‘%2F’. If a user’s home directory is required (and the remote server supports the syntax), use a leading path of ‘%7Euser/’. For example, to retrieve /etc/motd from ‘localhost’ as the user ‘myname’ with the password ‘mypass’, use ‘**ftp://myname:mypass@localhost/%2fetc/motd**’
- The exact **cd** and **get** commands can be controlled by careful choice of where to use ‘/’ and where to use ‘%2F’ (or ‘%2f’). For example, the following URLs correspond to the equivalents of the indicated commands:

<code>ftp://host/dir1/dir2/file</code>	“cd dir1”, “cd dir2”, “get file”.
<code>ftp://host/%2Fdir1/dir2/file</code>	“cd /dir1”, “cd dir2”, “get file”.
<code>ftp://host/dir1%2Fdir2/file</code>	“cd dir1/dir2”, “get file”.
<code>ftp://host/%2Fdir1%2Fdir2/file</code>	“cd /dir1/dir2”, “get file”.
<code>ftp://host/dir1%2Fdir2%2Ffile</code>	“get dir1/dir2/file”.
<code>ftp://host/%2Fdir1%2Fdir2%2Ffile</code>	“get /dir1/dir2/file”.

- You must have appropriate access permission for each of the intermediate directories that is used in the equivalent of a **cd** command.

http://[user[:password]@]host[:port]/path

An HTTP URL, retrieved using the HTTP protocol. If **set http_proxy** is defined, it is used as a URL to an HTTP proxy server. If HTTP authorization is required to retrieve *path*, and *user* (and optionally *password*) is in the URL, use them for the first attempt to authenticate.

https://[user[:password]@]host[:port]/path

An HTTPS URL, retrieved using the HTTPS protocol. If **set https_proxy** is defined, it is used as a URL to an HTTPS proxy server. If HTTPS authorization is required to retrieve *path*, and *user* (and optionally *password*) is in the URL, use them for the first attempt to authenticate. There is currently no certificate validation and verification.

file:///path

A local URL, copied from */path* on the local host.

about:topic

Display information regarding *topic*; no file is retrieved for this auto-fetched element. Supported values include:

about:ftp Information about **tnftp**.

about:version The version of **tnftp**. Useful to provide when reporting problems.

Unless noted otherwise above, and **-o output** is not given, the file is stored in the current directory as the basename(1) of *path*. Note that if a HTTP redirect is received, the fetch is retried using the new target URL supplied by the server, with a corresponding new *path*. Using an explicit **-o output** is recommended, to avoid writing to unexpected file names.

If a classic format or an FTP URL format has a trailing ‘/’ or an empty *path* component, then **tnftp** will connect to the site and **cd** to the directory given as the path, and leave the user in interactive mode ready for further input. This will not work if **set ftp_proxy** is being used.

Direct HTTP transfers use HTTP 1.1. Proxied FTP and HTTP transfers use HTTP 1.0.

If **-R** is given, all auto-fetches that don’t go via the FTP or HTTP proxies will be restarted. For FTP, this is implemented by using **reget** instead of **get**. For HTTP, this is implemented by using the ‘Range: bytes=’ HTTP/1.1 directive.

If WWW or proxy WWW authentication is required, you will be prompted to enter a username and password to authenticate with.

When specifying IPv6 numeric addresses in a URL, you need to surround the address in square brackets. E.g.: ‘**ftp://[::1]:21/**’. This is because colons are used in IPv6 numeric address as well as being the separator for the port number.

ABORTING A FILE TRANSFER

To abort a file transfer, use the terminal interrupt key (usually Ctrl-C). Sending transfers will be immediately halted. Receiving transfers will be halted by sending an FTP protocol ABOR command to the remote server, and discarding any further data received. The speed at which this is accomplished depends upon the remote server’s support for ABOR processing. If the remote server does not support the ABOR command, the prompt will not appear until the remote server has completed sending the requested file.

If the terminal interrupt key sequence is used whilst **tnftp** is awaiting a reply from the remote server for the ABOR processing, then the connection will be closed. This is different from the traditional behaviour (which ignores the terminal interrupt during this phase), but is considered more useful.

FILE NAMING CONVENTIONS

Files specified as arguments to **tnftp** commands are processed according to the following rules.

1. If the file name ‘-’ is specified, the *stdin* (for reading) or *stdout* (for writing) is used.
2. If the first character of the file name is ‘|’, the remainder of the argument is interpreted as a shell command. **tnftp** then forks a shell, using **popen(3)** with the argument supplied, and reads (writes) from the *stdout* (*stdin*). If the shell command includes spaces, the argument must be quoted; e.g.

- `"" | ls -lt"'. A particularly useful example of this mechanism is: 'dir "" | more'.`
3. Failing the above checks, if globbing is enabled, local file names are expanded according to the rules used in the `csh(1)`; see the `glob` command. If the `tnftp` command expects a single local file (e.g. `put`), only the first filename generated by the globbing operation is used.
 4. For `mget` commands and `get` commands with unspecified local file names, the local filename is the remote filename, which may be altered by a `case`, `ntrans`, or `nmap` setting. The resulting filename may then be altered if `runique` is on.
 5. For `mput` commands and `put` commands with unspecified remote file names, the remote filename is the local filename, which may be altered by a `ntrans` or `nmap` setting. The resulting filename may then be altered by the remote server if `sunique` is on.

FILE TRANSFER PARAMETERS

The FTP specification specifies many parameters which may affect a file transfer. The `type` may be one of “ascii”, “image” (binary), “ebcdic”, and “local byte size” (for PDP-10’s and PDP-20’s mostly). `tnftp` supports the ascii and image types of file transfer, plus local byte size 8 for `tenex` mode transfers.

`tnftp` supports only the default values for the remaining file transfer parameters: `mode`, `form`, and `struct`.

THE .netrc FILE

The `.netrc` file contains login and initialization information used by the auto-login process. It resides in the user’s home directory, unless overridden with the `-N netrc` option, or specified in the NETRC environment variable. The following tokens are recognized; they may be separated by spaces, tabs, or new-lines:

`machine name`

Identify a remote machine `name`. The auto-login process searches the `.netrc` file for a `machine` token that matches the remote machine specified on the `tnftp` command line or as an `open` command argument. Once a match is made, the subsequent `.netrc` tokens are processed, stopping when the end of file is reached or another `machine` or a `default` token is encountered.

`default` This is the same as `machine name` except that `default` matches any name. There can be only one `default` token, and it must be after all `machine` tokens. This is normally used as:

```
default login anonymous password user@site
```

thereby giving the user an automatic anonymous FTP login to machines not specified in `.netrc`. This can be overridden by using the `-n` flag to disable auto-login.

`login name`

Identify a user on the remote machine. If this token is present, the auto-login process will initiate a login using the specified `name`.

`password string`

Supply a password. If this token is present, the auto-login process will supply the specified string if the remote server requires a password as part of the login process. Note that if this token is present in the `.netrc` file for any user other than `anonymous`, `tnftp` will abort the auto-login process if the `.netrc` is readable by anyone besides the user.

`account string`

Supply an additional account password. If this token is present, the auto-login process will supply the specified string if the remote server requires an additional account password, or the auto-login process will initiate an ACCT command if it does not.

macdef *name*

Define a macro. This token functions like the **tnftp macdef** command functions. A macro is defined with the specified name; its contents begin with the next .netrc line and continue until a blank line (consecutive new-line characters) is encountered. Like the other tokens in the .netrc file, a **macdef** is applicable only to the **machine** definition preceding it. A **macdef** entry cannot be used by multiple **machine** definitions; rather, it must be defined following each **machine** it is intended to be used with. If a macro named **init** is defined, it is automatically executed as the last step in the auto-login process. For example,

```
default
macdef init
epsv4 off
```

followed by a blank line.

COMMAND LINE EDITING

tnftp supports interactive command line editing, via the **editline(3)** library. It is enabled with the **edit** command, and is enabled by default if input is from a tty. Previous lines can be recalled and edited with the arrow keys, and other GNU Emacs-style editing keys may be used as well.

The **editline(3)** library is configured with a .editrc file — refer to **editrc(5)** for more information.

An extra key binding is available to **tnftp** to provide context sensitive command and filename completion (including remote file completion). To use this, bind a key to the **editline(3)** command **ftp-complete**. By default, this is bound to the TAB key.

COMMAND LINE PROMPT

By default, **tnftp** displays a command line prompt of ‘**ftp>**’ to the user. This can be changed with the **set prompt** command.

A prompt can be displayed on the right side of the screen (after the command input) with the **set rprompt** command.

The following formatting sequences are replaced by the given information:

%/ The current remote working directory.

%c[[0]n], %.[[0]n]

The trailing component of the current remote working directory, or *n* trailing components if a digit *n* is given. If *n* begins with ‘0’, the number of skipped components precede the trailing component(s) in the format “/⟨number⟩trailing” (for ‘%c’) or “...trailing” (for ‘%.’).

%M The remote host name.

%m The remote host name, up to the first dot ‘.’.

%n The remote user name.

%% A single percent character ‘%’.

ENVIRONMENT

tnftp uses the following environment variables.

FTPANONPASS Password to send in an anonymous FTP transfer. Defaults to ``whoami`@’.

FTPMODE Overrides the default operation mode. Support values are:

	active	active mode FTP only
	auto	automatic determination of passive or active (this is the default)
	gate	gate-ftp mode
	passive	passive mode FTP only
FTPPROMPT		Command-line prompt to use. Defaults to ‘ftp>’. Refer to COMMAND LINE PROMPT for more information.
FTPRPROMPT		Command-line right side prompt to use. Defaults to empty string. Refer to COMMAND LINE PROMPT for more information.
FTPSERVER		Host to use as gate-ftp server when gate is enabled.
FTPSERVERPORT		Port to use when connecting to gate-ftp server when gate is enabled. Default is port returned by a <code>getservbyname(3)</code> lookup of “ftpgate/tcp”.
FTPUSERAGENT		The value to send for the HTTP User-Agent header.
HOME		For default location of a <code>.netrc</code> file, if one exists.
NETRC		An alternate location of the <code>.netrc</code> file.
PAGER		Used by various commands to display files. Defaults to <code>more(1)</code> if empty or not set.
SHELL		For default shell.
ftp_proxy		URL of FTP proxy to use when making FTP URL requests (if not defined, use the standard FTP protocol).
		See <code>http_proxy</code> for further notes about proxy use.
http_proxy		URL of HTTP proxy to use when making HTTP URL requests. If proxy authentication is required and there is a username and password in this URL, they will automatically be used in the first attempt to authenticate to the proxy.
		If “unsafe” URL characters are required in the username or password (for example ‘@’ or ‘/’), encode them with RFC 3986 ‘%XX’ encoding.
		Note that the use of a username and password in <code>ftp_proxy</code> and <code>http_proxy</code> may be incompatible with other programs that use it (such as <code>lynx(1)</code>).
		<i>NOTE:</i> this is not used for interactive sessions, only for command-line fetches.
https_proxy		URL of HTTPS proxy to use when making HTTPS URL requests.
		See <code>http_proxy</code> for further notes about proxy use.
no_proxy		A space or comma separated list of hosts (or domains) for which proxying is not to be used. Each entry may have an optional trailing ‘:port’, which restricts the matching to connections to that port.

EXTENDED PASSIVE MODE AND FIREWALLS

Some firewall configurations do not allow `tnftp` to use extended passive mode. If you find that even a simple `ls` appears to hang after printing a message such as this:

```
229 Entering Extended Passive Mode ( ||| 58551 | )
```

then you will need to disable extended passive mode with `epsv4 off`. See the above section **The .netrc File** for an example of how to make this automatic.

RFC 2616

Hypertext Transfer Protocol -- HTTP/1.1

RFC 2822

Internet Message Format

RFC 3659

Extensions to FTP

RFC 3986

Uniform Resource Identifier (URI)

HISTORY

The `tnftp` command appeared in 4.2BSD.

Various features such as command line editing, context sensitive command and file completion, dynamic progress bar, automatic fetching of files and URLs, modification time preservation, transfer rate throttling, configurable command line prompt, and other enhancements over the standard BSD `tnftp` were implemented in NetBSD 1.3 and later releases by Luke Mewburn <lukem@NetBSD.org>.

IPv6 support was added by the WIDE/KAME project (but may not be present in all non-NetBSD versions of this program, depending if the operating system supports IPv6 in a similar manner to KAME).

BUGS

Correct execution of many commands depends upon proper behavior by the remote server.

An error in the treatment of carriage returns in the 4.2BSD ascii-mode transfer code has been corrected. This correction may result in incorrect transfers of binary files to and from 4.2BSD servers using the ascii type. Avoid this problem by using the binary image type.

`tnftp` assumes that all IPv4 mapped addresses (IPv6 addresses with a form like `::ffff:10.1.1.1`) indicate IPv4 destinations which can be handled by `AF_INET` sockets. However, in certain IPv6 network configurations, this assumption is not true. In such an environment, IPv4 mapped addresses must be passed to `AF_INET6` sockets directly. For example, if your site uses a SIIT translator for IPv6-to-IPv4 translation, `tnftp` is unable to support your configuration.

NAME

getent – get entries from Name Service Switch libraries

SYNOPSIS

getent [option]... database key...

DESCRIPTION

The **getent** command displays entries from databases supported by the Name Service Switch libraries, which are configured in */etc/nsswitch.conf*. If one or more *key* arguments are provided, then only the entries that match the supplied keys will be displayed. Otherwise, if no *key* is provided, all entries will be displayed (unless the database does not support enumeration).

The *database* may be any of those supported by the GNU C Library, listed below:

ahosts	When no <i>key</i> is provided, use sethostent(3) , gethostent(3) , and endhostent(3) to enumerate the hosts database. This is identical to using hosts . When one or more <i>key</i> arguments are provided, pass each <i>key</i> in succession to getaddrinfo(3) with the address family AF_UNSPEC , enumerating each socket address structure returned.
ahostsv4	Same as ahosts , but use the address family AF_INET .
ahostsv6	Same as ahosts , but use the address family AF_INET6 . The call to getaddrinfo(3) in this case includes the AI_V4MAPPED flag.
aliases	When no <i>key</i> is provided, use setaliasent(3) , getaliasent(3) , and endaliasent(3) to enumerate the aliases database. When one or more <i>key</i> arguments are provided, pass each <i>key</i> in succession to getaliasbyname(3) and display the result.
ethers	When one or more <i>key</i> arguments are provided, pass each <i>key</i> in succession to ether_aton(3) and ether_ntohton(3) until a result is obtained, and display the result. Enumeration is not supported on ethers , so a <i>key</i> must be provided.
group	When no <i>key</i> is provided, use setgrent(3) , getgrent(3) , and endgrent(3) to enumerate the group database. When one or more <i>key</i> arguments are provided, pass each numeric <i>key</i> to getgrgid(3) and each nonnumeric <i>key</i> to getgrnam(3) and display the result.
gshadow	When no <i>key</i> is provided, use setsent(3) , getsent(3) , and endsent(3) to enumerate the gshadow database. When one or more <i>key</i> arguments are provided, pass each <i>key</i> in succession to getsgnam(3) and display the result.
hosts	When no <i>key</i> is provided, use sethostent(3) , gethostent(3) , and endhostent(3) to enumerate the hosts database. When one or more <i>key</i> arguments are provided, pass each <i>key</i> to gethostbyaddr(3) or gethostbyname2(3) , depending on whether a call to inet_pton(3) indicates that the <i>key</i> is an IPv6 or IPv4 address or not, and display the result.
initgroups	When one or more <i>key</i> arguments are provided, pass each <i>key</i> in succession to getgrouplist(3) and display the result. Enumeration is not supported on initgroups , so a <i>key</i> must be provided.
netgroup	When one <i>key</i> is provided, pass the <i>key</i> to setnetgrent(3) and, using getnetgrent(3) display the resulting string triple (<i>hostname</i> , <i>username</i> , <i>domainname</i>). Alternatively, three <i>keys</i> may be provided, which are interpreted as the <i>hostname</i> , <i>username</i> , and <i>domainname</i> to match to a netgroup name via innetgr(3) . Enumeration is not supported on netgroup , so either one or three <i>keys</i> must be provided.
networks	When no <i>key</i> is provided, use setnetent(3) , getnetent(3) , and endnetent(3) to enumerate the networks database. When one or more <i>key</i> arguments are provided, pass each numeric <i>key</i> to getnetbyaddr(3) and each nonnumeric <i>key</i> to getnetbyname(3) and display the result.
passwd	When no <i>key</i> is provided, use setpwent(3) , getpwent(3) , and endpwent(3) to enumerate the passwd database. When one or more <i>key</i> arguments are provided, pass each numeric <i>key</i> to getpwuid(3) and each nonnumeric <i>key</i> to getpwnam(3) and display the result.

- protocols** When no *key* is provided, use **setprotoent(3)**, **getprotoent(3)**, and **endprotoent(3)** to enumerate the protocols database. When one or more *key* arguments are provided, pass each numeric *key* to **getprotobynumber(3)** and each nonnumeric *key* to **getprotobynam(3)** and display the result.
- rpc** When no *key* is provided, use **setrpcent(3)**, **getrpcent(3)**, and **endrpcent(3)** to enumerate the rpc database. When one or more *key* arguments are provided, pass each numeric *key* to **getrpcbynumber(3)** and each nonnumeric *key* to **getrpcbynname(3)** and display the result.
- services** When no *key* is provided, use **setservent(3)**, **getservent(3)**, and **endservent(3)** to enumerate the services database. When one or more *key* arguments are provided, pass each numeric *key* to **getservbynumber(3)** and each nonnumeric *key* to **getservbynname(3)** and display the result.
- shadow** When no *key* is provided, use **setspent(3)**, **getspent(3)**, and **endspent(3)** to enumerate the shadow database. When one or more *key* arguments are provided, pass each *key* in succession to **getspnam(3)** and display the result.

OPTIONS

-s *service*, **--service** *service*

Override all databases with the specified service. (Since glibc 2.2.5.)

-s *database:service*, **--service** *database:service*

Override only specified databases with the specified service. The option may be used multiple times, but only the last service for each database will be used. (Since glibc 2.4.)

-i, **--no-idn**

Disables IDN encoding in lookups for **ahosts/getaddrinfo(3)** (Since glibc-2.13.)

-?, --help

Print a usage summary and exit.

--usage

Print a short usage summary and exit.

-V, **--version**

Print the version number, license, and disclaimer of warranty for **getent**.

EXIT STATUS

One of the following exit values can be returned by **getent**:

- 0** Command completed successfully.
- 1** Missing arguments, or *database* unknown.
- 2** One or more supplied *key* could not be found in the *database*.
- 3** Enumeration not supported on this *database*.

NAME

getfacl – get file access control lists

SYNOPSIS

getfacl [**-aceEsRLPtpndvh**] file ...

getfacl [**-aceEsRLPtpndvh**] –

DESCRIPTION

For each file, **getfacl** displays the file name, owner, the group, and the Access Control List (ACL). If a directory has a default ACL, **getfacl** also displays the default ACL. Non-directories cannot have default ACLs.

If **getfacl** is used on a file system that does not support ACLs, **getfacl** displays the access permissions defined by the traditional file mode permission bits.

The output format of **getfacl** is as follows:

```

1: # file: somedir/
2: # owner: lisa
3: # group: staff
4: # flags: -s-
5: user::rwx
6: user:joe:rwx          #effective:r-x
7: group::rwx            #effective:r-x
8: group:cool:r-x
9: mask::r-x
10: other::r-x
11: default:user::rwx
12: default:user:joe:rwx      #effective:r-x
13: default:group::r-x
14: default:mask::r-x
15: default:other::---
```

Lines 1–3 indicate the file name, owner, and owning group.

Line 4 indicates the setuid (s), setgid (s), and sticky (t) bits: either the letter representing the bit, or else a dash (–). This line is included if any of those bits is set and left out otherwise, so it will not be shown for most files. (See CONFORMANCE TO POSIX 1003.1e DRAFT STANDARD 17 below.)

Lines 5, 7 and 10 correspond to the user, group and other fields of the file mode permission bits. These three are called the base ACL entries. Lines 6 and 8 are named user and named group entries. Line 9 is the effective rights mask. This entry limits the effective rights granted to all groups and to named users. (The file owner and others permissions are not affected by the effective rights mask; all other entries are.) Lines 11–15 display the default ACL associated with this directory. Directories may have a default ACL. Regular files never have a default ACL.

The default behavior for **getfacl** is to display both the ACL and the default ACL, and to include an effective rights comment for lines where the rights of the entry differ from the effective rights.

If output is to a terminal, the effective rights comment is aligned to column 40. Otherwise, a single tab character separates the ACL entry and the effective rights comment.

The ACL listings of multiple files are separated by blank lines. The output of **getfacl** can also be used as input to **setfacl**.

PERMISSIONS

Process with search access to a file (i.e., processes with read access to the containing directory of a file) are also granted read access to the file's ACLs. This is analogous to the permissions required for accessing the file mode.

OPTIONS

- a, --access*
Display the file access control list.
- d, --default*
Display the default access control list.
- c, --omit-header*
Do not display the comment header (the first three lines of each file's output).
- e, --all-effective*
Print all effective rights comments, even if identical to the rights defined by the ACL entry.
- E, --no-effective*
Do not print effective rights comments.
- s, --skip-base*
Skip files that only have the base ACL entries (owner, group, others).
- R, --recursive*
List the ACLs of all files and directories recursively.
- L, --logical*
Logical walk, follow symbolic links to directories. The default behavior is to follow symbolic link arguments, and skip symbolic links encountered in subdirectories. Only effective in combination with *-R*.
- P, --physical*
Physical walk, do not follow symbolic links to directories. This also skips symbolic link arguments. Only effective in combination with *-R*.
- t, --tabular*
Use an alternative tabular output format. The ACL and the default ACL are displayed side by side. Permissions that are ineffective due to the ACL mask entry are displayed capitalized. The entry tag names for the ACL_USER_OBJ and ACL_GROUP_OBJ entries are also displayed in capital letters, which helps in spotting those entries.
- p, --absolute-names*
Do not strip leading slash characters ('/'). The default behavior is to strip leading slash characters.
- n, --numeric*
List numeric user and group IDs
- v, --version*
Print the version of getfacl and exit.
- h, --help*
Print help explaining the command line options.
- End of command line options. All remaining parameters are interpreted as file names, even if they start with a dash character.
- If the file name parameter is a single dash character, getfacl reads a list of files from standard input.

CONFORMANCE TO POSIX 1003.1e DRAFT STANDARD 17

If the environment variable `POSIXLY_CORRECT` is defined, the default behavior of `getfacl` changes in the following ways: Unless otherwise specified, only the ACL is printed. The default ACL is only printed if the *-d* option is given. If no command line parameter is given, `getfacl` behaves as if it was invoked as "getfacl

–”. No flags comments indicating the setuid, setgid, and sticky bits are generated.

NAME

getfattr – get extended attributes of filesystem objects

SYNOPSIS

```
getfattr [-hRLP] -n name [-e en] pathname...
getfattr [-hRLP] -d [-e en] [-m pattern] pathname...
```

DESCRIPTION

For each file, **getfattr** displays the file name, and the set of extended attribute names (and optionally values) which are associated with that file. Per default only attributes in the user namespace are displayed, see **-m**.

The output format of **getfattr -d** is as follows:

```
1: # file: somedir/
2: user.name0="value0"
3: user.name1="value1"
4: user.name2="value2"
5: ...
```

Line 1 identifies the file name for which the following lines are being reported. The remaining lines (lines 2 to 4 above) show the *name* and *value* pairs associated with the specified file.

OPTIONS

-n name, --name=name

Dump the value of the named extended attribute.

-d, --dump

Dump the values of all matched extended attributes.

-e en, --encoding=en

Encode values after retrieving them. Valid values of *en* are "text", "hex", and "base64". Values encoded as text strings are enclosed in double quotes ("), while strings encoded as hexadecimal and base64 are prefixed with 0x and 0s, respectively.

-h, --no-dereference

Do not dereference symlinks. Instead of the file a symlink refers to, the symlink itself is examined. Unless doing a logical (-L) traversal, do not traverse symlinks to directories.

-m pattern, --match=pattern

Only include attributes with names matching the regular expression *pattern*. The default value for *pattern* is "^user\\.", which includes all the attributes in the user namespace. Specify "-" for including all attributes. Refer to **attr(5)** for a more detailed discussion of namespaces.

--absolute-names

Do not strip leading slash characters ('/'). The default behaviour is to strip leading slash characters.

--only-values

Dump out the raw extended attribute value(s) without encoding them.

-R, --recursive

List the attributes of all files and directories recursively.

-L, --logical

Logical walk, follow symbolic links to directories. The default behaviour is to follow symbolic link arguments unless **--no-dereference** is given, and to skip symbolic links encountered in subdirectories. Only effective in combination with **-R**.

-P, --physical

Physical walk, do not follow symbolic links to directories. This also skips symbolic link arguments. Only effective in combination with **-R**.

--version

Print the version of **getfattr** and exit.

--help

Print help explaining the command line options.

-- End of command line options. All remaining parameters are interpreted as file names, even if they start with a dash character.

NAME

getgroups, setgroups – get/set list of supplementary group IDs

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <unistd.h>
int getgroups(int size, gid_t list[]);
#include <grp.h>
int setgroups(size_t size, const gid_t *_Nullable list);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros**(7)):

```
setgroups():
  Since glibc 2.19:
    _DEFAULT_SOURCE
  glibc 2.19 and earlier:
    _BSD_SOURCE
```

DESCRIPTION

getgroups() returns the supplementary group IDs of the calling process in *list*. The argument *size* should be set to the maximum number of items that can be stored in the buffer pointed to by *list*. If the calling process is a member of more than *size* supplementary groups, then an error results.

It is unspecified whether the effective group ID of the calling process is included in the returned list. (Thus, an application should also call **getegid**(2) and add or remove the resulting value.)

If *size* is zero, *list* is not modified, but the total number of supplementary group IDs for the process is returned. This allows the caller to determine the size of a dynamically allocated *list* to be used in a further call to **getgroups()**.

setgroups() sets the supplementary group IDs for the calling process. Appropriate privileges are required (see the description of the **EPERM** error, below). The *size* argument specifies the number of supplementary group IDs in the buffer pointed to by *list*. A process can drop all of its supplementary groups with the call:

```
setgroups(0, NULL);
```

RETURN VALUE

On success, **getgroups()** returns the number of supplementary group IDs. On error, -1 is returned, and *errno* is set to indicate the error.

On success, **setgroups()** returns 0. On error, -1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT

list has an invalid address.

getgroups() can additionally fail with the following error:

EINVAL

size is less than the number of supplementary group IDs, but is not zero.

setgroups() can additionally fail with the following errors:

EINVAL

size is greater than **NGROUPS_MAX** (32 before Linux 2.6.4; 65536 since Linux 2.6.4).

ENOMEM

Out of memory.

EPERM

The calling process has insufficient privilege (the caller does not have the **CAP_SETGID** capability in the user namespace in which it resides).

EPERM (since Linux 3.19)

The use of **setgroups()** is denied in this user namespace. See the description of */proc/pid/setgroups* in **user_namespaces(7)**.

STANDARDS

getgroups(): SVr4, 4.3BSD, POSIX.1-2001, POSIX.1-2008.

setgroups(): SVr4, 4.3BSD. Since **setgroups()** requires privilege, it is not covered by POSIX.1.

NOTES

A process can have up to **NGROUPS_MAX** supplementary group IDs in addition to the effective group ID. The constant **NGR_OUPS_MAX** is defined in *<limits.h>*. The set of supplementary group IDs is inherited from the parent process, and preserved across an **execve(2)**.

The maximum number of supplementary group IDs can be found at run time using **sysconf(3)**:

```
long ngroups_max;
ngroups_max = sysconf(_SC_NGROUPS_MAX);
```

The maximum return value of **getgroups()** cannot be larger than one more than this value. Since Linux 2.6.4, the maximum number of supplementary group IDs is also exposed via the Linux-specific read-only file, */proc/sys/kernel/ngroups_max*.

The original Linux **getgroups()** system call supported only 16-bit group IDs. Subsequently, Linux 2.4 added **getgroups32()**, supporting 32-bit IDs. The glibc **getgroups()** wrapper function transparently deals with the variation across kernel versions.

C library/kernel differences

At the kernel level, user IDs and group IDs are a per-thread attribute. However, POSIX requires that all threads in a process share the same credentials. The NPTL threading implementation handles the POSIX requirements by providing wrapper functions for the various system calls that change process UIDs and GIDs. These wrapper functions (including the one for **setgroups()**) employ a signal-based technique to ensure that when one thread changes credentials, all of the other threads in the process also change their credentials. For details, see **nptl(7)**.

NAME

`gethostname`, `sethostname` – get/set hostname

LIBRARY

Standard C library (`libc`, `-lc`)

SYNOPSIS

```
#include <unistd.h>
int gethostname(char *name, size_t len);
int sethostname(const char *name, size_t len);
```

Feature Test Macro Requirements for glibc (see **feature_test_macros**(7)):

```
gethostname():
_XOPEN_SOURCE >= 500 || _POSIX_C_SOURCE >= 200112L
|| /* glibc 2.19 and earlier */ _BSD_SOURCE

sethostname():
Since glibc 2.21:
_DEFAULT_SOURCE
In glibc 2.19 and 2.20:
_DEFAULT_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
Up to and including glibc 2.19:
_BSD_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
```

DESCRIPTION

These system calls are used to access or to change the system hostname. More precisely, they operate on the hostname associated with the calling process's UTS namespace.

sethostname() sets the hostname to the value given in the character array *name*. The *len* argument specifies the number of bytes in *name*. (Thus, *name* does not require a terminating null byte.)

gethostname() returns the null-terminated hostname in the character array *name*, which has a length of *len* bytes. If the null-terminated hostname is too large to fit, then the name is truncated, and no error is returned (but see NOTES below). POSIX.1 says that if such truncation occurs, then it is unspecified whether the returned buffer includes a terminating null byte.

RETURN VALUE

On success, zero is returned. On error, `-1` is returned, and *errno* is set to indicate the error.

ERRORS**FAULT**

name is an invalid address.

EINVAL

len is negative or, for **sethostname()**, *len* is larger than the maximum allowed size.

ENAMETOOLONG

(glibc **gethostname()**) *len* is smaller than the actual size. (Before glibc 2.1, glibc uses **EINVAL** for this case.)

EPERM

For **sethostname()**, the caller did not have the **CAP_SYS_ADMIN** capability in the user namespace associated with its UTS namespace (see **namespaces**(7)).

STANDARDS

SVr4, 4.4BSD (these interfaces first appeared in 4.2BSD). POSIX.1-2001 and POSIX.1-2008 specify **gethostname()** but not **sethostname()**.

NOTES

SUSv2 guarantees that "Host names are limited to 255 bytes". POSIX.1 guarantees that "Host names (not including the terminating null byte) are limited to **HOST_NAME_MAX** bytes". On Linux, **HOST_NAME_MAX** is defined with the value 64, which has been the limit since Linux 1.0 (earlier

kernels imposed a limit of 8 bytes).

C library/kernel differences

The GNU C library does not employ the **gethostname()** system call; instead, it implements **gethostname()** as a library function that calls **uname(2)** and copies up to *len* bytes from the returned *nodename* field into *name*. Having performed the copy, the function then checks if the length of the *nodename* was greater than or equal to *len*, and if it is, then the function returns -1 with *errno* set to **ENAMETOOLONG**; in this case, a terminating null byte is not included in the returned *name*.

Versions of glibc before glibc 2.2 handle the case where the length of the *nodename* was greater than or equal to *len* differently: nothing is copied into *name* and the function returns -1 with *errno* set to **ENAME-TOOLONG**.

NAME

getxattr, lgetxattr, fgetxattr – retrieve an extended attribute value

LIBRARY

Standard C library (*libc*, *-lc*)

SYNOPSIS

```
#include <sys/xattr.h>

ssize_t getxattr(const char *path, const char *name,
                 void value[.size], size_t size);
ssize_t lgetxattr(const char *path, const char *name,
                  void value[.size], size_t size);
ssize_t fgetxattr(int fd, const char *name,
                  void value[.size], size_t size);
```

DESCRIPTION

Extended attributes are *name:value* pairs associated with inodes (files, directories, symbolic links, etc.). They are extensions to the normal attributes which are associated with all inodes in the system (i.e., the **stat(2)** data). A complete overview of extended attributes concepts can be found in **xattr(7)**.

getxattr() retrieves the value of the extended attribute identified by *name* and associated with the given *path* in the filesystem. The attribute value is placed in the buffer pointed to by *value*; *size* specifies the size of that buffer. The return value of the call is the number of bytes placed in *value*.

lgetxattr() is identical to **getxattr()**, except in the case of a symbolic link, where the link itself is interrogated, not the file that it refers to.

fgetxattr() is identical to **getxattr()**, only the open file referred to by *fd* (as returned by **open(2)**) is interrogated in place of *path*.

An extended attribute *name* is a null-terminated string. The name includes a namespace prefix; there may be several, disjoint namespaces associated with an individual inode. The value of an extended attribute is a chunk of arbitrary textual or binary data that was assigned using **setxattr(2)**.

If *size* is specified as zero, these calls return the current size of the named extended attribute (and leave *value* unchanged). This can be used to determine the size of the buffer that should be supplied in a subsequent call. (But, bear in mind that there is a possibility that the attribute value may change between the two calls, so that it is still necessary to check the return status from the second call.)

RETURN VALUE

On success, these calls return a nonnegative value which is the size (in bytes) of the extended attribute value. On failure, -1 is returned and *errno* is set to indicate the error.

ERRORS

E2BIG The size of the attribute value is larger than the maximum size allowed; the attribute cannot be retrieved. This can happen on filesystems that support very large attribute values such as NFSv4, for example.

ENODATA

The named attribute does not exist, or the process has no access to this attribute.

ENOTSUP

Extended attributes are not supported by the filesystem, or are disabled.

ERANGE

The *size* of the *value* buffer is too small to hold the result.

In addition, the errors documented in **stat(2)** can also occur.

VERSIONS

These system calls have been available since Linux 2.4; glibc support is provided since glibc 2.3.

STANDARDS

These system calls are Linux-specific.

EXAMPLES

See **listxattr(2)**.

SEE ALSO

getattr(1), **setattr(1)**, **listxattr(2)**, **open(2)**, **removexattr(2)**, **setxattr(2)**, **stat(2)**, **symlink(7)**, **xattr(7)**

NAME

gpasswd – administer /etc/group and /etc/gshadow

SYNOPSIS

gpasswd [*option*] *group*

DESCRIPTION

The **gpasswd** command is used to administer /etc/group, and /etc/gshadow. Every group can have administrators, members and a password.

System administrators can use the **-A** option to define group administrator(s) and the **-M** option to define members. They have all rights of group administrators and members.

gpasswd called by a group administrator with a group name only prompts for the new password of the *group*.

If a password is set the members can still use **newgrp(1)** without a password, and non-members must supply the password.

Notes about group passwords

Group passwords are an inherent security problem since more than one person is permitted to know the password. However, groups are a useful tool for permitting co-operation between different users.

OPTIONS

Except for the **-A** and **-M** options, the options cannot be combined.

The options which apply to the **gpasswd** command are:

-a, --add *user*

Add the *user* to the named *group*.

-d, --delete *user*

Remove the *user* from the named *group*.

-h, --help

Display help message and exit.

-Q, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-r, --remove-password

Remove the password from the named *group*. The group password will be empty. Only group members will be allowed to use **newgrp** to join the named *group*.

-R, --restrict

Restrict the access to the named *group*. The group password is set to "!". Only group members with a password will be allowed to use **newgrp** to join the named *group*.

-A, --administrators *user*,...

Set the list of administrative users.

-M, --members *user*,...

Set the list of group members.

CAVEATS

This tool only operates on the /etc/group and /etc/gshadow files. Thus you cannot change any NIS or LDAP group. This must be performed on the corresponding server.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

ENCRYPT_METHOD (string)

This defines the system default encryption algorithm for encrypting passwords (if no algorithm are specified on the command line).

It can take one of these values: *DES* (default), *MD5*, *SHA256*, *SHA512*.

Note: this parameter overrides the **MD5_CRYPT_ENAB** variable.

Note: This only affect the generation of group passwords. The generation of user passwords is done by PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

MD5_CRYPT_ENAB (boolean)

Indicate if passwords must be encrypted using the MD5-based algorithm. If set to *yes*, new passwords will be encrypted using the MD5-based algorithm compatible with the one used by recent releases of FreeBSD. It supports passwords of unlimited length and longer salt strings. Set to *no* if you need to copy encrypted passwords to other systems which don't understand the new algorithm. Default is *no*.

This variable is superseded by the **ENCRYPT_METHOD** variable or by any command line option used to configure the encryption algorithm.

This variable is deprecated. You should use **ENCRYPT_METHOD**.

Note: This only affect the generation of group passwords. The generation of user passwords is done by PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

SHA_CRYPT_MIN_ROUNDS (number), **SHA_CRYPT_MAX_ROUNDS** (number)

When **ENCRYPT_METHOD** is set to *SHA256* or *SHA512*, this defines the number of SHA rounds used by the encryption algorithm by default (when the number of rounds is not specified on the command line).

With a lot of rounds, it is more difficult to brute forcing the password. But note also that more CPU resources will be needed to authenticate users.

If not specified, the libc will choose the default number of rounds (5000).

The values must be inside the 1000–999,999,999 range.

If only one of the **SHA_CRYPT_MIN_ROUNDS** or **SHA_CRYPT_MAX_ROUNDS** values is set, then this value will be used.

If **SHA_CRYPT_MIN_ROUNDS > SHA_CRYPT_MAX_ROUNDS**, the highest value will be used.

Note: This only affect the generation of group passwords. The generation of user passwords is done by

PAM and subject to the PAM configuration. It is recommended to set this variable consistently with the PAM configuration.

FILES

- /etc/group
Group account information.
- /etc/gshadow

NAME

grep, **egrep**, **fgrep**, **rgrep** – print lines that match patterns

SYNOPSIS

```
grep [OPTION...] PATTERNs [FILE...]
grep [OPTION...] -e PATTERNs ... [FILE...]
grep [OPTION...] -f PATTERN_FILE ... [FILE...]
```

DESCRIPTION

grep searches for *PATTERNs* in each *FILE*. *PATTERNs* is one or more patterns separated by newline characters, and **grep** prints each line that matches a pattern. Typically *PATTERNs* should be quoted when **grep** is used in a shell command.

A *FILE* of “–” stands for standard input. If no *FILE* is given, recursive searches examine the working directory, and nonrecursive searches read standard input.

In addition, the variant programs **egrep**, **fgrep** and **rgrep** are the same as **grep -E**, **grep -F**, and **grep -r**, respectively. These variants are deprecated, but are provided for backward compatibility.

OPTIONS**Generic Program Information**

--help Output a usage message and exit.

-V, --version

Output the version number of **grep** and exit.

Pattern Syntax

-E, --extended-regexp

Interpret *PATTERNs* as extended regular expressions (EREs, see below).

-F, --fixed-strings

Interpret *PATTERNs* as fixed strings, not regular expressions.

-G, --basic-regexp

Interpret *PATTERNs* as basic regular expressions (BREs, see below). This is the default.

-P, --perl-regexp

Interpret I<PATTERNs> as Perl-compatible regular expressions (PCREs). This option is experimental when combined with the **-z** (**--null-data**) option, and **grep -P** may warn of unimplemented features.

Matching Control

-e PATTERNs, --regexp=PATTERNs

Use *PATTERNs* as the patterns. If this option is used multiple times or is combined with the **-f** (**--file**) option, search for all patterns given. This option can be used to protect a pattern beginning with “–”.

-f FILE, --file=FILE

Obtain patterns from *FILE*, one per line. If this option is used multiple times or is combined with the **-e** (**--regexp**) option, search for all patterns given. The empty file contains zero patterns, and therefore matches nothing.

-i, --ignore-case

Ignore case distinctions in patterns and input data, so that characters that differ only in case match each other.

--no-ignore-case

Do not ignore case distinctions in patterns and input data. This is the default. This option is useful for passing to shell scripts that already use **-i**, to cancel its effects because the two options override each other.

-v, --invert-match

Invert the sense of matching, to select non-matching lines.

-w, --word-regexp

Select only those lines containing matches that form whole words. The test is that the matching substring must either be at the beginning of the line, or preceded by a non-word constituent character. Similarly, it must be either at the end of the line or followed by a non-word constituent character. Word-constituent characters are letters, digits, and the underscore. This option has no effect if **-x** is also specified.

-x, --line-regexp

Select only those matches that exactly match the whole line. For a regular expression pattern, this is like parenthesizing the pattern and then surrounding it with ^ and \$.

-y Obsolete synonym for **-i**.**General Output Control****-c, --count**

Suppress normal output; instead print a count of matching lines for each input file. With the **-v**, **--invert-match** option (see below), count non-matching lines.

--color[=WHEN], --colour[=WHEN]

Surround the matched (non-empty) strings, matching lines, context lines, file names, line numbers, byte offsets, and separators (for fields and groups of context lines) with escape sequences to display them in color on the terminal. The colors are defined by the environment variable **GREP_COLORS**. The deprecated environment variable **GREP_COLOR** is still supported, but its setting does not have priority. *WHEN* is **never**, **always**, or **auto**.

-L, --files-without-match

Suppress normal output; instead print the name of each input file from which no output would normally have been printed.

-l, --files-with-matches

Suppress normal output; instead print the name of each input file from which output would normally have been printed. Scanning each input file stops upon first match.

-m NUM, --max-count=NUM

Stop reading a file after *NUM* matching lines. If the input is standard input from a regular file, and *NUM* matching lines are output, **grep** ensures that the standard input is positioned to just after the last matching line before exiting, regardless of the presence of trailing context lines. This enables a calling process to resume a search. When **grep** stops after *NUM* matching lines, it outputs any trailing context lines. When the **-c** or **--count** option is also used, **grep** does not output a count greater than *NUM*. When the **-v** or **--invert-match** option is also used, **grep** stops after outputting *NUM* non-matching lines.

-o, --only-matching

Print only the matched (non-empty) parts of a matching line, with each such part on a separate output line.

-q, --quiet, --silent

Quiet; do not write anything to standard output. Exit immediately with zero status if any match is found, even if an error was detected. Also see the **-s** or **--no-messages** option.

-s, --no-messages

Suppress error messages about nonexistent or unreadable files.

Output Line Prefix Control**-b, --byte-offset**

Print the 0-based byte offset within the input file before each line of output. If **-o** (**--only-matching**) is specified, print the offset of the matching part itself.

-H, --with-filename

Print the file name for each match. This is the default when there is more than one file to search. This is a GNU extension.

-h, --no-filename

Suppress the prefixing of file names on output. This is the default when there is only one file (or only standard input) to search.

--label=LABEL

Display input actually coming from standard input as input coming from file *LABEL*. This can be useful for commands that transform a file's contents before searching, e.g., `gzip -cd foo.gz | grep --label=foo -H 'some pattern'`. See also the **-H** option.

-n, --line-number

Prefix each line of output with the 1-based line number within its input file.

-T, --initial-tab

Make sure that the first character of actual line content lies on a tab stop, so that the alignment of tabs looks normal. This is useful with options that prefix their output to the actual content: **-H**, **-n**, and **-b**. In order to improve the probability that lines from a single file will all start at the same column, this also causes the line number and byte offset (if present) to be printed in a minimum size field width.

-Z, --null

Output a zero byte (the ASCII **NUL** character) instead of the character that normally follows a file name. For example, `grep -lZ` outputs a zero byte after each file name instead of the usual newline. This option makes the output unambiguous, even in the presence of file names containing unusual characters like newlines. This option can be used with commands like **find -print0**, **perl -0**, **sort -z**, and **xargs -0** to process arbitrary file names, even those that contain newline characters.

Context Line Control**-A NUM, --after-context=NUM**

Print *NUM* lines of trailing context after matching lines. Places a line containing a group separator (--) between contiguous groups of matches. With the **-o** or **--only-matching** option, this has no effect and a warning is given.

-B NUM, --before-context=NUM

Print *NUM* lines of leading context before matching lines. Places a line containing a group separator (--) between contiguous groups of matches. With the **-o** or **--only-matching** option, this has no effect and a warning is given.

-C NUM, -NUM, --context=NUM

Print *NUM* lines of output context. Places a line containing a group separator (--) between contiguous groups of matches. With the **-o** or **--only-matching** option, this has no effect and a warning is given.

--group-separator=SEP

When **-A**, **-B**, or **-C** are in use, print *SEP* instead of **--** between groups of lines.

--no-group-separator

When **-A**, **-B**, or **-C** are in use, do not print a separator between groups of lines.

File and Directory Selection**-a, --text**

Process a binary file as if it were text; this is equivalent to the **--binary-files=text** option.

--binary-files=TYPE

If a file's data or metadata indicate that the file contains binary data, assume that the file is of type *TYPE*. Non-text bytes indicate binary data; these are either output bytes that are improperly encoded for the current locale, or null input bytes when the **-z** option is not given.

By default, *TYPE* is **binary**, and **grep** suppresses output after null input binary data is discovered, and suppresses output lines that contain improperly encoded data. When some output is suppressed, **grep** follows any output with a one-line message saying that a binary file matches.

If *TYPE* is **without-match**, when **grep** discovers null input binary data it assumes that the rest of the file does not match; this is equivalent to the **-I** option.

If *TYPE* is **text**, **grep** processes a binary file as if it were text; this is equivalent to the **-a** option.

When *type* is **binary**, **grep** may treat non-text bytes as line terminators even without the **-z** option. This means choosing **binary** versus **text** can affect whether a pattern matches a file. For example, when *type* is **binary** the pattern **q\$** might match **q** immediately followed by a null byte, even though this is not matched when *type* is **text**. Conversely, when *type* is **binary** the pattern **.** (period) might not match a null byte.

Warning: The **-a** option might output binary garbage, which can have nasty side effects if the output is a terminal and if the terminal driver interprets some of it as commands. On the other hand, when reading files whose text encodings are unknown, it can be helpful to use **-a** or to set **LC_ALL='C'** in the environment, in order to find more matches even if the matches are unsafe for direct display.

-D ACTION, --devices=ACTION

If an input file is a device, FIFO or socket, use *ACTION* to process it. By default, *ACTION* is **read**, which means that devices are read just as if they were ordinary files. If *ACTION* is **skip**, devices are silently skipped.

-d ACTION, --directories=ACTION

If an input file is a directory, use *ACTION* to process it. By default, *ACTION* is **read**, i.e., read directories just as if they were ordinary files. If *ACTION* is **skip**, silently skip directories. If *ACTION* is **recurse**, read all files under each directory, recursively, following symbolic links only if they are on the command line. This is equivalent to the **-r** option.

--exclude=GLOB

Skip any command-line file with a name suffix that matches the pattern *GLOB*, using wildcard matching; a name suffix is either the whole name, or a trailing part that starts with a non-slash character immediately after a slash (/) in the name. When searching recursively, skip any subfile whose base name matches *GLOB*; the base name is the part after the last slash. A pattern can use *****, **?**, and **[...]** as wildcards, and **** to quote a wildcard or backslash character literally.

--exclude-from=FILE

Skip files whose base name matches any of the file-name globs read from *FILE* (using wildcard matching as described under **--exclude**).

--exclude-dir=GLOB

Skip any command-line directory with a name suffix that matches the pattern *GLOB*. When searching recursively, skip any subdirectory whose base name matches *GLOB*. Ignore any redundant trailing slashes in *GLOB*.

-I Process a binary file as if it did not contain matching data; this is equivalent to the **--binary-files=without-match** option.

--include=GLOB

Search only files whose base name matches *GLOB* (using wildcard matching as described under **--exclude**). If contradictory **--include** and **--exclude** options are given, the last matching one wins. If no **--include** or **--exclude** options match, a file is included unless the first such option is **--include**.

-r, --recursive

Read all files under each directory, recursively, following symbolic links only if they are on the command line. Note that if no file operand is given, B`<grep>` searches the working directory. This is equivalent to the **-d recurse** option.

-R, --dereference-recursive

Read all files under each directory, recursively. Follow all symbolic links, unlike **-r**.

Other Options**--line-buffered**

Use line buffering on output. This can cause a performance penalty.

-U, --binary

Treat the file(s) as binary. By default, under MS-DOS and MS-Windows, **grep** guesses whether a file is text or binary as described for the **--binary-files** option. If **grep** decides the file is a text file, it strips the CR characters from the original file contents (to make regular expressions with ^ and \$ work correctly). Specifying **-U** overrules this guesswork, causing all files to be read and passed to the matching mechanism verbatim; if the file is a text file with CR/LF pairs at the end of each line, this will cause some regular expressions to fail. This option has no effect on platforms other than MS-DOS and MS-Windows.

-z, --null-data

Treat input and output data as sequences of lines, each terminated by a zero byte (the ASCII NUL character) instead of a newline. Like the **-Z** or **--null** option, this option can be used with commands like **sort -z** to process arbitrary file names.

REGULAR EXPRESSIONS

A regular expression is a pattern that describes a set of strings. Regular expressions are constructed analogously to arithmetic expressions, by using various operators to combine smaller expressions.

grep understands three different versions of regular expression syntax: “basic” (BRE), “extended” (ERE) and “perl” (PCRE). In GNU **grep** there is no difference in available functionality between basic and extended syntaxes. In other implementations, basic regular expressions are less powerful. The following description applies to extended regular expressions; differences for basic regular expressions are summarized afterwards. Perl-compatible regular expressions give additional functionality, and are documented in B<pcresyntax>(3) and B<pcrepattern>(3), but work only if PCRE support is enabled.

The fundamental building blocks are the regular expressions that match a single character. Most characters, including all letters and digits, are regular expressions that match themselves. Any meta-character with special meaning may be quoted by preceding it with a backslash.

The period **.** matches any single character. It is unspecified whether it matches an encoding error.

Character Classes and Bracket Expressions

A *bracket expression* is a list of characters enclosed by [and]. It matches any single character in that list. If the first character of the list is the caret ^ then it matches any character *not* in the list; it is unspecified whether it matches an encoding error. For example, the regular expression **[0123456789]** matches any single digit.

Within a bracket expression, a *range expression* consists of two characters separated by a hyphen. It matches any single character that sorts between the two characters, inclusive, using the locale’s collating sequence and character set. For example, in the default C locale, **[a-d]** is equivalent to **[abcd]**. Many locales sort characters in dictionary order, and in these locales **[a-d]** is typically not equivalent to **[abcd]**; it might be equivalent to **[aBbCcDd]**, for example. To obtain the traditional interpretation of bracket expressions, you can use the C locale by setting the **LC_ALL** environment variable to the value **C**.

Finally, certain named classes of characters are predefined within bracket expressions, as follows. Their names are self explanatory, and they are **[:alnum:]**, **[:alpha:]**, **[:blank:]**, **[:cntrl:]**, **[:digit:]**, **[:graph:]**, **[:lower:]**, **[:print:]**, **[:punct:]**, **[:space:]**, **[:upper:]**, and **[:xdigit:]**. For example, **[[[:alnum:]]]** means the character class of numbers and letters in the current locale. In the C locale and ASCII character set encoding, this is the same as **[0-9A-Za-z]**. (Note that the brackets in these class names are part of the symbolic names, and must be included in addition to the brackets delimiting the bracket expression.) Most meta-characters lose their special meaning inside bracket expressions. To include a literal] place it first in the list. Similarly, to include a literal ^ place it anywhere but first. Finally, to include a literal – place it last.

Anchoring

The caret ^ and the dollar sign \$ are meta-characters that respectively match the empty string at the beginning and end of a line.

The Backslash Character and Special Expressions

The symbols \< and \> respectively match the empty string at the beginning and end of a word. The symbol \b matches the empty string at the edge of a word, and \B matches the empty string provided it's *not* at the edge of a word. The symbol \w is a synonym for [_[:alnum:]] and \W is a synonym for [^_[:alnum:]].

Repetition

A regular expression may be followed by one of several repetition operators:

- ? The preceding item is optional and matched at most once.
- * The preceding item will be matched zero or more times.
- + The preceding item will be matched one or more times.
- {n} The preceding item is matched exactly *n* times.
- {n,} The preceding item is matched *n* or more times.
- {,m} The preceding item is matched at most *m* times. This is a GNU extension.
- {n,m} The preceding item is matched at least *n* times, but not more than *m* times.

Concatenation

Two regular expressions may be concatenated; the resulting regular expression matches any string formed by concatenating two substrings that respectively match the concatenated expressions.

Alternation

Two regular expressions may be joined by the infix operator |; the resulting regular expression matches any string matching either alternate expression.

Precedence

Repetition takes precedence over concatenation, which in turn takes precedence over alternation. A whole expression may be enclosed in parentheses to override these precedence rules and form a subexpression.

Back-references and Subexpressions

The back-reference *n*, where *n* is a single digit, matches the substring previously matched by the *n*th parenthesized subexpression of the regular expression.

Basic vs Extended Regular Expressions

In basic regular expressions the meta-characters ?, +, {, |, (, and) lose their special meaning; instead use the backslashed versions \?, \+, \{, \|, \(), and \).

EXIT STATUS

Normally the exit status is 0 if a line is selected, 1 if no lines were selected, and 2 if an error occurred. However, if the **-q** or **--quiet** or **--silent** is used and a line is selected, the exit status is 0 even if an error occurred.

ENVIRONMENT

The behavior of **grep** is affected by the following environment variables.

The locale for category **LC_foo** is specified by examining the three environment variables **LC_ALL**, **LC_foo**, **LANG**, in that order. The first of these variables that is set specifies the locale. For example, if **LC_ALL** is not set, but **LC_MESSAGES** is set to **pt_BR**, then the Brazilian Portuguese locale is used for the **LC_MESSAGES** category. The C locale is used if none of these environment variables are set, if the locale catalog is not installed, or if **grep** was not compiled with national language support (NLS). The shell command **locale -a** lists locales that are currently available.

GREP_COLOR

This variable specifies the color used to highlight matched (non-empty) text. It is deprecated in favor of **GREP_COLORS**, but still supported. The **mt**, **ms**, and **mc** capabilities of **GREP_COLORS** have priority over it. It can only specify the color used to highlight the matching non-empty text in any matching line (a selected line when the **-v** command-line option is omitted, or a context line when **-v** is specified). The default is **01;31**, which means a bold red foreground text on the terminal's default background.

GREP_COLORS

Specifies the colors and other attributes used to highlight various parts of the output. Its value is a colon-separated list of capabilities that defaults to **ms=01;31;mc=01;31;sl=:cx=:fn=35:ln=32:bn=32:se=36** with the **rv** and **ne** boolean capabilities omitted (i.e., false). Supported capabilities are as follows.

sl= SGR substring for whole selected lines (i.e., matching lines when the **-v** command-line option is omitted, or non-matching lines when **-v** is specified). If however the boolean **rv** capability and the **-v** command-line option are both specified, it applies to context matching lines instead. The default is empty (i.e., the terminal's default color pair).

cx= SGR substring for whole context lines (i.e., non-matching lines when the **-v** command-line option is omitted, or matching lines when **-v** is specified). If however the boolean **rv** capability and the **-v** command-line option are both specified, it applies to selected non-matching lines instead. The default is empty (i.e., the terminal's default color pair).

rv Boolean value that reverses (swaps) the meanings of the **sl=** and **cx=** capabilities when the **-v** command-line option is specified. The default is false (i.e., the capability is omitted).

mt=01;31

SGR substring for matching non-empty text in any matching line (i.e., a selected line when the **-v** command-line option is omitted, or a context line when **-v** is specified). Setting this is equivalent to setting both **ms=** and **mc=** at once to the same value. The default is a bold red text foreground over the current line background.

ms=01;31

SGR substring for matching non-empty text in a selected line. (This is only used when the **-v** command-line option is omitted.) The effect of the **sl=** (or **cx=** if **rv**) capability remains active when this kicks in. The default is a bold red text foreground over the current line background.

mc=01;31

SGR substring for matching non-empty text in a context line. (This is only used when the **-v** command-line option is specified.) The effect of the **cx=** (or **sl=** if **rv**) capability remains active when this kicks in. The default is a bold red text foreground over the current line background.

fn=35 SGR substring for file names prefixing any content line. The default is a magenta text foreground over the terminal's default background.

ln=32 SGR substring for line numbers prefixing any content line. The default is a green text foreground over the terminal's default background.

bn=32 SGR substring for byte offsets prefixing any content line. The default is a green text foreground over the terminal's default background.

se=36 SGR substring for separators that are inserted between selected line fields (:), between context line fields (-), and between groups of adjacent lines when nonzero context is specified (--). The default is a cyan text foreground over the terminal's default background.

ne Boolean value that prevents clearing to the end of line using Erase in Line (EL) to Right (\33[K) each time a colorized item ends. This is needed on terminals on which EL is not supported. It is otherwise useful on terminals for which the **back_color_erase** (**bce**) boolean terminfo capability does not apply, when the chosen highlight colors do not affect the background, or when EL is too slow or causes too much flicker. The default is false (i.e., the capability is omitted).

Note that boolean capabilities have no =... part. They are omitted (i.e., false) by default and become true when specified.

See the Select Graphic Rendition (SGR) section in the documentation of the text terminal that is used for permitted values and their meaning as character attributes. These substring values are integers in decimal representation and can be concatenated with semicolons. **grep** takes care of assembling the result into a complete SGR sequence (**\33[...m**). Common values to concatenate include **1** for bold, **4** for underline, **5** for blink, **7** for inverse, **39** for default foreground color, **30** to **37** for foreground colors, **90** to **97** for 16-color mode foreground colors, **38;5;0** to **38;5;255** for 88-color and 256-color modes foreground colors, **49** for default background color, **40** to **47** for background colors, **100** to **107** for 16-color mode background colors, and **48;5;0** to **48;5;255** for 88-color and 256-color modes background colors.

LC_ALL, LC_COLLATE, LANG

These variables specify the locale for the **LC_COLLATE** category, which determines the collating sequence used to interpret range expressions like **[a-z]**.

LC_ALL, LC_CTYPE, LANG

These variables specify the locale for the **LC_CTYPE** category, which determines the type of characters, e.g., which characters are whitespace. This category also determines the character encoding, that is, whether text is encoded in UTF-8, ASCII, or some other encoding. In the C or POSIX locale, all characters are encoded as a single byte and every byte is a valid character.

LC_ALL, LC_MESSAGES, LANG

These variables specify the locale for the **LC_MESSAGES** category, which determines the language that **grep** uses for messages. The default C locale uses American English messages.

POSIXLY_CORRECT

If set, **grep** behaves as POSIX requires; otherwise, **grep** behaves more like other GNU programs. POSIX requires that options that follow file names must be treated as file names; by default, such options are permuted to the front of the operand list and are treated as options. Also, POSIX requires that unrecognized options be diagnosed as “illegal”, but since they are not really against the law the default is to diagnose them as “invalid”. **POSIXLY_CORRECT** also disables **_N_GNU_nonoption_argv_flags_**, described below.

_N_GNU_nonoption_argv_flags_

(Here *N* is **grep**’s numeric process ID.) If the *i*th character of this environment variable’s value is **1**, do not consider the *i*th operand of **grep** to be an option, even if it appears to be one. A shell can put this variable in the environment for each command it runs, specifying which operands are the results of file name wildcard expansion and therefore should not be treated as options. This behavior is available only with the GNU C library, and only when **POSIXLY_CORRECT** is not set.

NOTES

This man page is maintained only fitfully; the full documentation is often more up-to-date.

Reporting Bugs

Email bug reports to the bug-reporting address [<bug-grep@gnu.org>](mailto:bug-grep@gnu.org). An email archive [<https://lists.gnu.org/mailman/listinfo/bug-grep>](https://lists.gnu.org/mailman/listinfo/bug-grep) and a bug tracker [<https://debbugs.gnu.org/cgi/pkgreport.cgi?package=grep>](https://debbugs.gnu.org/cgi/pkgreport.cgi?package=grep) are available.

Known Bugs

Large repetition counts in the **{n,m}** construct may cause **grep** to use lots of memory. In addition, certain other obscure regular expressions require exponential time and space, and may cause **grep** to run out of memory.

Back-references are very slow, and may require exponential time.

EXAMPLE

The following example outputs the location and contents of any line containing “f” and ending in “.c”, within all files in the current directory whose names contain “g” and end in “.h”. The **-n** option outputs line numbers, the **--** argument treats expansions of “*g*.h” starting with “-” as file names not options, and the empty file /dev/null causes file names to be output even if only one file name happens to be of the form “*g*.h”.

```
$ grep -n -- 'f.*\.c$' *g*.h /dev/null
argmatch.h:1:/* definitions and prototypes for argmatch.c
```

The only line that matches is line 1 of argmatch.h. Note that the regular expression syntax used in the pattern differs from the globbing syntax that the shell uses to match file names.

```
info grep
```

should give you access to the complete manual.

NAME

group – user group file

DESCRIPTION

The */etc/group* file is a text file that defines the groups on the system. There is one entry per line, with the following format:

group_name:*password*:*GID*:*user_list*

The fields are as follows:

group_name

the name of the group.

password

the (encrypted) group password. If this field is empty, no password is needed.

GID

the numeric group ID.

user_list

a list of the usernames that are members of this group, separated by commas.

FILES

/etc/group

BUGS

As the 4.2BSD **initgroups**(3) man page says: no one seems to keep */etc/group* up-to-date.

SEE ALSO

chgrp(1), **gpasswd(1)**, **groups(1)**, **login(1)**, **newgrp(1)**, **sg(1)**, **getgrent(3)**, **getgrnam(3)**, **gshadow(5)**, **passwd(5)**, **vigr(8)**

NAME

`group.conf` – configuration file for the pam_group module

DESCRIPTION

The pam_group PAM module does not authenticate the user, but instead it grants group memberships (in the credential setting phase of the authentication module) to the user. Such memberships are based on the service they are applying for.

For this module to function correctly there must be a correctly formatted /etc/security/group.conf file present. White spaces are ignored and lines maybe extended with '\' (escaped newlines). Text following a '#' is ignored to the end of the line.

The syntax of the lines is as follows:

`services;ttys;users;times;groups`

The first field, the *services* field, is a logic list of PAM service names that the rule applies to.

The second field, the *tty* field, is a logic list of terminal names that this rule applies to.

The third field, the *users* field, is a logic list of users, or a UNIX group, or a netgroup of users to whom this rule applies. Group names are preceded by a '%' symbol, while netgroup names are preceded by a '@' symbol.

A logic list namely means individual tokens that are optionally prefixed with '!' (logical not) and separated with '&' (logical and) and '||' (logical or).

For these items the simple wildcard '*' may be used only once. With UNIX groups or netgroups no wildcards or logic operators are allowed.

The *times* field is used to indicate "when" these groups are to be given to the user. The format here is a logic list of day/time-range entries. The days are specified by a sequence of two character entries, MoTuSa for example is Monday Tuesday and Saturday. Note that repeated days are unset MoMo = no day, and MoWk = all weekdays bar Monday. The two character combinations accepted are Mo Tu We Th Fr Sa Su Wk Wd Al, the last two being week-end days and all 7 days of the week respectively. As a final example, AlFr means all days except Friday.

Each day/time-range can be prefixed with a '!' to indicate "anything but". The time-range part is two 24-hour times HHMM, separated by a hyphen, indicating the start and finish time (if the finish time is smaller than the start time it is deemed to apply on the following day).

The *groups* field is a comma or space separated list of groups that the user inherits membership of. These groups are added if the previous fields are satisfied by the user's request.

For a rule to be active, ALL of service+ttys+users must be satisfied by the applying process.

EXAMPLES

These are some example lines which might be specified in /etc/security/group.conf.

Running 'xsh' on tty* (any ttyXXX device), the user 'us' is given access to the floppy (through membership of the floppy group)

```
xsh;tty*&!ttyp*;us;Al0000-2400;floppy
```

Running 'xsh' on tty* (any ttyXXX device), the users 'sword', 'pike' and 'shield' are given access to games (through membership of the floppy group) after work hours.

```
xsh; tty* ;sword|pike|shield;!Wk0900-1800;games, sound
xsh; tty* ;*;Al0900-1800;floppy
```

Any member of the group 'admin' running 'xsh' on tty*, is granted access (at any time) to the group 'plugdev'

```
xsh; tty* ;%admin;Al0000-2400;plugdev
```

NAME

groupadd – create a new group

SYNOPSIS

groupadd [*options*] *group*

DESCRIPTION

The **groupadd** command creates a new group account using the values specified on the command line plus the default values from the system. The new group will be entered into the system files as needed.

OPTIONS

The options which apply to the **groupadd** command are:

-f, --force

This option causes the command to simply exit with success status if the specified group already exists. When used with **-g**, and the specified GID already exists, another (unique) GID is chosen (i.e. **-g** is turned off).

-g, --gid *GID*

The numerical value of the group's ID. This value must be unique, unless the **-o** option is used. The value must be non-negative. The default is to use the smallest ID value greater than or equal to **GID_MIN** and greater than every other group.

See also the **-r** option and the **GID_MAX** description.

-h, --help

Display help message and exit.

-K, --key *KEY=VALUE*

Overrides /etc/login.defs defaults (**GID_MIN**, **GID_MAX** and others). Multiple **-K** options can be specified.

Example: **-K GID_MIN=100 -K GID_MAX=499**

Note: **-K GID_MIN=10,GID_MAX=499** doesn't work yet.

-o, --non-unique

This option permits to add a group with a non-unique GID.

-p, --password *PASSWORD*

The encrypted password, as returned by **crypt(3)**. The default is to disable the password.

Note: This option is not recommended because the password (or encrypted password) will be visible by users listing the processes.

You should make sure the password respects the system's password policy.

-r, --system

Create a system group.

The numeric identifiers of new system groups are chosen in the **SYS_GID_MIN**–**SYS_GID_MAX** range, defined in login.defs, instead of **GID_MIN**–**GID_MAX**.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-P, --prefix *PREFIX_DIR*

Apply changes in the *PREFIX_DIR* directory and use the configuration files from the *PREFIX_DIR* directory. This option does not chroot and is intended for preparing a cross-compilation target. Some limitations: NIS and LDAP users/groups are not verified. PAM authentication is using the host files. No SELINUX support.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

GID_MAX (number), **GID_MIN** (number)

Range of group IDs used for the creation of regular groups by **useradd**, **groupadd**, or **newusers**.

The default value for **GID_MIN** (resp. **GID_MAX**) is 1000 (resp. 60000).

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

SYS_GID_MAX (number), **SYS_GID_MIN** (number)

Range of group IDs used for the creation of system groups by **useradd**, **groupadd**, or **newusers**.

The default value for **SYS_GID_MIN** (resp. **SYS_GID_MAX**) is 101 (resp. **GID_MIN**-1).

FILES

/etc/group

Group account information.

/etc/gshadow

Secure group account information.

/etc/login.defs

Shadow password suite configuration.

CAVEATS

It is usually recommended to only use groupnames that begin with a lower case letter or an underscore, followed by lower case letters, digits, underscores, or dashes. They can end with a dollar sign. In regular expression terms: [a-z_][a-z0-9_-]*[\$]?

On Debian, the only constraints are that groupnames must neither start with a dash ('-') nor plus ('+') nor tilde ('~') nor contain a colon (':'), a comma (','), or a whitespace (space: ' ', end of line: '\n', tabulation: '\t', etc.).

On Ubuntu, the same constraints as Debian are in place, with the additional constraint that the groupname cannot be fully numeric. This includes octal and hexadecimal syntax.

Groupnames may only be up to 32 characters long.

You may not add a NIS or LDAP group. This must be performed on the corresponding server.

If the groupname already exists in an external group database such as NIS or LDAP, **groupadd** will deny the group creation request.

EXIT VALUES

The **groupadd** command exits with the following values:

0

success

2

invalid command syntax

3

invalid argument to option

4

GID not unique (when **-o** not used)

9

group name not unique

10

can't update group file

NAME

groupdel – delete a group

SYNOPSIS

groupdel [*options*] *GROUP*

DESCRIPTION

The **groupdel** command modifies the system account files, deleting all entries that refer to *GROUP*. The named group must exist.

OPTIONS

The options which apply to the **groupdel** command are:

-h, --help

Display help message and exit.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-P, --prefix *PREFIX_DIR*

Apply changes in the *PREFIX_DIR* directory and use the configuration files from the *PREFIX_DIR* directory. This option does not chroot and is intended for preparing a cross-compilation target. Some limitations: NIS and LDAP users/groups are not verified. PAM authentication is using the host files. No SELINUX support.

CAVEATS

You may not remove the primary group of any existing user. You must remove the user before you remove the group.

You should manually check all file systems to ensure that no files remain owned by this group.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

FILES

/etc/group

Group account information.

/etc/gshadow

Secure group account information.

EXIT VALUES

The **groupdel** command exits with the following values:

0

success

2

invalid command syntax

6
specified group doesn't exist

8
can't remove user's primary group

10
can't update group file

SEE ALSO

NAME

groupmod – modify a group definition on the system

SYNOPSIS

groupmod [*options*] *GROUP*

DESCRIPTION

The **groupmod** command modifies the definition of the specified *GROUP* by modifying the appropriate entry in the group database.

OPTIONS

The options which apply to the **groupmod** command are:

-g, --gid *GID*

The group ID of the given *GROUP* will be changed to *GID*.

The value of *GID* must be a non-negative decimal integer. This value must be unique, unless the **-o** option is used.

Users who use the group as primary group will be updated to keep the group as their primary group.

Any files that have the old group ID and must continue to belong to *GROUP*, must have their group ID changed manually.

No checks will be performed with regard to the **GID_MIN**, **GID_MAX**, **SYS_GID_MIN**, or **SYS_GID_MAX** from /etc/login.defs.

-h, --help

Display help message and exit.

-n, --new-name *NEW_GROUP*

The name of the group will be changed from *GROUP* to *NEW_GROUP* name.

-o, --non-unique

When used with the **-g** option, allow to change the group *GID* to a non-unique value.

-p, --password *PASSWORD*

The encrypted password, as returned by **crypt(3)**.

Note: This option is not recommended because the password (or encrypted password) will be visible by users listing the processes.

You should make sure the password respects the system's password policy.

-R, --root *CHROOT_DIR*

Apply changes in the *CHROOT_DIR* directory and use the configuration files from the *CHROOT_DIR* directory.

-P, --prefix *PREFIX_DIR*

Apply changes in the *PREFIX_DIR* directory and use the configuration files from the *PREFIX_DIR* directory. This option does not chroot and is intended for preparing a cross-compilation target. Some limitations: NIS and LDAP users/groups are not verified. PAM authentication is using the host files. No SELINUX support.

CONFIGURATION

The following configuration variables in /etc/login.defs change the behavior of this tool:

MAX_MEMBERS_PER_GROUP (number)

Maximum members per group entry. When the maximum is reached, a new group entry (line) is started in /etc/group (with the same name, same password, and same GID).

The default value is 0, meaning that there are no limits in the number of members in a group.

This feature (split group) permits to limit the length of lines in the group file. This is useful to make sure that lines for NIS groups are not larger than 1024 characters.

If you need to enforce such limit, you can use 25.

Note: split groups may not be supported by all tools (even in the Shadow toolsuite). You should not use this variable unless you really need it.

FILES

/etc/group	Group account information.
/etc/gshadow	Secure group account information.
/etc/login.defs	Shadow password suite configuration.
/etc/passwd	User account information.

EXIT VALUES

The **groupmod** command exits with the following values:

<i>0</i>	E_SUCCESS: success
<i>2</i>	E_USAGE: invalid command syntax
<i>3</i>	E_BAD_ARG: invalid argument to option
<i>4</i>	E_GID_IN_USE: specified group doesn't exist
<i>6</i>	E_NOTFOUND: specified group doesn't exist
<i>9</i>	E_NAME_IN_USE: group name already in use
<i>10</i>	E_GRP_UPDATE: can't update group file
<i>11</i>	E_CLEANUP_SERVICE: can't setup cleanup service
<i>12</i>	E_PAM_USERNAME: can't determine your username for use with pam
<i>13</i>	E_PAM_ERROR: pam returned an error, see syslog facility id groupmod for the PAM error message

NAME

grub-install – install GRUB to a device

SYNOPSIS

grub-install [OPTION...] [OPTION] [INSTALL_DEVICE]

DESCRIPTION

Install GRUB on your drive.

--compress=no|xz|gz|lzo
compress GRUB files [optional]

--disable-shim-lock
disable shim_lock verifier

--dtb=FILE
embed a specific DTB

-d, --directory=DIR
use images and modules under DIR [default=/usr/lib/grub/<platform>]

--fonts=FONTS
install FONTS [default=unicode]

--install-modules=MODULES
install only MODULES and their dependencies [default=all]

-k, --pubkey=FILE
embed FILE as public key for signature checking

--locale-directory=DIR use translations under DIR
[default=/usr/share/locale]

--locales=LOCALES
install only LOCALES [default=all]

--modules=MODULES
pre-load specified modules MODULES

--sbat=FILE
SBAT metadata

--themes=THEMES
install THEMES [default=starfield]

-v, --verbose
print verbose messages.

--allow-floppy
make the drive also bootable as floppy (default for fdX devices). May break on some BIOSes.

--boot-directory=DIR
install GRUB images under the directory DIR/grub instead of the boot/grub directory

--bootloader-id=ID
the ID of bootloader. This option is only available on EFI and Macs.

--core-compress=xz|none|auto
choose the compression to use for core image

--disk-module=MODULE
disk module to use (biosdisk or native). This option is only available on BIOS target.

--efi-directory=DIR
use DIR as the EFI System Partition root.

--force
install even if problems are detected

--force-file-id
use identifier file even if UUID is available

--label-bgcolor=COLOR
use COLOR for label background

--label-color=COLOR
use COLOR for label

--label-font=FILE
use FILE as font for label

--macppc-directory=DIR use DIR for PPC MAC install.

--no-bootsector
do not install bootsector

--no-extra-removable
Do not install bootloader code to the removable media path. This option is only available on EFI.

--no-nvram
don't update the 'boot-device'/'Boot*' NVRAM variables. This option is only available on EFI and IEEE1275 targets.

--no-rs-codes
Do not apply any reed-solomon codes when embedding core.img. This option is only available on x86 BIOS targets.

--no-uefi-secure-boot
do not install an image usable with UEFI Secure Boot, even if the system was currently started using it. This option is only available on EFI.

--product-version=STRING
use STRING as product version

--recheck
delete device map if it already exists

--removable
the installation device is removable. This option is only available on EFI.

-s, --skip-fs-probe
do not probe for filesystems in DEVICE

--target=TARGET
install GRUB for TARGET platform [default=i386-pc]; available targets: arm-coreboot, arm-efi, arm-uboot, arm64-efi, i386-coreboot, i386-efi, i386-ieee1275, i386-multiboot, i386-pc, i386-qemu, i386-xen, i386-xen_pv, ia64-efi, mips-arc, mips-qemu_mips, mipsel-arc, mipsel-loongson, mipsel-qemu_mips, powerpc-ieee1275, riscv32-efi, riscv64-efi, sparc64-ieee1275, x86_64-efi, x86_64-xen

--uefi-secure-boot
install an image usable with UEFI Secure Boot. This option is only available on EFI and if the grub-efi-amd64-signed package is installed.

-?, --help
give this help list

--usage
give a short usage message

-V, --version
print program version

Mandatory or optional arguments to long options are also mandatory or optional for any corresponding short options.

INSTALL_DEVICE must be system device filename. grub-install copies GRUB images into boot/grub. On some platforms, it may also install GRUB into the boot sector.

REPORTING BUGS

Report bugs to <bug-grub@gnu.org>.

SEE ALSO

grub-mkconfig(8), grub-mkimage(1), grub-mkrescue(1)

The full documentation for **grub-install** is maintained as a Texinfo manual. If the **info** and **grub-install** programs are properly installed at your site, the command

info grub-install

should give you access to the complete manual.

NAME

grub-mkconfig – generate a GRUB configuration file

SYNOPSIS

grub-mkconfig [*OPTION*]

DESCRIPTION

Generate a grub config file

-o, --output=FILE

output generated config to FILE [default=stdout]

-h, --help

print this message and exit

-V, --version

print the version information and exit

REPORTING BUGS

Report bugs to <bug-grub@gnu.org>.

SEE ALSO

grub-install(8)

The full documentation for **grub-mkconfig** is maintained as a Texinfo manual. If the **info** and **grub-mkconfig** programs are properly installed at your site, the command

info grub-mkconfig

should give you access to the complete manual.

NAME

gzip, *gunzip*, *zcat* – compress or expand files

SYNOPSIS

```
gzip [ -acdfhklLnNrtvV19 ] [-S suffix] [ name ... ]
gunzip [ -acfhlkLlnNrtvV ] [-S suffix] [ name ... ]
zcat [ -fhLV ] [ name ... ]
```

DESCRIPTION

Gzip reduces the size of the named files using Lempel-Ziv coding (LZ77). Whenever possible, each file is replaced by one with the extension **.gz**, while keeping the same ownership modes, access and modification times. (The default extension is **z** for MSDOS, OS/2 FAT, Windows NT FAT and Atari.) If no files are specified, or if a file name is **"."**, the standard input is compressed to the standard output. *Gzip* will only attempt to compress regular files. In particular, it will ignore symbolic links.

If the compressed file name is too long for its file system, *gzip* truncates it. *Gzip* attempts to truncate only the parts of the file name longer than 3 characters. (A part is delimited by dots.) If the name consists of small parts only, the longest parts are truncated. For example, if file names are limited to 14 characters, *gzip.msdos.exe* is compressed to *gzi.msd.exe.gz*. Names are not truncated on systems which do not have a limit on file name length.

By default, *gzip* keeps the original file name and timestamp in the compressed file. These are used when decompressing the file with the **-N** option. This is useful when the compressed file name was truncated or when the timestamp was not preserved after a file transfer.

Compressed files can be restored to their original form using *gzip -d* or *gunzip* or *zcat*. If the original name saved in the compressed file is not suitable for its file system, a new name is constructed from the original one to make it legal.

gunzip takes a list of files on its command line and replaces each file whose name ends with **.gz**, **-gz**, **.z**, **-z**, or **_z** (ignoring case) and which begins with the correct magic number with an uncompressed file without the original extension. *gunzip* also recognizes the special extensions **.tgz** and **.taz** as shorthands for **.tar.gz** and **.tar.Z** respectively. When compressing, *gzip* uses the **.tgz** extension if necessary instead of truncating a file with a **.tar** extension.

gunzip can currently decompress files created by *gzip*, *zip*, *compress*, *compress -H* or *pack*. The detection of the input format is automatic. When using the first two formats, *gunzip* checks a 32 bit CRC. For *pack* and *gunzip* checks the uncompressed length. The standard *compress* format was not designed to allow consistency checks. However *gunzip* is sometimes able to detect a bad **.Z** file. If you get an error when uncompressing a **.Z** file, do not assume that the **.Z** file is correct simply because the standard *uncompress* does not complain. This generally means that the standard *uncompress* does not check its input, and happily generates garbage output. The SCO compress **-H** format (lzh compression method) does not include a CRC but also allows some consistency checks.

Files created by *zip* can be uncompressed by *gzip* only if they have a single member compressed with the 'deflation' method. This feature is only intended to help conversion of tar.zip files to the tar.gz format. To extract a *zip* file with a single member, use a command like *gunzip <foo.zip* or *gunzip -S .zip foo.zip*. To extract zip files with several members, use *unzip* instead of *gunzip*.

zcat is identical to *gunzip -c*. (On some systems, *zcat* may be installed as *gzcat* to preserve the original link to *compress*.) *zcat* uncompresses either a list of files on the command line or its standard input and writes the uncompressed data on standard output. *zcat* will uncompress files that have the correct magic number whether they have a **.gz** suffix or not.

Gzip uses the Lempel-Ziv algorithm used in *zip* and PKZIP. The amount of compression obtained depends on the size of the input and the distribution of common substrings. Typically, text such as source code or English is reduced by 60–70%. Compression is generally much better than that achieved by LZW (as used in *compress*), Huffman coding (as used in *pack*), or adaptive Huffman coding (*compact*).

Compression is always performed, even if the compressed file is slightly larger than the original. The worst case expansion is a few bytes for the *gzip* file header, plus 5 bytes every 32K block, or an expansion ratio of

0.015% for large files. Note that the actual number of used disk blocks almost never increases. *gzip* preserves the mode, ownership and timestamps of files when compressing or decompressing.

OPTIONS

-a --ascii

Ascii text mode: convert end-of-lines using local conventions. This option is supported only on some non-Unix systems. For MSDOS, CR LF is converted to LF when compressing, and LF is converted to CR LF when decompressing.

-c --stdout --to-stdout

Write output on standard output; keep original files unchanged. If there are several input files, the output consists of a sequence of independently compressed members. To obtain better compression, concatenate all input files before compressing them.

-d --decompress --uncompress

Decompress.

-f --force

Force compression or decompression even if the file has multiple links or the corresponding file already exists, or if the compressed data is read from or written to a terminal. If the input data is not in a format recognized by *gzip*, and if the option **--stdout** is also given, copy the input data without change to the standard output: let *zcat* behave as *cat*. If **-f** is not given, and when not running in the background, *gzip* prompts to verify whether an existing file should be overwritten.

-h --help

Display a help screen and quit.

-k --keep

Keep (don't delete) input files during compression or decompression.

-l --list For each compressed file, list the following fields:

- compressed size: size of the compressed file
- uncompressed size: size of the uncompressed file
- ratio: compression ratio (0.0% if unknown)
- uncompressed_name: name of the uncompressed file

The uncompressed size is given as -1 for files not in gzip format, such as compressed .Z files. To get the uncompressed size for such a file, you can use:

```
zcat file.Z | wc -c
```

In combination with the **--verbose** option, the following fields are also displayed:

- method: compression method
- crc: the 32-bit CRC of the uncompressed data
- date & time: timestamp for the uncompressed file

The compression methods currently supported are deflate, compress, lzh (SCO compress -H) and pack. The crc is given as fffffff for a file not in gzip format.

With **--name**, the uncompressed name, date and time are those stored within the compress file if present.

With **--verbose**, the size totals and compression ratio for all files is also displayed, unless some sizes are unknown. With **--quiet**, the title and totals lines are not displayed.

-L --license

Display the *gzip* license and quit.

-n --no-name

When compressing, do not save the original file name and timestamp by default. (The original name is always saved if the name had to be truncated.) When decompressing, do not restore the original file name if present (remove only the *gzip* suffix from the compressed file name) and do not restore the original timestamp if present (copy it from the compressed file). This option is the default when decompressing.

-N --name

When compressing, always save the original file name and timestamp; this is the default. When decompressing, restore the original file name and timestamp if present. This option is useful on systems which have a limit on file name length or when the timestamp has been lost after a file transfer.

-q --quiet

Suppress all warnings.

-r --recursive

Travel the directory structure recursively. If any of the file names specified on the command line are directories, *gzip* will descend into the directory and compress all the files it finds there (or decompress them in the case of *gunzip*).

-S .suf --suffix .suf

When compressing, use suffix *.suf* instead of *.gz*. Any non-empty suffix can be given, but suffixes other than *.z* and *.gz* should be avoided to avoid confusion when files are transferred to other systems.

When decompressing, add *.suf* to the beginning of the list of suffixes to try, when deriving an output file name from an input file name.

--synchronous

Use synchronous output. With this option, *gzip* is less likely to lose data during a system crash, but it can be considerably slower.

-t --test

Test. Check the compressed file integrity.

-v --verbose

Verbose. Display the name and percentage reduction for each file compressed or decompressed.

-V --version

Version. Display the version number and compilation options then quit.

-# --fast --best

Regulate the speed of compression using the specified digit *#*, where **-1** or **--fast** indicates the fastest compression method (less compression) and **-9** or **--best** indicates the slowest compression method (best compression). The default compression level is **-6** (that is, biased towards high compression at expense of speed).

--rsyncable

When you synchronize a compressed file between two computers, this option allows rsync to transfer only files that were changed in the archive instead of the entire archive. Normally, after a change is made to any file in the archive, the compression algorithm can generate a new version of the archive that does not match the previous version of the archive. In this case, rsync transfers the entire new version of the archive to the remote computer. With this option, rsync can transfer only the changed files as well as a small amount of metadata that is required to update the archive structure in the area that was changed.

ADVANCED USAGE

Multiple compressed files can be concatenated. In this case, *gunzip* will extract all members at once. For example:

```
gzip -c file1 > foo.gz
gzip -c file2 >> foo.gz
```

Then

```
gunzip -c foo
```

is equivalent to

```
cat file1 file2
```

In case of damage to one member of a .gz file, other members can still be recovered (if the damaged member is removed). However, you can get better compression by compressing all members at once:

```
cat file1 file2 | gzip > foo.gz
```

compresses better than

```
gzip -c file1 file2 > foo.gz
```

If you want to recompress concatenated files to get better compression, do:

```
gzip -cd old.gz | gzip > new.gz
```

If a compressed file consists of several members, the uncompressed size and CRC reported by the --list option applies to the last member only. If you need the uncompressed size for all members, you can use:

```
gzip -cd file.gz | wc -c
```

If you wish to create a single archive file with multiple members so that members can later be extracted independently, use an archiver such as tar or zip. GNU tar supports the -z option to invoke gzip transparently. gzip is designed as a complement to tar, not as a replacement.

ENVIRONMENT

The obsolescent environment variable **GZIP** can hold a set of default options for *gzip*. These options are interpreted first and can be overwritten by explicit command line parameters. As this can cause problems when using scripts, this feature is supported only for options that are reasonably likely to not cause too much harm, and *gzip* warns if it is used. This feature will be removed in a future release of *gzip*.

You can use an alias or script instead. For example, if *gzip* is in the directory **/usr/bin** you can prepend **\$HOME/bin** to your **PATH** and create an executable script **\$HOME/bin/gzip** containing the following:

```
#!/bin/sh
export PATH=/usr/bin
exec gzip -9 "$@"
```

SEE ALSO

znew(1), *zcmp(1)*, *zmore(1)*, *zforce(1)*, *gzexe(1)*, *zip(1)*, *unzip(1)*, *compress(1)*

The *gzip* file format is specified in P. Deutsch, GZIP file format specification version 4.3, <<https://www.ietf.org/rfc/rfc1952.txt>>, Internet RFC 1952 (May 1996). The *zip* deflation format is specified in P. Deutsch, DEFLATE Compressed Data Format Specification version 1.3, <<https://www.ietf.org/rfc/rfc1951.txt>>, Internet RFC 1951 (May 1996).

DIAGNOSTICS

Exit status is normally 0; if an error occurs, exit status is 1. If a warning occurs, exit status is 2.

Usage: gzip [-cdfhklLnNrtvV19] [-S suffix] [file ...]

 Invalid options were specified on the command line.

file: not in gzip format

 The file specified to *gunzip* has not been compressed.

file: Corrupt input. Use zcat to recover some data.

 The compressed file has been damaged. The data up to the point of failure can be recovered using

```
zcat file > recover
```

file: compressed with *xx* bits, can only handle *yy* bits

File was compressed (using LZW) by a program that could deal with more *bits* than the decompress code on this machine. Recompress the file with gzip, which compresses better and uses less memory.

file: already has .gz suffix -- unchanged

 The file is assumed to be already compressed. Rename the file and try again.

file already exists; do you wish to overwrite (y or n)?

 Respond "y" if you want the output file to be replaced; "n" if not.

gunzip: corrupt input

 A SIGSEGV violation was detected which usually means that the input file has been corrupted.

xx.x% Percentage of the input saved by compression.

 (Relevant only for -v and -l.)

-- not a regular file or directory: ignored

 When the input file is not a regular file or directory, (e.g. a symbolic link, socket, FIFO, device file), it is left unaltered.

-- has *xx* other links: unchanged

 The input file has links; it is left unchanged. See *ln(1)* for more information. Use the -f flag to force compression of multiply-linked files.

CAVEATS

When writing compressed data to a tape, it is generally necessary to pad the output with zeroes up to a block boundary. When the data is read and the whole block is passed to *gunzip* for decompression, *gunzip* detects that there is extra trailing garbage after the compressed data and emits a warning by default. You can use the --quiet option to suppress the warning.

BUGS

The gzip format represents the input size modulo 2^32, so the --list option reports incorrect uncompressed sizes and compression ratios for uncompressed files 4 GB and larger. To work around this problem, you can use the following command to discover a large uncompressed file's true size:

```
zcat file.gz | wc -c
```

The --list option reports sizes as -1 and crc as ffffffff if the compressed file is on a non seekable media.

In some rare cases, the --best option gives worse compression than the default compression level (-6). On some highly redundant files, *compress* compresses better than *gzip*.

NAME

gzip, *gunzip*, *zcat* – compress or expand files

SYNOPSIS

```
gzip [ -acdfhklLnNrtvV19 ] [-S suffix] [ name ... ]
gunzip [ -acfhlkLlnNrtvV ] [-S suffix] [ name ... ]
zcat [ -fhLV ] [ name ... ]
```

DESCRIPTION

Gzip reduces the size of the named files using Lempel-Ziv coding (LZ77). Whenever possible, each file is replaced by one with the extension **.gz**, while keeping the same ownership modes, access and modification times. (The default extension is **z** for MSDOS, OS/2 FAT, Windows NT FAT and Atari.) If no files are specified, or if a file name is "**-**", the standard input is compressed to the standard output. *Gzip* will only attempt to compress regular files. In particular, it will ignore symbolic links.

If the compressed file name is too long for its file system, *gzip* truncates it. *Gzip* attempts to truncate only the parts of the file name longer than 3 characters. (A part is delimited by dots.) If the name consists of small parts only, the longest parts are truncated. For example, if file names are limited to 14 characters, *gzip.msdos.exe* is compressed to *gzi.msd.exe.gz*. Names are not truncated on systems which do not have a limit on file name length.

By default, *gzip* keeps the original file name and timestamp in the compressed file. These are used when decompressing the file with the **-N** option. This is useful when the compressed file name was truncated or when the timestamp was not preserved after a file transfer.

Compressed files can be restored to their original form using *gzip -d* or *gunzip* or *zcat*. If the original name saved in the compressed file is not suitable for its file system, a new name is constructed from the original one to make it legal.

gunzip takes a list of files on its command line and replaces each file whose name ends with **.gz**, **-gz**, **.z**, **-z**, or **_z** (ignoring case) and which begins with the correct magic number with an uncompressed file without the original extension. *gunzip* also recognizes the special extensions **.tgz** and **.taz** as shorthands for **.tar.gz** and **.tar.Z** respectively. When compressing, *gzip* uses the **.tgz** extension if necessary instead of truncating a file with a **.tar** extension.

gunzip can currently decompress files created by *gzip*, *zip*, *compress*, *compress -H* or *pack*. The detection of the input format is automatic. When using the first two formats, *gunzip* checks a 32 bit CRC. For *pack* and *gunzip* checks the uncompressed length. The standard *compress* format was not designed to allow consistency checks. However *gunzip* is sometimes able to detect a bad **.Z** file. If you get an error when uncompressing a **.Z** file, do not assume that the **.Z** file is correct simply because the standard *uncompress* does not complain. This generally means that the standard *uncompress* does not check its input, and happily generates garbage output. The SCO compress **-H** format (lzh compression method) does not include a CRC but also allows some consistency checks.

Files created by *zip* can be uncompressed by *gzip* only if they have a single member compressed with the 'deflation' method. This feature is only intended to help conversion of tar.zip files to the tar.gz format. To extract a *zip* file with a single member, use a command like *gunzip <foo.zip* or *gunzip -S .zip foo.zip*. To extract zip files with several members, use *unzip* instead of *gunzip*.

zcat is identical to *gunzip -c*. (On some systems, *zcat* may be installed as *gzcat* to preserve the original link to *compress*.) *zcat* uncompresses either a list of files on the command line or its standard input and writes the uncompressed data on standard output. *zcat* will uncompress files that have the correct magic number whether they have a **.gz** suffix or not.

Gzip uses the Lempel-Ziv algorithm used in *zip* and PKZIP. The amount of compression obtained depends on the size of the input and the distribution of common substrings. Typically, text such as source code or English is reduced by 60–70%. Compression is generally much better than that achieved by LZW (as used in *compress*), Huffman coding (as used in *pack*), or adaptive Huffman coding (*compact*).

Compression is always performed, even if the compressed file is slightly larger than the original. The worst case expansion is a few bytes for the *gzip* file header, plus 5 bytes every 32K block, or an expansion ratio of

0.015% for large files. Note that the actual number of used disk blocks almost never increases. *gzip* preserves the mode, ownership and timestamps of files when compressing or decompressing.

OPTIONS

-a --ascii

Ascii text mode: convert end-of-lines using local conventions. This option is supported only on some non-Unix systems. For MSDOS, CR LF is converted to LF when compressing, and LF is converted to CR LF when decompressing.

-c --stdout --to-stdout

Write output on standard output; keep original files unchanged. If there are several input files, the output consists of a sequence of independently compressed members. To obtain better compression, concatenate all input files before compressing them.

-d --decompress --uncompress

Decompress.

-f --force

Force compression or decompression even if the file has multiple links or the corresponding file already exists, or if the compressed data is read from or written to a terminal. If the input data is not in a format recognized by *gzip*, and if the option --stdout is also given, copy the input data without change to the standard output: let *zcat* behave as *cat*. If -f is not given, and when not running in the background, *gzip* prompts to verify whether an existing file should be overwritten.

-h --help

Display a help screen and quit.

-k --keep

Keep (don't delete) input files during compression or decompression.

-l --list For each compressed file, list the following fields:

compressed size: size of the compressed file
 uncompressed size: size of the uncompressed file
 ratio: compression ratio (0.0% if unknown)
 uncompressed_name: name of the uncompressed file

The uncompressed size is given as -1 for files not in gzip format, such as compressed .Z files. To get the uncompressed size for such a file, you can use:

```
zcat file.Z | wc -c
```

In combination with the --verbose option, the following fields are also displayed:

method: compression method
 crc: the 32-bit CRC of the uncompressed data
 date & time: timestamp for the uncompressed file

The compression methods currently supported are deflate, compress, lzh (SCO compress -H) and pack. The crc is given as fffffff for a file not in gzip format.

With --name, the uncompressed name, date and time are those stored within the compress file if present.

With --verbose, the size totals and compression ratio for all files is also displayed, unless some sizes are unknown. With --quiet, the title and totals lines are not displayed.

-L --license

Display the *gzip* license and quit.

-n --no-name

When compressing, do not save the original file name and timestamp by default. (The original name is always saved if the name had to be truncated.) When decompressing, do not restore the original file name if present (remove only the *gzip* suffix from the compressed file name) and do not restore the original timestamp if present (copy it from the compressed file). This option is the default when decompressing.

-N --name

When compressing, always save the original file name and timestamp; this is the default. When decompressing, restore the original file name and timestamp if present. This option is useful on systems which have a limit on file name length or when the timestamp has been lost after a file transfer.

-q --quiet

Suppress all warnings.

-r --recursive

Travel the directory structure recursively. If any of the file names specified on the command line are directories, *gzip* will descend into the directory and compress all the files it finds there (or decompress them in the case of *gunzip*).

-S .suf --suffix .suf

When compressing, use suffix *.suf* instead of *.gz*. Any non-empty suffix can be given, but suffixes other than *.z* and *.gz* should be avoided to avoid confusion when files are transferred to other systems.

When decompressing, add *.suf* to the beginning of the list of suffixes to try, when deriving an output file name from an input file name.

--synchronous

Use synchronous output. With this option, *gzip* is less likely to lose data during a system crash, but it can be considerably slower.

-t --test

Test. Check the compressed file integrity.

-v --verbose

Verbose. Display the name and percentage reduction for each file compressed or decompressed.

-V --version

Version. Display the version number and compilation options then quit.

-# --fast --best

Regulate the speed of compression using the specified digit *#*, where **-1** or **--fast** indicates the fastest compression method (less compression) and **-9** or **--best** indicates the slowest compression method (best compression). The default compression level is **-6** (that is, biased towards high compression at expense of speed).

--rsyncable

When you synchronize a compressed file between two computers, this option allows rsync to transfer only files that were changed in the archive instead of the entire archive. Normally, after a change is made to any file in the archive, the compression algorithm can generate a new version of the archive that does not match the previous version of the archive. In this case, rsync transfers the entire new version of the archive to the remote computer. With this option, rsync can transfer only the changed files as well as a small amount of metadata that is required to update the archive structure in the area that was changed.

ADVANCED USAGE

Multiple compressed files can be concatenated. In this case, *gunzip* will extract all members at once. For example:

```
gzip -c file1 > foo.gz
gzip -c file2 >> foo.gz
```

Then

```
gunzip -c foo
```

is equivalent to

```
cat file1 file2
```

In case of damage to one member of a .gz file, other members can still be recovered (if the damaged member is removed). However, you can get better compression by compressing all members at once:

```
cat file1 file2 | gzip > foo.gz
```

compresses better than

```
gzip -c file1 file2 > foo.gz
```

If you want to recompress concatenated files to get better compression, do:

```
gzip -cd old.gz | gzip > new.gz
```

If a compressed file consists of several members, the uncompressed size and CRC reported by the --list option applies to the last member only. If you need the uncompressed size for all members, you can use:

```
gzip -cd file.gz | wc -c
```

If you wish to create a single archive file with multiple members so that members can later be extracted independently, use an archiver such as tar or zip. GNU tar supports the -z option to invoke gzip transparently. gzip is designed as a complement to tar, not as a replacement.

ENVIRONMENT

The obsolescent environment variable **GZIP** can hold a set of default options for *gzip*. These options are interpreted first and can be overwritten by explicit command line parameters. As this can cause problems when using scripts, this feature is supported only for options that are reasonably likely to not cause too much harm, and *gzip* warns if it is used. This feature will be removed in a future release of *gzip*.

You can use an alias or script instead. For example, if *gzip* is in the directory **/usr/bin** you can prepend **\$HOME/bin** to your **PATH** and create an executable script **\$HOME/bin/gzip** containing the following:

```
#!/bin/sh
export PATH=/usr/bin
exec gzip -9 "$@"
```

NAME

head – output the first part of files

SYNOPSIS

head [*OPTION*]... [*FILE*]...

DESCRIPTION

Print the first 10 lines of each FILE to standard output. With more than one FILE, precede each with a header giving the file name.

With no FILE, or when FILE is **-**, read standard input.

Mandatory arguments to long options are mandatory for short options too.

-c, --bytes=*JNUM*

print the first NUM bytes of each file; with the leading **'-**', print all but the last NUM bytes of each file

-n, --lines=*JNUM*

print the first NUM lines instead of the first 10; with the leading **'-**', print all but the last NUM lines of each file

-q, --quiet, --silent

never print headers giving file names

-v, --verbose

always print headers giving file names

-z, --zero-terminated

line delimiter is NUL, not newline

--help display this help and exit

--version

output version information and exit

NUM may have a multiplier suffix: b 512, kB 1000, K 1024, MB 1000*1000, M 1024*1024, GB 1000*1000*1000, G 1024*1024*1024, and so on for T, P, E, Z, Y. Binary prefixes can be used, too: KiB=K, MiB=M, and so on.

NAME

hostname – show or set the system's host name
domainname – show or set the system's NIS/YP domain name
ypdomainname – show or set the system's NIS/YP domain name
nisdomainname – show or set the system's NIS/YP domain name
dnsdomainname – show the system's DNS domain name

SYNOPSIS

```
hostname [-a|--alias] [-d|--domain] [-f|--fqdn|--long] [-A|--all-fqdns] [-i|--ip-address]
[-I|--all-ip-addresses] [-s|--short] [-y|--yp|--nis]
hostname [-b|--boot] [-F|--file filename] [hostname]
hostname [-h|--help] [-V|--version]

domainname [nisdomain] [-F file]
ypdomainname [nisdomain] [-F file]
nisdomainname [nisdomain] [-F file]

dnsdomainname
```

DESCRIPTION

Hostname is used to display the system's DNS name, and to display or set its hostname or NIS domain name.

GET NAME

When called without any arguments, the program displays the current names:

hostname will print the name of the system as returned by the **gethostname(2)** function.

domainname will print the NIS domainname of the system. **domainname** uses the **gethostname(2)** function, while **ypdomainname** and **nisdomainname** use the **getdomainname(2)**.

dnsdomainname will print the domain part of the FQDN (Fully Qualified Domain Name). The complete FQDN of the system is returned with **hostname --fqdn** (but see the warnings in section **THE FQDN** below).

SET NAME

When called with one argument or with the **--file** option, the commands set the host name or the NIS/YP domain name. **hostname** uses the **sethostname(2)** function, while all of the three **domainname**, **ypdomainname** and **nisdomainname** use **setdomainname(2)**. Note, that this is effective only until the next reboot. Edit /etc/hostname for permanent change.

Note, that only the super-user can change the names.

It is not possible to set the FQDN or the DNS domain name with the **dnsdomainname** command (see **THE FQDN** below).

The host name is usually set once at system startup in */etc/init.d/hostname.sh* (normally by reading the contents of a file which contains the host name, e.g. */etc/hostname*).

THE FQDN

The FQDN (Fully Qualified Domain Name) of the system is the name that the **resolver(3)** returns for the host name, such as, *ursula.example.com*. It is usually the hostname followed by the DNS domain name (the part after the first dot). You can check the FQDN using **hostname --fqdn** or the domain name using **dnsdomainname**.

You cannot change the FQDN with **hostname** or **dnsdomainname**.

The recommended method of setting the FQDN is to make the hostname be an alias for the fully qualified

name using */etc/hosts*, DNS, or NIS. For example, if the hostname was "ursula", one might have a line in */etc/hosts* which reads

```
127.0.1.1  ursula.example.com ursula
```

Technically: The FQDN is the name **getaddrinfo**(3) returns for the host name returned by **gethostname**(2). The DNS domain name is the part after the first dot.

Therefore it depends on the configuration of the resolver (usually in */etc/host.conf*) how you can change it. Usually the hosts file is parsed before DNS or NIS, so it is most common to change the FQDN in */etc/hosts*.

If a machine has multiple network interfaces/addresses or is used in a mobile environment, then it may either have multiple FQDNs/domain names or none at all. Therefore avoid using **hostname --fqdn**, **hostname --domain** and **dnsdomainname**. **hostname --ip-address** is subject to the same limitations so it should be avoided as well.

OPTIONS

-a, --alias

Display the alias name of the host (if used). This option is deprecated and should not be used anymore.

-A, --all-fqdns

Displays all FQDNs of the machine. This option enumerates all configured network addresses on all configured network interfaces, and translates them to DNS domain names. Addresses that cannot be translated (i.e. because they do not have an appropriate reverse IP entry) are skipped. Note that different addresses may resolve to the same name, therefore the output may contain duplicate entries. Do not make any assumptions about the order of the output.

-b, --boot

Always set a hostname; this allows the file specified by **-F** to be non-existent or empty, in which case the default hostname *localhost* will be used if none is yet set.

-d, --domain

Display the name of the DNS domain. Don't use the command **domainname** to get the DNS domain name because it will show the NIS domain name and not the DNS domain name. Use **dnsdomainname** instead. See the warnings in section **THE FQDN** above, and avoid using this option.

-f, --fqdn, --long

Display the FQDN (Fully Qualified Domain Name). A FQDN consists of a short host name and the DNS domain name. Unless you are using bind or NIS for host lookups you can change the FQDN and the DNS domain name (which is part of the FQDN) in the */etc/hosts* file. See the warnings in section **THE FQDN** above and use **hostname --all-fqdns** instead wherever possible.

-F, --file filename

Read the host name from the specified file. Comments (lines starting with a '#') are ignored.

-i, --ip-address

Display the network address(es) of the host name. Note that this works only if the host name can be resolved. Avoid using this option; use **hostname --all-ip-addresses** instead.

-I, --all-ip-addresses

Display all network addresses of the host. This option enumerates all configured addresses on all network interfaces. The loopback interface and IPv6 link-local addresses are omitted. Contrary to option **-i**, this option does not depend on name resolution. Do not make any assumptions about the order of the output.

-s, --short

Display the short host name. This is the host name cut at the first dot.

-V, --version

Print version information on standard output and exit successfully.

-y, --yp, --nis

Display the NIS domain name. If a parameter is given (or **--file name**) then root can also set a new NIS domain.

-h, --help

Print a usage message and exit.

NOTES

The address families **hostname** tries when looking up the FQDN, aliases and network addresses of the host are determined by the configuration of your resolver. For instance, on GNU Libc systems, the resolver can be instructed to try IPv6 lookups first by using the **inet6** option in **/etc/resolv.conf**.

FILES

/etc/hostname Historically this file was supposed to only contain the hostname and not the full canonical FQDN. Nowadays most software is able to cope with a full FQDN here. This file is read at boot time by the system initialization scripts to set the hostname.

/etc/hosts Usually, this is where one sets the domain name by aliasing the host name to the FQDN.

NAME

hostname – Local hostname configuration file

SYNOPSIS

/etc/hostname

DESCRIPTION

The /etc/hostname file configures the name of the local system. Unless overridden as described in the next section, **systemd**(1) will set this hostname during boot using the **sethostname**(2) system call.

The file should contain a single newline-terminated hostname string. Comments (lines starting with a "#") are ignored. The hostname should be composed of up to 64 7-bit ASCII lower-case alphanumeric characters or hyphens forming a valid DNS domain name. It is recommended that this name contains only a single label, i.e. without any dots. Invalid characters will be filtered out in an attempt to make the name valid, but obviously it is recommended to use a valid name and not rely on this filtering.

You may use **hostnamectl**(1) to change the value of this file during runtime from the command line. Use **systemd-firstboot**(1) to initialize it on mounted (but not booted) system images.

HOSTNAME SEMANTICS

systemd(1) and the associated tools will obtain the hostname in the following ways:

- If the kernel commandline parameter *systemd.hostname=* specifies a valid hostname, **systemd**(1) will use it to set the hostname during early boot, see **kernel-command-line**(7),
- Otherwise, the "static" hostname specified by /etc/hostname as described above will be used.
- Otherwise, a transient hostname may be set during runtime, for example based on information in a DHCP lease, see **systemd-hostnamed.service**(8). Both **NetworkManager**^[1] and **systemd-networkd.service**(8) allow this. Note that **systemd-hostnamed.service**(8) gives higher priority to the static hostname, so the transient hostname will only be used if the static hostname is not configured.
- Otherwise, a fallback hostname configured at compilation time will be used ("localhost").

Effectively, the static hostname has higher priority than a transient hostname, which has higher priority than the fallback hostname. Transient hostnames are equivalent, so setting a new transient hostname causes the previous transient hostname to be forgotten. The hostname specified on the kernel command line is like a transient hostname, with the exception that it has higher priority when the machine boots. Also note that those are the semantics implemented by **systemd** tools, but other programs may also set the hostname.

HISTORY

The simple configuration file format of /etc/hostname originates from Debian GNU/Linux.

NOTES

1. NetworkManager
<https://developer.gnome.org/NetworkManager/stable/>

NAME

hostname – hostname resolution description

DESCRIPTION

Hostnames are domains, where a domain is a hierarchical, dot-separated list of subdomains; for example, the machine "monet", in the "example" subdomain of the "com" domain would be represented as "monet.example.com".

Each element of the hostname must be from 1 to 63 characters long and the entire hostname, including the dots, can be at most 253 characters long. Valid characters for hostnames are **ASCII**(7) letters from *a* to *z*, the digits from *0* to *9*, and the hyphen (–). A hostname may not start with a hyphen.

Hostnames are often used with network client and server programs, which must generally translate the name to an address for use. (This task is generally performed by either **getaddrinfo**(3) or the obsolete **gethostbyname**(3).)

Hostnames are resolved by the NSS framework in glibc according to the **hosts** configuration in **nsswitch.conf**. The DNS-based name resolver (in the **dns** NSS service module) resolves them in the following fashion.

If the name consists of a single component, that is, contains no dot, and if the environment variable **HOSTALIASES** is set to the name of a file, that file is searched for any string matching the input hostname. The file should consist of lines made up of two white-space separated strings, the first of which is the hostname alias, and the second of which is the complete hostname to be substituted for that alias. If a case-insensitive match is found between the hostname to be resolved and the first field of a line in the file, the substituted name is looked up with no further processing.

If the input name ends with a trailing dot, the trailing dot is removed, and the remaining name is looked up with no further processing.

If the input name does not end with a trailing dot, it is looked up by searching through a list of domains until a match is found. The default search list includes first the local domain, then its parent domains with at least 2 name components (longest first). For example, in the domain cs.example.com, the name lithium.cchem will be checked first as lithium.cchem.cs.example and then as lithium.cchem.example.com. lithium.cchem.com will not be tried, as there is only one component remaining from the local domain. The search path can be changed from the default by a system-wide configuration file (see **resolver**(5)).

NAME

hostnamectl – Control the system hostname

SYNOPSIS

hostnamectl [OPTIONS...] {COMMAND}

DESCRIPTION

hostnamectl may be used to query and change the system hostname and related settings.

systemd-hostnamed.service(8) and this tool distinguish three different hostnames: the high-level "pretty" hostname which might include all kinds of special characters (e.g. "Lennart's Laptop"), the "static" hostname which is the user-configured hostname (e.g. "lennarts-laptop"), and the transient hostname which is a fallback value received from network configuration (e.g. "node12345678"). If a static hostname is set to a valid value, then the transient hostname is not used.

Note that the pretty hostname has little restrictions on the characters and length used, while the static and transient hostnames are limited to the usually accepted characters of Internet domain names, and 64 characters at maximum (the latter being a Linux limitation).

Use **systemd-firstboot**(1) to initialize the system hostname for mounted (but not booted) system images.

COMMANDS

The following commands are understood:

status

Show system hostname and related information. If no command is specified, this is the implied default.

hostname [*NAME*]

If no argument is given, print the system hostname. If an optional argument *NAME* is provided then the command changes the system hostname to *NAME*. By default, this will alter the pretty, the static, and the transient hostname alike; however, if one or more of **--static**, **--transient**, **--pretty** are used, only the selected hostnames are changed. If the pretty hostname is being set, and static or transient are being set as well, the specified hostname will be simplified in regards to the character set used before the latter are updated. This is done by removing special characters and spaces. This ensures that the pretty and the static hostname are always closely related while still following the validity rules of the specific name. This simplification of the hostname string is not done if only the transient and/or static hostnames are set, and the pretty hostname is left untouched.

The static and transient hostnames must each be either a single DNS label (a string composed of 7-bit ASCII lower-case characters and no spaces or dots, limited to the format allowed for DNS domain name labels), or a sequence of such labels separated by single dots that forms a valid DNS FQDN. The hostname must be at most 64 characters, which is a Linux limitation (DNS allows longer names).

icon-name [*NAME*]

If no argument is given, print the icon name of the system. If an optional argument *NAME* is provided then the command changes the icon name to *NAME*. The icon name is used by some graphical applications to visualize this host. The icon name should follow the [Icon Naming Specification](#)^[1].

chassis [*TYPE*]

If no argument is given, print the chassis type. If an optional argument *TYPE* is provided then the command changes the chassis type to *TYPE*. The chassis type is used by some graphical applications to visualize the host or alter user interaction. Currently, the following chassis types are defined: "desktop", "laptop", "convertible", "server", "tablet", "handset", "watch", "embedded", as well as the special chassis types "vm" and "container" for virtualized systems that lack an immediate physical chassis.

deployment [*ENVIRONMENT*]

If no argument is given, print the deployment environment. If an optional argument *ENVIRONMENT* is provided then the command changes the deployment environment to *ENVIRONMENT*. Argument *ENVIRONMENT* must be a single word without any control characters. One of the following is

suggested: "development", "integration", "staging", "production".

location [LOCATION]

If no argument is given, print the location string for the system. If an optional argument *LOCATION* is provided then the command changes the location string for the system to *LOCATION*. Argument *LOCATION* should be a human-friendly, free-form string describing the physical location of the system, if it is known and applicable. This may be as generic as "Berlin, Germany" or as specific as "Left Rack, 2nd Shelf".

OPTIONS

The following options are understood:

--no-ask-password

Do not query the user for authentication for privileged operations.

--static, --transient, --pretty

If **status** is invoked (or no explicit command is given) and one of these switches is specified, **hostnamectl** will print out just this selected hostname.

If used with **set-hostname**, only the selected hostname(s) will be updated. When more than one of these switches are specified, all the specified hostnames will be updated.

-H, --host=

Execute the operation remotely. Specify a hostname, or a username and hostname separated by "@", to connect to. The hostname may optionally be suffixed by a port ssh is listening on, separated by ":" , and then a container name, separated by "/", which connects directly to a specific container on the specified host. This will use SSH to talk to the remote machine manager instance. Container names may be enumerated with **machinectl -H HOST**. Put IPv6 addresses in brackets.

-M, --machine=

Execute operation on a local container. Specify a container name to connect to, optionally prefixed by a user name to connect as and a separating "@" character. If the special string ".host" is used in place of the container name, a connection to the local system is made (which is useful to connect to a specific user's user bus: "--user --machine=lennart@.host"). If the "@" syntax is not used, the connection is made as root user. If the "@" syntax is used either the left hand side or the right hand side may be omitted (but not both) in which case the local user name and ".host" are implied.

-h, --help

Print a short help text and exit.

--version

Print a short version string and exit.

--json=MODE

Shows output formatted as JSON. Expects one of "short" (for the shortest possible output without any redundant whitespace or line breaks), "pretty" (for a pretty version of the same, with indentation and line breaks) or "off" (to turn off JSON output, the default).

EXIT STATUS

On success, 0 is returned, a non-zero failure code otherwise.

NAME

hpfsck — check integrity of an HFS+ volume

SYNOPSIS

hpfsck [**-v**] *source-path*

Description

hpfsck checks the integrity of an HFS+ volume. With the **-v** option, the data contained in the volume header is output as well.

NAME

id – print real and effective user and group IDs

SYNOPSIS

id [*OPTION*]... [*USER*]...

DESCRIPTION

Print user and group information for each specified *USER*, or (when *USER* omitted) for the current user.

-a ignore, for compatibility with other versions

-Z, --context print only the security context of the process

-g, --group print only the effective group ID

-G, --groups print all group IDs

-n, --name print a name instead of a number, for **-ugG**

-r, --real print the real ID instead of the effective ID, with **-ugG**

-u, --user print only the effective user ID

-z, --zero delimit entries with NUL characters, not whitespace;
not permitted in default format

--help display this help and exit

--version output version information and exit

Without any OPTION, print some useful set of identified information.

NAME

`system_data_types` – overview of system data types

DESCRIPTION

aiocb

Include: `<aio.h>`.

```
struct aiocb {
    int             aio_fildes;      /* File descriptor */
    off_t           aio_offset;     /* File offset */
    volatile void * aio_buf;        /* Location of buffer */
    size_t          aio_nbytes;     /* Length of transfer */
    int             aio_reqprio;    /* Request priority offset */
    struct sigevent aio_sigevent;  /* Signal number and value */
    int             aio_lio_opcode; /* Operation to be performed */
};
```

For further information about this structure, see [aio\(7\)](#).

Conforming to: POSIX.1-2001 and later.

See also: [aio_cancel\(3\)](#), [aio_error\(3\)](#), [aio_fsync\(3\)](#), [aio_read\(3\)](#), [aio_return\(3\)](#), [aio_suspend\(3\)](#), [aio_write\(3\)](#), [lio_listio\(3\)](#)

clock_t

Include: `<time.h>` or `<sys/types.h>`. Alternatively, `<sys/time.h>`.

Used for system time in clock ticks or **CLOCKS_PER_SEC** (defined in `<time.h>`). According to POSIX, it shall be an integer type or a real-floating type.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: [times\(2\)](#), [clock\(3\)](#)

clockid_t

Include: `<sys/types.h>`. Alternatively, `<time.h>`.

Used for clock ID type in the clock and timer functions. According to POSIX, it shall be defined as an arithmetic type.

Conforming to: POSIX.1-2001 and later.

See also: [clock_adjtime\(2\)](#), [clock_getres\(2\)](#), [clock_nanosleep\(2\)](#), [timer_create\(2\)](#), [clock_getcpuclockid\(3\)](#)

dev_t

Include: `<sys/types.h>`. Alternatively, `<sys/stat.h>`.

Used for device IDs. According to POSIX, it shall be an integer type. For further details of this type, see [makedev\(3\)](#).

Conforming to: POSIX.1-2001 and later.

See also: [mknod\(2\)](#), [stat\(2\)](#)

div_t

Include: `<stdlib.h>`.

```
typedef struct {
    int quot; /* Quotient */
    int rem; /* Remainder */
} div_t;
```

It is the type of the value returned by the [div\(3\)](#) function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: [div\(3\)](#)

double_t

Include: <math.h>.

The implementation's most efficient floating type at least as wide as *double*. Its type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <float.h>):

- 0 *double_t* is *double*.
- 1 *double_t* is *double*.
- 2 *double_t* is *long double*.

For other values of **FLT_EVAL_METHOD**, the type of *double_t* is implementation-defined.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *float_t* type in this page.

fd_set

Include: <sys/select.h>. Alternatively, <sys/time.h>.

A structure type that can represent a set of file descriptors. According to POSIX, the maximum number of file descriptors in an *fd_set* structure is the value of the macro **FD_SETSIZE**.

Conforming to: POSIX.1-2001 and later.

See also: **select**(2)

fenv_t

Include: <fenv.h>.

This type represents the entire floating-point environment, including control modes and status flags; for further details, see **fenv**(3).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fenv**(3)

fexcept_t

Include: <fenv.h>.

This type represents the floating-point status flags collectively; for further details see **fenv**(3).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fenv**(3)

FILE

Include: <stdio.h>. Alternatively, <wchar.h>.

An object type used for streams.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **fclose**(3), **flockfile**(3), **fopen**(3), **fprintf**(3), **fread**(3), **fscanf**(3), **stdin**(3), **stdio**(3)

float_t

Include: <math.h>.

The implementation's most efficient floating type at least as wide as *float*. Its type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <float.h>):

- 0 *float_t* is *float*.
- 1 *float_t* is *double*.
- 2 *float_t* is *long double*.

For other values of **FLT_EVAL_METHOD**, the type of *float_t* is implementation-defined.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *double_t* type in this page.

gid_t

Include: <sys/types.h>. Alternatively, <grp.h>, <pwd.h>, <signal.h>, <stropts.h>, <sys/ipc.h>, <sys/stat.h>, or <unistd.h>.

A type used to hold group IDs. According to POSIX, this shall be an integer type.

Conforming to: POSIX.1-2001 and later.

See also: chown(2), getgid(2), getegid(2), getgroups(2), getresgid(2), getgrnam(2), credentials(7)

id_t

Include: <sys/types.h>. Alternatively, <sys/resource.h>.

A type used to hold a general identifier. According to POSIX, this shall be an integer type that can be used to contain a *pid_t*, *uid_t*, or *gid_t*.

Conforming to: POSIX.1-2001 and later.

See also: getpriority(2), waitid(2)

imaxdiv_t

Include: <inttypes.h>.

```
typedef struct {
    intmax_t      quot; /* Quotient */
    intmax_t      rem;   /* Remainder */
} imaxdiv_t;
```

It is the type of the value returned by the imaxdiv(3) function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: imaxdiv(3)

intmax_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

A signed integer type capable of representing any value of any signed integer type supported by the implementation. According to the C language standard, it shall be capable of storing values in the range [INTMAX_MIN, INTMAX_MAX].

The macro INTMAX_C() expands its argument to an integer constant of type *intmax_t*.

The length modifier for *intmax_t* for the printf(3) and the scanf(3) families of functions is **j**; resulting commonly in %**jd** or %**ji** for printing *intmax_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

Bugs: *intmax_t* is not large enough to represent values of type __int128 in implementations where __int128 is defined and long long is less than 128 bits wide.

See also: the *uintmax_t* type in this page.

intN_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

int8_t, *int16_t*, *int32_t*, *int64_t*

A signed integer type of a fixed width of exactly N bits, N being the value specified in its type name. According to the C language standard, they shall be capable of storing values in the range [INTN_MIN, INTN_MAX], substituting N by the appropriate number.

According to POSIX, *int8_t*, *int16_t*, and *int32_t* are required; *int64_t* is only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The length modifiers for the *intN_t* types for the printf(3) family of functions are expanded by macros of the forms **PRIIdN** and **PRIiN** (defined in <inttypes.h>); resulting for example in %"**PRI64**" or %"**PRIi64**" for printing *int64_t* values. The length modifiers for the *intN_t*

types for the **scanf**(3) family of functions are expanded by macros of the forms **SCNdN** and **SCNiN**, (defined in *<inttypes.h>*); resulting for example in **%"SCNd8"** or **%"SCNi8"** for scanning *int8_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intmax_t*, *uintN_t*, and *uintmax_t* types in this page.

intptr_t

Include: *<stdint.h>*. Alternatively, *<inttypes.h>*.

A signed integer type such that any valid (*void **) value can be converted to this type and back. According to the C language standard, it shall be capable of storing values in the range [**INTPTR_MIN**, **INTPTR_MAX**].

The length modifier for *intptr_t* for the **printf**(3) family of functions is expanded by the macros **PRIIdPTR** and **PRIiPTR** (defined in *<inttypes.h>*); resulting commonly in **%"PRIIdPTR"** or **%"PRIiPTR"** for printing *intptr_t* values. The length modifier for *intptr_t* for the **scanf**(3) family of functions is expanded by the macros **SCNdPTR** and **SCNiPTR**, (defined in *<inttypes.h>*); resulting commonly in **%"SCNdPTR"** or **%"SCNiPTR"** for scanning *intptr_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *uintptr_t* and *void ** types in this page.

lconv

Include: *<locale.h>*.

```
struct lconv {                                /* Values in the "C" locale: */
    char    *decimal_point;                  /* ". " */
    char    *thousands_sep;                 /* " " */
    char    *grouping;                      /* " " */
    char    *mon_decimal_point;             /* " " */
    char    *mon_thousands_sep;             /* " " */
    char    *mon_grouping;                  /* " " */
    char    *positive_sign;                 /* " " */
    char    *negative_sign;                 /* " " */
    char    *currency_symbol;               /* " " */
    char    frac_digits;                   /* CHAR_MAX */
    char    p_cs_precedes;                 /* CHAR_MAX */
    char    n_cs_precedes;                 /* CHAR_MAX */
    char    p_sep_by_space;                /* CHAR_MAX */
    char    n_sep_by_space;                /* CHAR_MAX */
    char    p_sign_posn;                   /* CHAR_MAX */
    char    n_sign_posn;                   /* CHAR_MAX */
    char    *int_curr_symbol;              /* " " */
    char    int_frac_digits;               /* CHAR_MAX */
    char    int_p_cs_precedes;             /* CHAR_MAX */
    char    int_n_cs_precedes;             /* CHAR_MAX */
    char    int_p_sep_by_space;             /* CHAR_MAX */
    char    int_n_sep_by_space;             /* CHAR_MAX */
    char    int_p_sign_posn;                /* CHAR_MAX */
    char    int_n_sign_posn;                /* CHAR_MAX */
};
```

Contains members related to the formatting of numeric values. In the "C" locale, its members have the values shown in the comments above.

Conforming to: C11 and later; POSIX.1-2001 and later.

See also: **setlocale**(3), **localeconv**(3), **charsets**(5), **locale**(7)

ldiv_t

Include: <stdlib.h>.

```
typedef struct {
    long      quot; /* Quotient */
    long      rem;   /* Remainder */
} ldiv_t;
```

It is the type of the value returned by the **ldiv(3)** function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **ldiv(3)**

lldiv_t

Include: <stdlib.h>.

```
typedef struct {
    long long  quot; /* Quotient */
    long long  rem;  /* Remainder */
} lldiv_t;
```

It is the type of the value returned by the **lldiv(3)** function.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **lldiv(3)**

off_t

Include: <sys/types.h>. Alternatively, <aio.h>, <fcntl.h>, <stdio.h>, <sys/mman.h>, <sys/stat.h>, or <unistd.h>.

Used for file sizes. According to POSIX, this shall be a signed integer type.

Versions: <aio.h> and <stdio.h> define *off_t* since POSIX.1-2008.

Conforming to: POSIX.1-2001 and later.

Notes: On some architectures, the width of this type can be controlled with the feature test macro **_FILE_OFFSET_BITS**.

See also: **lseek(2)**, **mmap(2)**, **posix_fadvise(2)**, **pread(2)**, **truncate(2)**, **fseeko(3)**, **lockf(3)**, **posix_fallocate(3)**, **feature_test_macros(7)**

pid_t

Include: <sys/types.h>. Alternatively, <fcntl.h>, <sched.h>, <signal.h>, <spawn.h>, <sys/msg.h>, <sys/sem.h>, <sys/shm.h>, <sys/wait.h>, <termios.h>, <time.h>, <unistd.h>, or <utmpx.h>.

This type is used for storing process IDs, process group IDs, and session IDs. According to POSIX, it shall be a signed integer type, and the implementation shall support one or more programming environments where the width of *pid_t* is no greater than the width of the type *long*.

Conforming to: POSIX.1-2001 and later.

See also: **fork(2)**, **getpid(2)**, **getppid(2)**, **getsid(2)**, **gettid(2)**, **getpgid(2)**, **kill(2)**, **pidfd_open(2)**, **sched_setscheduler(2)**, **waitpid(2)**, **sigqueue(3)**, **credentials(7)**,

ptrdiff_t

Include: <stddef.h>.

Used for a count of elements, and array indices. It is the result of subtracting two pointers. According to the C language standard, it shall be a signed integer type capable of storing values in the range [**PTRDIFF_MIN**, **PTRDIFF_MAX**].

The length modifier for *ptrdiff_t* for the **printf(3)** and the **scanf(3)** families of functions is **t**; resulting commonly in **%td** or **%ti** for printing *ptrdiff_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the `size_t` and `ssize_t` types in this page.

regex_t

Include: <`regex.h`>.

```
typedef struct {
    size_t re_nsub; /* Number of parenthesized subexpressions. */
} regex_t;
```

This is a structure type used in regular expression matching. It holds a compiled regular expression, compiled with `regcomp(3)`.

Conforming to: POSIX.1-2001 and later.

See also: `regex(3)`

regmatch_t

Include: <`regex.h`>.

```
typedef struct {
    regoff_t rm_so; /* Byte offset from start of string
                      to start of substring */
    regoff_t rm_eo; /* Byte offset from start of string of
                      the first character after the end of
                      substring */
} regmatch_t;
```

This is a structure type used in regular expression matching.

Conforming to: POSIX.1-2001 and later.

See also: `regexec(3)`

regoff_t

Include: <`regex.h`>.

According to POSIX, it shall be a signed integer type capable of storing the largest value that can be stored in either a `ptrdiff_t` type or a `ssize_t` type.

Versions: Prior to POSIX.1-2008, the type was capable of storing the largest value that can be stored in either an `off_t` type or a `ssize_t` type.

Conforming to: POSIX.1-2001 and later.

See also: the `regmatch_t` structure and the `ptrdiff_t` and `ssize_t` types in this page.

sigevent

Include: <`signal.h`>. Alternatively, <`aio.h`>, <`mqueue.h`>, or <`time.h`>.

```
struct sigevent {
    int           sigev_notify; /* Notification type */
    int           sigev_signo;  /* Signal number */
    union sigval  sigev_value; /* Signal value */
    void         (*sigev_notify_function)(union sigval);
                  /* Notification function */
    pthread_attr_t *sigev_notify_attributes;
                  /* Notification attributes */
};
```

For further details about this type, see `sigevent(7)`.

Versions: <`aio.h`> and <`time.h`> define `sigevent` since POSIX.1-2008.

Conforming to: POSIX.1-2001 and later.

See also: `timer_create(2)`, `getaddrinfo_a(3)`, `lio_listio(3)`, `mq_notify(3)`

See also the *aiocb* structure in this page.

siginfo_t

Include: <signal.h>. Alternatively, <sys/wait.h>.

```
typedef struct {
    int      si_signo; /* Signal number */
    int      si_code;  /* Signal code */
    pid_t   si_pid;   /* Sending process ID */
    uid_t   si_uid;   /* Real user ID of sending process */
    void    *si_addr; /* Address of faulting instruction */
    int     si_status; /* Exit value or signal */
    union sigval si_value; /* Signal value */
} siginfo_t;
```

Information associated with a signal. For further details on this structure (including additional, Linux-specific fields), see **sigaction**(2).

Conforming to: POSIX.1-2001 and later.

See also: **pidfd_send_signal**(2), **rt_sigqueueinfo**(2), **sigaction**(2), **sigwaitinfo**(2), **psiginfo**(3)

sigset_t

Include: <signal.h>. Alternatively, <spawn.h>, or <sys/select.h>.

This is a type that represents a set of signals. According to POSIX, this shall be an integer or structure type.

Conforming to: POSIX.1-2001 and later.

See also: **epoll_pwait**(2), **ppoll**(2), **pselect**(2), **sigaction**(2), **signalfd**(2), **sigpending**(2), **sigprocmask**(2), **sigsuspend**(2), **sigwaitinfo**(2), **signal**(7)

sigval

Include: <signal.h>.

```
union sigval {
    int     sigval_int; /* Integer value */
    void   *sigval_ptr; /* Pointer value */
};
```

Data passed with a signal.

Conforming to: POSIX.1-2001 and later.

See also: **pthread_sigqueue**(3), **sigqueue**(3), **sigevent**(7)

See also the *sigevent* structure and the *siginfo_t* type in this page.

size_t

Include: <stddef.h> or <sys/types.h>. Alternatively, <aio.h>, <glob.h>, <grp.h>, <iconv.h>, <monetary.h>, <mqueue.h>, <ndbm.h>, <pwd.h>, <regex.h>, <search.h>, <signal.h>, <stdio.h>, <stdlib.h>, <string.h>, <strings.h>, <sys/mman.h>, <sys/msg.h>, <sys/sem.h>, <sys/shm.h>, <sys/socket.h>, <sys/uio.h>, <time.h>, <unistd.h>, <wchar.h>, or <wctype.h>.

Used for a count of bytes. It is the result of the *sizeof* operator. According to the C language standard, it shall be an unsigned integer type capable of storing values in the range [0, **SIZE_MAX**]. According to POSIX, the implementation shall support one or more programming environments where the width of *size_t* is no greater than the width of the type *long*.

The length modifier for *size_t* for the **printf**(3) and the **scanf**(3) families of functions is **z**; resulting commonly in **%zu** or **%zx** for printing *size_t* values.

Versions: <aio.h>, <glob.h>, <grp.h>, <iconv.h>, <mqueue.h>, <pwd.h>, <signal.h>, and <sys/socket.h> define *size_t* since POSIX.1-2008.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **read(2)**, **write(2)**, **fread(3)**, **fwrite(3)**, **memcmp(3)**, **memcpy(3)**, **memset(3)**, **off-setof(3)**

See also the *ptrdiff_t* and *ssize_t* types in this page.

ssize_t

Include: <sys/types.h>. Alternatively, <aio.h>, <monetary.h>, <mqueue.h>, <stdio.h>, <sys/msg.h>, <sys/socket.h>, <sys/uio.h>, or <unistd.h>.

Used for a count of bytes or an error indication. According to POSIX, it shall be a signed integer type capable of storing values at least in the range [-1, **SSIZE_MAX**], and the implementation shall support one or more programming environments where the width of *ssize_t* is no greater than the width of the type *long*.

Glibc and most other implementations provide a length modifier for *ssize_t* for the **printf(3)** and the **scanf(3)** families of functions, which is **z**; resulting commonly in **%zd** or **%zi** for printing *ssize_t* values. Although **z** works for *ssize_t* on most implementations, portable POSIX programs should avoid using it—for example, by converting the value to *intmax_t* and using its length modifier (**j**).

Conforming to: POSIX.1-2001 and later.

See also: **read(2)**, **readlink(2)**, **readv(2)**, **recv(2)**, **send(2)**, **write(2)**

See also the *ptrdiff_t* and *size_t* types in this page.

suseconds_t

Include: <sys/types.h>. Alternatively, <sys/select.h>, or <sys/time.h>.

Used for time in microseconds. According to POSIX, it shall be a signed integer type capable of storing values at least in the range [-1, 1000000], and the implementation shall support one or more programming environments where the width of *suseconds_t* is no greater than the width of the type *long*.

Conforming to: POSIX.1-2001 and later.

See also: the *timeval* structure in this page.

time_t

Include: <time.h> or <sys/types.h>. Alternatively, <sched.h>, <sys/msg.h>, <sys/select.h>, <sys/sem.h>, <sys/shm.h>, <sys/stat.h>, <sys/time.h>, or <utime.h>.

Used for time in seconds. According to POSIX, it shall be an integer type.

Versions: <sched.h> defines *time_t* since POSIX.1-2008.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **stime(2)**, **time(2)**, **ctime(3)**, **difftime(3)**

timer_t

Include: <sys/types.h>. Alternatively, <time.h>.

Used for timer ID returned by **timer_create(2)**. According to POSIX, there are no defined comparison or assignment operators for this type.

Conforming to: POSIX.1-2001 and later.

See also: **timer_create(2)**, **timer_delete(2)**, **timer_getoverrun(2)**, **timer_settime(2)**

timespec

Include: <time.h>. Alternatively, <aio.h>, <mqueue.h>, <sched.h>, <signal.h>, <sys/select.h>, or <sys/stat.h>.

```
struct timespec {
    time_t tv_sec; /* Seconds */
```

```
    long      tv_nsec; /* Nanoseconds */
}
```

Describes times in seconds and nanoseconds.

Conforming to: C11 and later; POSIX.1-2001 and later.

See also: **clock_gettime(2)**, **clock_nanosleep(2)**, **nanosleep(2)**, **timerfd_gettime(2)**, **timer_gettime(2)**

timeval

Include: <sys/time.h>. Alternatively, <sys/resource.h>, <sys/select.h>, or <utmpx.h>.

```
struct timeval {
    time_t      tv_sec;   /* Seconds */
    suseconds_t tv_usec; /* Microseconds */
};
```

Describes times in seconds and microseconds.

Conforming to: POSIX.1-2001 and later.

See also: **gettimeofday(2)**, **select(2)**, **utimes(2)**, **adjtime(3)**, **futimes(3)**, **timeradd(3)**

uid_t

Include: <sys/types.h>. Alternatively, <pwd.h>, <signal.h>, <stropts.h>, <sys/ipc.h>, <sys/stat.h>, or <unistd.h>.

A type used to hold user IDs. According to POSIX, this shall be an integer type.

Conforming to: POSIX.1-2001 and later.

See also: **chown(2)**, **getuid(2)**, **geteuid(2)**, **getresuid(2)**, **getpwnam(2)**, **credentials(7)**

uintmax_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

An unsigned integer type capable of representing any value of any unsigned integer type supported by the implementation. According to the C language standard, it shall be capable of storing values in the range [0, **UINTMAX_MAX**].

The macro **UINTMAX_C()** expands its argument to an integer constant of type *uintmax_t*.

The length modifier for *uintmax_t* for the **printf(3)** and the **scanf(3)** families of functions is **j**; resulting commonly in **%ju** or **%jx** for printing *uintmax_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

Bugs: *uintmax_t* is not large enough to represent values of type *unsigned __int128* in implementations where *unsigned __int128* is defined and *unsigned long long* is less than 128 bits wide.

See also: the *intmax_t* type in this page.

uintN_t

Include: <stdint.h>. Alternatively, <inttypes.h>.

uint8_t, *uint16_t*, *uint32_t*, *uint64_t*

An unsigned integer type of a fixed width of exactly N bits, N being the value specified in its type name. According to the C language standard, they shall be capable of storing values in the range [0, **UINTN_MAX**], substituting N by the appropriate number.

According to POSIX, *uint8_t*, *uint16_t*, and *uint32_t* are required; *uint64_t* is only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The length modifiers for the *uintN_t* types for the **printf(3)** family of functions are expanded by macros of the forms **PRIuN**, **PRIoN**, **PRIxN**, and **PRIXN** (defined in <inttypes.h>); resulting for example in **%"PRIu32"** or **%"PRIx32"** for printing *uint32_t* values. The length modifiers for

the *uintN_t* types for the **scanf**(3) family of functions are expanded by macros of the forms **SCNuN**, **SCNoN**, **SCNxN**, and **SCNXN** (defined in *<inttypes.h>*); resulting for example in **%"SCNu16"** or **%"SCNx16"** for scanning *uint16_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intmax_t*, *intN_t*, and *uintmax_t* types in this page.

uintptr_t

Include: *<stdint.h>*. Alternatively, *<inttypes.h>*.

An unsigned integer type such that any valid (*void **) value can be converted to this type and back. According to the C language standard, it shall be capable of storing values in the range [0, **UINTPTR_MAX**].

The length modifier for *uintptr_t* for the **printf**(3) family of functions is expanded by the macros **PRIupTR**, **PRIoPTR**, **PRIxPTR**, and **PRIxPTR** (defined in *<inttypes.h>*); resulting commonly in **%"PRIupTR"** or **%"PRIxPTR"** for printing *uintptr_t* values. The length modifier for *uintptr_t* for the **scanf**(3) family of functions is expanded by the macros **SCNuPTR**, **SCNoPTR**, **SCNxPTR**, and **SCNXPTR** (defined in *<inttypes.h>*); resulting commonly in **%"SCNuPTR"** or **%"SCNxPTR"** for scanning *uintptr_t* values.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: the *intptr_t* and *void ** types in this page.

va_list

Include: *<stdarg.h>*. Alternatively, *<stdio.h>*, or *<wchar.h>*.

Used by functions with a varying number of arguments of varying types. The function must declare an object of type *va_list* which is used by the macros **va_start**(3), **va_arg**(3), **va_copy**(3), and **va_end**(3) to traverse the list of arguments.

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **va_start**(3), **va_arg**(3), **va_copy**(3), **va_end**(3)

*void **

According to the C language standard, a pointer to any object type may be converted to a pointer to *void* and back. POSIX further requires that any pointer, including pointers to functions, may be converted to a pointer to *void* and back.

Conversions from and to any other pointer type are done implicitly, not requiring casts at all. Note that this feature prevents any kind of type checking: the programmer should be careful not to convert a *void ** value to a type incompatible to that of the underlying data, because that would result in undefined behavior.

This type is useful in function parameters and return value to allow passing values of any type. The function will typically use some mechanism to know the real type of the data being passed via a pointer to *void*.

A value of this type can't be dereferenced, as it would give a value of type *void*, which is not possible. Likewise, pointer arithmetic is not possible with this type. However, in GNU C, pointer arithmetic is allowed as an extension to the standard; this is done by treating the size of a *void* or of a function as 1. A consequence of this is that *sizeof* is also allowed on *void* and on function types, and returns 1.

The conversion specifier for *void ** for the **printf**(3) and the **scanf**(3) families of functions is **p**.

Versions: The POSIX requirement about compatibility between *void ** and function pointers was added in POSIX.1-2008 Technical Corrigendum 1 (2013).

Conforming to: C99 and later; POSIX.1-2001 and later.

See also: **malloc**(3), **memcmp**(3), **memcpy**(3), **memset**(3)

See also the *intptr_t* and *uintptr_t* types in this page.

NOTES

The structures described in this manual page shall contain, at least, the members shown in their definition, in no particular order.

Most of the integer types described in this page don't have a corresponding length modifier for the `printf(3)` and the `scanf(3)` families of functions. To print a value of an integer type that doesn't have a length modifier, it should be converted to `intmax_t` or `uintmax_t` by an explicit cast. To scan into a variable of an integer type that doesn't have a length modifier, an intermediate temporary variable of type `intmax_t` or `uintmax_t` should be used. When copying from the temporary variable to the destination variable, the value could overflow. If the type has upper and lower limits, the user should check that the value is within those limits, before actually copying the value. The example below shows how these conversions should be done.

Conventions used in this page

In "Conforming to" we only concern ourselves with C99 and later and POSIX.1-2001 and later. Some types may be specified in earlier versions of one of these standards, but in the interests of simplicity we omit details from earlier standards.

In "Include", we first note the "primary" header(s) that define the type according to either the C or POSIX.1 standards. Under "Alternatively", we note additional headers that the standards specify shall define the type.

EXAMPLES

The program shown below scans from a string and prints a value stored in a variable of an integer type that doesn't have a length modifier. The appropriate conversions from and to `intmax_t`, and the appropriate range checks, are used as explained in the notes section above.

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>

int
main (void)
{
    static const char *const str = "500000 us in half a second";
    suseconds_t us;
    intmax_t tmp;

    /* Scan the number from the string into the temporary variable */

    sscanf(str, "%jd", &tmp);

    /* Check that the value is within the valid range of suseconds_t */

    if (tmp < -1 || tmp > 1000000) {
        fprintf(stderr, "Scanned value outside valid range!\n");
        exit(EXIT_FAILURE);
    }

    /* Copy the value to the suseconds_t variable 'us' */

    us = tmp;

    /* Even though suseconds_t can hold the value -1, this isn't
       a sensible number of microseconds */
}
```

```
if (us < 0) {
    fprintf(stderr, "Scanned value shouldn't be negative!\n");
    exit(EXIT_FAILURE);
}

/* Print the value */

printf("There are %jd microseconds in half a second.\n",
       (intmax_t) us);

exit(EXIT_SUCCESS);
}
```

NAME

ifcfg – simplistic script which replaces ifconfig IP management

SYNOPSIS

ifcfg [*DEVICE*] [*command*] *ADDRESS* [*PEER*]

DESCRIPTION

This manual page documents briefly the **ifcfg** command.

This is a simplistic script replacing one option of **ifconfig**, namely, IP address management. It not only adds addresses, but also carries out Duplicate Address Detection RFC-DHCP, sends unsolicited ARP to update the caches of other hosts sharing the interface, adds some control routes and restarts Router Discovery when it is necessary.

IFCONFIG - COMMAND SYNTAX**DEVICE**

- it may have alias, suffix, separated by colon.

command

- add, delete or stop.

ADDRESS

- optionally followed by prefix length.

peer - optional peer address for pointpoint interfaces.

NOTES

This script is not suitable for use with IPv6.

SEE ALSO

IP Command reference **ip-cref.ps**

NAME

ifconfig – configure a network interface

SYNOPSIS

```
ifconfig [-v] [-a] [-s] [interface]
ifconfig [-v] interface [aftype] options | address ...
```

DESCRIPTION

Ifconfig is used to configure the kernel-resident network interfaces. It is used at boot time to set up interfaces as necessary. After that, it is usually only needed when debugging or when system tuning is needed.

If no arguments are given, **ifconfig** displays the status of the currently active interfaces. If a single **interface** argument is given, it displays the status of the given interface only; if a single **-a** argument is given, it displays the status of all interfaces, even those that are down. Otherwise, it configures an interface.

Address Families

If the first argument after the interface name is recognized as the name of a supported address family, that address family is used for decoding and displaying all protocol addresses. Currently supported address families include **inet** (TCP/IP, default), **inet6** (IPv6), **ax25** (AMPR Packet Radio), **ddp** (Appletalk Phase 2), **ipx** (Novell IPX) and **netrom** (AMPR Packet radio). All numbers supplied as parts in IPv4 dotted decimal notation may be decimal, octal, or hexadecimal, as specified in the ISO C standard (that is, a leading 0x or 0X implies hexadecimal; otherwise, a leading '0' implies octal; otherwise, the number is interpreted as decimal). Use of hexadecimal and octal numbers is not RFC-compliant and therefore its use is discouraged.

OPTIONS

- a** display all interfaces which are currently available, even if down
- s** display a short list (like netstat -i)
- v** be more verbose for some error conditions

interface

The name of the interface. This is usually a driver name followed by a unit number, for example **eth0** for the first Ethernet interface. If your kernel supports alias interfaces, you can specify them with syntax like **eth0:0** for the first alias of eth0. You can use them to assign more addresses. To delete an alias interface use **ifconfig eth0:0 down**. Note: for every scope (i.e. same net with address/netmask combination) all aliases are deleted, if you delete the first (primary).

up This flag causes the interface to be activated. It is implicitly specified if an address is assigned to the interface; you can suppress this behavior when using an alias interface by appending an **-** to the alias (e.g. **eth0:0-**). It is also suppressed when using the IPv4 0.0.0.0 address as the kernel will use this to implicitly delete alias interfaces.

down This flag causes the driver for this interface to be shut down.

[–]arp Enable or disable the use of the ARP protocol on this interface.

[–]promisc

Enable or disable the **promiscuous** mode of the interface. If selected, all packets on the network will be received by the interface.

[–]allmulti

Enable or disable **all-multicast** mode. If selected, all multicast packets on the network will be received by the interface.

mtu N This parameter sets the Maximum Transfer Unit (MTU) of an interface.

dstaddr addr

Set the remote IP address for a point-to-point link (such as PPP). This keyword is now obsolete; use the **pointopoint** keyword instead.

netmask addr

Set the IP network mask for this interface. This value defaults to the usual class A, B or C network mask (as derived from the interface IP address), but it can be set to any value.

add addr/prefixlen

Add an IPv6 address to an interface.

del addr/prefixlen

Remove an IPv6 address from an interface.

tunnel ::aa.bb.cc.dd

Create a new SIT (IPv6-in-IPv4) device, tunnelling to the given destination.

irq addr

Set the interrupt line used by this device. Not all devices can dynamically change their IRQ setting.

io_addr addr

Set the start address in I/O space for this device.

mem_start addr

Set the start address for shared memory used by this device. Only a few devices need this.

media type

Set the physical port or medium type to be used by the device. Not all devices can change this setting, and those that can vary in what values they support. Typical values for **type** are **10base2** (thin Ethernet), **10baseT** (twisted-pair 10Mbps Ethernet), **AUI** (external transceiver) and so on. The special medium type of **auto** can be used to tell the driver to auto-sense the media. Again, not all drivers can do this.

[–]broadcast [addr]

If the address argument is given, set the protocol broadcast address for this interface. Otherwise, set (or clear) the **IFF_BROADCAST** flag for the interface.

[–]pointopoint [addr]

This keyword enables the **point-to-point** mode of an interface, meaning that it is a direct link between two machines with nobody else listening on it.

If the address argument is also given, set the protocol address of the other side of the link, just like the obsolete **dstaddr** keyword does. Otherwise, set or clear the **IFF_POINTOPOINT** flag for the interface.

hw class address

Set the hardware address of this interface, if the device driver supports this operation. The keyword must be followed by the name of the hardware class and the printable ASCII equivalent of the hardware address. Hardware classes currently supported include **ether** (Ethernet), **ax25** (AMPR AX.25), **ARCnet** and **netrom** (AMPR NET/ROM).

multicast

Set the multicast flag on the interface. This should not normally be needed as the drivers set the flag correctly themselves.

address

The IP address to be assigned to this interface.

txqueuelen length

Set the length of the transmit queue of the device. It is useful to set this to small values for slower devices with a high latency (modem links, ISDN) to prevent fast bulk transfers from disturbing interactive traffic like telnet too much.

NOTES

Since kernel release 2.2 there are no explicit interface statistics for alias interfaces anymore. The statistics printed for the original address are shared with all alias addresses on the same device. If you want per-address statistics you should add explicit accounting rules for the address using the **iptables(8)** command.

Interrupt problems with Ethernet device drivers fail with EAGAIN (*SIOCSIFFLAGS: Resource temporarily unavailable*) it is most likely a interrupt conflict. See <http://www.scyld.com/expert/irq-conflict.html> for more information.

FILES

/proc/net/dev
/proc/net/if_inet6

BUGS

Ifconfig uses the ioctl access method to get the full address information, which limits hardware addresses to 8 bytes. Because Infiniband hardware address has 20 bytes, only the first 8 bytes are displayed correctly. Please use **ip link** command from **iproute2** package to display link layer informations including the hardware address.

While appletalk DDP and IPX addresses will be displayed they cannot be altered by this command.

NAME

`info` – read Info documents

SYNOPSIS

`info [OPTION]... [MENU-ITEM ...]`

DESCRIPTION

Read documentation in Info format.

Frequently-used options:

-a, --all

use all matching manuals

-k, --apropos=STRING

look up STRING in all indices of all manuals

-d, --directory=DIR

add DIR to INFOPATH

-f, --file=MANUAL

specify Info manual to visit

-h, --help

display this help and exit

--index-search=STRING

go to node pointed by index entry STRING

-n, --node=NODENAME

specify nodes in first visited Info file

-o, --output=FILE

output selected nodes to FILE

-O, --show-options, --usage

go to command-line options node

--subnodes

recursively output menu items

-v, --variable VAR=VALUE

assign VALUE to Info variable VAR

--version

display version information and exit

-w, --where, --location

print physical location of Info file

The first non-option argument, if present, is the menu entry to start from; it is searched for in all 'dir' files along INFOPATH. If it is not present, info merges all 'dir' files and shows the result. Any remaining arguments are treated as the names of menu items relative to the initial node visited.

For a summary of key bindings, type H within Info.

EXAMPLES

`info` show top-level dir menu

`info info-stnd`

show the manual for this Info program

`info emacs`

start at emacs node from top-level dir

`info emacs buffers`

select buffers menu entry in emacs manual

```
info emacs -n Files
      start at Files node within emacs manual
info '(emacs)Files'
      alternative way to start at Files node
info --show-options emacs
      start at node with emacs' command line options
info --subnodes -o out.txt emacs
      dump entire emacs manual to out.txt
info -f ./foo.info
      show file ./foo.info, not searching dir
```

REPORTING BUGS

Email bug reports to bug-texinfo@gnu.org, general questions and discussion to help-texinfo@gnu.org.
Texinfo home page: <http://www.gnu.org/software/texinfo/>

COPYRIGHT

<<http://gnu.org/licenses/gpl.html>>
This is free software: you are free to change and redistribute it. There is NO WARRANTY, to the extent permitted by law.

SEE ALSO

The full documentation for **info** is maintained as a Texinfo manual. If the **info** program is properly installed at your site, the command

info info

should give you access to the complete manual. (Or, if you have Emacs, M-x info will lead to the manual.)

NAME

asn1parse, ca, ciphers, cms, crl, crl2pkcs7, dgst, dhparam, dsa, dsaparam, ec, ecpam, enc, engine, errstr, gendsa, genkey, genrsa, info, kdf, mac, nseq, ocsp, passwd, pkcs12, pkcs7, pkcs8, pkey, pkeyparam, pkeyutl, prime, rand, rehash, req, rsa, rsautl, s_client, s_server, s_time, sess_id, smime, speed, spkac, srp, storeutl, ts, verify, version, x509 – OpenSSL application commands

SYNOPSIS

openssl cmd -help | [-option | -option arg] ... [arg] ...

DESCRIPTION

Every *cmd* listed above is a (sub-)command of the **openssl**(1) application. It has its own detailed manual page at **openssl-cmd**(1). For example, to view the manual page for the **openssl dgst** command, type `man openssl-dgst`.

OPTIONS

Among others, every subcommand has a help option.

-help

Print out a usage message for the subcommand.

SEE ALSO

openssl(1), **openssl-asn1parse**(1), **openssl-ca**(1), **openssl-ciphers**(1), **openssl-cms**(1), **openssl-crl**(1), **openssl-crl2pkcs7**(1), **openssl-dgst**(1), **openssl-dhparam**(1), **openssl-dsa**(1), **openssl-dsaparam**(1), **openssl-ec**(1), **openssl-ecparam**(1), **openssl-enc**(1), **openssl-engine**(1), **openssl-errstr**(1), **openssl-gendsa**(1), **openssl-genkey**(1), **openssl-genrsa**(1), **openssl-info**(1), **openssl-kdf**(1), **openssl-mac**(1), **openssl-nseq**(1), **openssl-ocsp**(1), **openssl-passwd**(1), **openssl-pkcs12**(1), **openssl-pkcs7**(1), **openssl-pkcs8**(1), **openssl-pkey**(1), **openssl-pkeyparam**(1), **openssl-pkeyutl**(1), **openssl-prime**(1), **openssl-rand**(1), **openssl-rehash**(1), **openssl-req**(1), **openssl-rsa**(1), **openssl-rsautl**(1), **openssl-s_client**(1), **openssl-s_server**(1), **openssl-s_time**(1), **openssl-sess_id**(1), **openssl-smime**(1), **openssl-speed**(1), **openssl-spkac**(1), **openssl-srp**(1), **openssl-storeutl**(1), **openssl-ts**(1), **openssl-verify**(1), **openssl-version**(1), **openssl-x509**(1),

HISTORY

Initially, the manual page entry for the **openssl cmd** command used to be available at *cmd*(1). Later, the alias **openssl-cmd**(1) was introduced, which made it easier to group the **openssl** commands using the **apropos**(1) command or the shell's tab completion.

In order to reduce cluttering of the global manual page namespace, the manual page entries without the 'openssl-' prefix have been deprecated in OpenSSL 3.0 and will be removed in OpenSSL 4.0.

NAME

info – readable online documentation

DESCRIPTION

The Info file format is an easily-parsable representation for online documents. It can be read by *emacs(1)* and *info(1)* among other programs.

Info files are usually created from *texinfo(5)* sources by *makeinfo(1)*, but can be created from scratch if so desired.

For a full description of the Texinfo language and associated tools, please see the Texinfo manual (written in Texinfo itself). Most likely, running this command from your shell:

```
info texinfo  
or this key sequence from inside Emacs:  
M-x info RET m texinfo RET  
will get you there.
```

AVAILABILITY

<http://www.gnu.org/software/texinfo/>

REPORTING BUGS

Please send bug reports to bug-texinfo@gnu.org, general questions and discussion to help-texinfo@gnu.org.

SEE ALSO

info(1), *install-info(1)*, *makeinfo(1)*, *texi2dvi(1)*,
texindex(1).
emacs(1), *tex(1)*.
texinfo(5).

NAME

insmod – Simple program to insert a module into the Linux Kernel

SYNOPSIS

insmod [*filename*] [*module options...*]

DESCRIPTION

insmod is a trivial program to insert a module into the kernel. Most users will want to use **modprobe(8)** instead, which is more clever and can handle module dependencies.

Only the most general of error messages are reported: as the work of trying to link the module is now done inside the kernel, the **dmesg** usually gives more information about errors.

```

DESCRIPTION

ip route is used to manipulate entries in the kernel routing tables.

Route types:

unicast - the route entry describes real paths to the destinations covered by the route prefix.

unreachable - these destinations are unreachable. Packets are discarded and the ICMP message *host unreachable* is generated. The local senders get an *EHOSTUNREACH* error.

blackhole - these destinations are unreachable. Packets are discarded silently. The local senders get an *EINVAL* error.

prohibit - these destinations are unreachable. Packets are discarded and the ICMP message *communication administratively prohibited* is generated. The local senders get an *EACCES* error.

local - the destinations are assigned to this host. The packets are looped back and delivered locally.

broadcast - the destinations are broadcast addresses. The packets are sent as link broadcasts.

throw - a special control route used together with policy rules. If such a route is selected, lookup in this table is terminated pretending that no route was found. Without policy routing it is equivalent to the absence of the route in the routing table. The packets are dropped and the ICMP message *net unreachable* is generated. The local senders get an *ENETUNREACH* error.

nat - a special NAT route. Destinations covered by the prefix are considered to be

dummy (or external) addresses which require translation to real (or internal) ones before forwarding. The addresses to translate to are selected with the attribute **via**. **Warning:** Route NAT is no longer supported in Linux 2.6.

anycast - *not implemented* the destinations are *anycast* addresses assigned to this host. They are mainly equivalent to **local** with one difference: such addresses are invalid when used as the source address of any packet.

multicast - a special type used for multicast routing. It is not present in normal routing tables.

Route tables: Linux-2.x can pack routes into several routing tables identified by a number in the range from 1 to $2^{32}-1$ or by name from the file **/etc/iproute2/rt_tables** By default all normal routes are inserted into the **main** table (ID 254) and the kernel only uses this table when calculating routes. Values (0, 253, 254, and 255) are reserved for built-in use.

Actually, one other table always exists, which is invisible but even more important. It is the **local** table (ID 255). This table consists of routes for local and broadcast addresses. The kernel maintains this table automatically and the administrator usually need not modify it or even look at it.

The multiple routing tables enter the game when *policy routing* is used.

```
ip route add
    add new route
ip route change
    change route
ip route replace
    change or add new one
```

to TYPE PREFIX (default)

the destination prefix of the route. If **TYPE** is omitted, **ip** assumes type **unicast**. Other values of **TYPE** are listed above. **PREFIX** is an IP or IPv6 address optionally followed by a slash and the prefix length. If the length of the prefix is missing, **ip** assumes a full-length host route. There is also a special **PREFIX default** - which is equivalent to IP **0/0** or to IPv6 **::/0**.

tos TOS

dsfield TOS

the Type Of Service (TOS) key. This key has no associated mask and the longest match is understood as: First, compare the TOS of the route and of the packet. If they are not equal, then the packet may still match a route with a zero TOS. **TOS** is either an 8 bit hexadecimal number or an identifier from **/etc/iproute2/rt_dsfield**.

metric NUMBER

preference NUMBER

the preference value of the route. **NUMBER** is an arbitrary 32bit number, where routes with lower values are preferred.

table *TABLEID*

the table to add this route to. *TABLEID* may be a number or a string from the file */etc/iproute2/rt_tables*. If this parameter is omitted, ip assumes the **main** table, with the exception of **local**, **broadcast** and **nat** routes, which are put into the **local** table by default.

vrf *NAME*

the vrf name to add this route to. Implicitly means the table associated with the VRF.

dev *NAME*

the output device name.

via [*FAMILY*] *ADDRESS*

the address of the nexthop router, in the address family *FAMILY*. Actually, the sense of this field depends on the route type. For normal **unicast** routes it is either the true next hop router or, if it is a direct route installed in BSD compatibility mode, it can be a local address of the interface. For NAT routes it is the first address of the block of translated IP destinations.

src *ADDRESS*

the source address to prefer when sending to the destinations covered by the route prefix.

realm *REALMID*

the realm to which this route is assigned. *REALMID* may be a number or a string from the file */etc/iproute2/rt_realms*.

mtu *MTU***mtu lock** *MTU*

the MTU along the path to the destination. If the modifier **lock** is not used, the MTU may be updated by the kernel due to Path MTU Discovery. If the modifier **lock** is used, no path MTU discovery will be tried, all packets will be sent without the DF bit in IPv4 case or fragmented to MTU for IPv6.

window *NUMBER*

the maximal window for TCP to advertise to these destinations, measured in bytes. It limits maximal data bursts that our TCP peers are allowed to send to us.

rtt *TIME*

the initial RTT ('Round Trip Time') estimate. If no suffix is specified the units are raw values passed directly to the routing code to maintain compatibility with previous releases. Otherwise if a suffix of s, sec or secs is used to specify seconds and ms, msec or msecs to specify milliseconds.

rttvar *TIME* (**Linux 2.3.15+** only)

the initial RTT variance estimate. Values are specified as with **rtt** above.

rto_min *TIME* (**Linux 2.6.23+** only)

the minimum TCP Retransmission TimeOut to use when communicating with this destination. Values are specified as with **rtt** above.

ssthresh NUMBER (Linux 2.3.15+ only)

an estimate for the initial slow start threshold.

cwnd NUMBER (Linux 2.3.15+ only)

the clamp for congestion window. It is ignored if the **lock** flag is not used.

initcwnd NUMBER (Linux 2.5.70+ only)

the initial congestion window size for connections to this destination. Actual window size is this value multiplied by the MSS (“Maximal Segment Size”) for same connection. The default is zero, meaning to use the values specified in RFC2414.

initrwnd NUMBER (Linux 2.6.33+ only)

the initial receive window size for connections to this destination. Actual window size is this value multiplied by the MSS of the connection. The default value is zero, meaning to use Slow Start value.

features FEATURES (Linux 3.18+only)

Enable or disable per-route features. Only available feature at this time is **ecn** to enable explicit congestion notification when initiating connections to the given destination network. When responding to a connection request from the given network, **ecn** will also be used even if the **net.ipv4.tcp_ecn** sysctl is set to 0.

quickack BOOL (Linux 3.11+ only)

Enable or disable quick ack for connections to this destination.

fastopen_no_cookie BOOL (Linux 4.15+ only)

Enable TCP Fastopen without a cookie for connections to this destination.
